Tamoxifen is the most extensively studied systemic therapy for DCIS. In the NSABP B-24 study, 1804 women with DCIS treated with lumpectomy and radiation therapy were randomly assigned to tamoxifen 10 mg by mouth twice per day for 5 years or placebo. At 5 years, tamoxifen resulted in 5.2% absolute risk reduction of all breast cancers.[133] The benefit was mainly the result of decreased ipsilateral invasive disease and contralateral noninvasive disease, whereas the risk of regional or distant metastases was not significantly different among the two study arms. Serious but rare side effects of tamoxifen were deep venous thrombosis (1%), nonfatal pulmonary embolism (0.2%), and uterine cancer (~0.1%).[133] Subsequent analysis of available tumor tissue was performed to evaluate the impact of ER status on tamoxifen benefit.[134] Tamoxifen improved outcomes in women with ER+ DCIS. In ER– DCIS, tamoxifen did not improve IBE, but there was a nonsignificant decrease in CBC events (HR 0.46, 95% CI 0.12–1.80; $P = .35$).[134] The number of ER– DCIS cases was small in this subanalysis, precluding definitive conclusions.

The UK, Australia, and New Zealand (UK/ANZ) DCIS trial randomly assigned women who had BCS for DCIS with negative margins to receive additional treatment with radiation, tamoxifen, both, or none; 1576 women were randomly assigned to tamoxifen versus no tamoxifen.[135] At median follow-up of 12.7

Table 38–3 Systemic Therapy for DCIS Phase 3 Clinical Trials

	NSABP B-24[133]	UK/ANZ[135]	NSABP B-35[139]
Study Treatment[a] (n)	Tamoxifen (899) vs placebo (899)	Tamoxifen (794) vs none (782)[b]	Anastrozole (1552) vs tamoxifen (1552)
Patient population	DCIS BCS + RT Pre/Postmenopausal	DCIS BCS +/– RT Pre/Postmenopausal	HR + DCIS BCS + RT Postmenopausal
Median follow-up	5 y	12.7 y	9.0 y
Breast cancer events (all)	HR 0.63 *P* = .009	HR 0.71 *P* = .002	HR 0.73 *P* = .0234
Ipsilateral events	HR 0.70 *P* = .04	HR 0.78 *P* = .04	HR 0.83 *P* = .34
Contralateral events	HR 0.48 *P* = .01	HR 0.44 *P* = .005	HR 0.64 *P* = .0322
Invasive breast cancer	HR 0.57 *P* = .004	HR 0.81 *P* = .2	HR 0.62 *P* = .0123
DCIS	HR 0.69 *P* = .08	HR 0.67 *P* = .008	HR 0.88 *P* = .52

[a]All treatments given for 5 years.
[b]2 × 2 factorial randomization: radiation vs none; tamoxifen vs none.
BCS, breast-conserving surgery; DCIS, ductal carcinoma in situ; HR, hazard ratio; HR+, hormone receptor–positive; RT, radiation therapy.

years, breast cancer events (ipsilateral and contralateral) were reduced with tamoxifen (HR 0.71, 95% CI 0.58–0.88; *P* = .002), but subset analysis revealed benefit only in patients who did not receive radiation. For IBE, tamoxifen significantly reduced DCIS, but not invasive cancers. Tamoxifen treatment significantly reduced CBC (HR 0.44, 95% CI 0.25–0.77; *P* = .005).[135]

A Cochrane meta-analysis analyzed data on 3375 patients from the phase 3 B-24 and UK/ANZ DCIS trials.[136] Five years of adjuvant tamoxifen decreased the risk of both ipsilateral (HR 0.75, 95% CI 0.61–0.92; *P* = .006) and contralateral DCIS (RR 0.50, 95% CI 0.28–0.87; *P* = .01). Reduction in invasive CBC events was observed, whereas invasive IBE neared statistical significance. Tamoxifen did not improve all-cause mortality (RR 1.11, 95% CI 0.89–1.39). It was determined that 15 patients need to be treated with tamoxifen to prevent one breast cancer event.[136]

Although tamoxifen has demonstrated benefit in patients with DCIS, treatment does not improve mortality and is associated with significant side effects. Therefore, a phase 3 study evaluated tamoxifen treatment at a lower dose of 5 mg daily over a shorter time period of 3 years. The study randomly assigned 500 women with HR+/unknown DCIS, atypical ductal hyperplasia, or lobular carcinoma in situ, of whom 346 (69%) had DCIS.[137] At median follow-up of 5 years, low-dose tamoxifen reduced the rate of invasive breast cancer and DCIS (HR 0.48, 95% CI 0.26–0.92; *P* = .02). In the tamoxifen arm, one patient developed a deep venous thrombosis, and one was diagnosed with stage I endometrial cancer; one patient on placebo had a pulmonary embolism. The number needed to treat with low-dose tamoxifen to prevent one breast cancer was 22, and the number needed to harm was 218 based on observed serious adverse events.[137]

Anastrozole is an AI currently approved for the treatment HR+ invasive breast cancer. The IBIS II trial assessed the efficacy and safety of anastrozole for the prevention of breast cancer in high-risk postmenopausal women. Of the 3864 women randomly assigned, 326 were treated with ipsilateral mastectomy for ER+ DCIS and had reduction in subsequent breast cancer with anastrozole, which did not meet statistical significance (HR 0.44, 95% CI 0.17–1.15).[138] Subsequently, the NSABP B-35 phase 3 study randomly assigned more than 3000 postmenopausal women with HR+ DCIS treated with lumpectomy and radiation to 5 years of adjuvant ET with tamoxifen versus anastrozole.[139] Anastrozole treatment resulted in decreased breast cancer–free interval (ipsilateral/contralateral breast cancer or recurrence in regional or distant sites) with HR 0.73 (95% CI 0.56–0.96; *P* = .0234) at median follow-up of 9 years. Notably, improvement was not observed until more than 5 years of follow-up and was primarily seen in women younger than 60 years of age. CBC was decreased with anastrozole (HR 0.64, 95% CI 0.43–0.96; *P* = .0322), but IBE was similar in the two treatment arms.[139]

At MDACC, ET is recommended for patients with ER+ DCIS who have had BCS, but not for those with ER– DCIS. Tamoxifen administered 20 mg daily for a 5-year course is approved adjuvant ET for DCIS. Based on available data, AI therapy with anastrozole is at

least as effective as tamoxifen and can be considered in postmenopausal women, especially those younger than 60 years or those at risk for thrombosis. An individual patient's comorbidities and preferences should be taken into account when choosing a drug given the differing toxicity profiles.

HIGH-DOSE CHEMOTHERAPY WITH TRANSPLANTATION

The efficacy of more aggressive chemotherapeutic regimens, including high-dose chemotherapy with bone marrow or stem cell support has been investigated in women with poor-prognosis, early-stage, or metastatic breast cancer. Despite encouraging initial results, two meta-analyses failed to show a survival benefit.[140,141] Thus, HDC with stem cell support is not used in the management of breast cancer at MDACC.

RISK REDUCTION STRATEGIES FOR PATIENTS WITH MUTATIONS IN *BRCA1, BRCA2,* AND OTHER BREAST CANCER SUSCEPTIBILITY GENES

Although family history of breast cancer, especially in a first-degree relative, has been identified as a risk factor for the development of breast cancer, most women with breast cancer do not have a significant family history.[142] Approximately 3% to 4% of women with breast cancer have inheritance of highly penetrant germline mutations in the *BRCA1* or *BRCA2* genes; the risk is higher, approximately 10% to 20%, with triple-negative breast cancer.[143] Women with BRCA mutations have a cumulative lifetime risk of invasive breast cancer of approximately 70% (range 50%–90%),[143,144] ovarian cancer risk of 40% to 44%, and 17% to 18%[144,145] for *BRCA1* and *BRCA2* mutations, respectively.

Mutations also increase the risk of breast cancer in males with lifetime risk to age 70 to 80 of 1.2% to 1.8% with *BRCA1* mutations and 7% to 8% with *BRCA2*, much higher than the approximately 0.1% lifetime risk in men without a mutation.[61] BRCA mutations are also associated with increased risk of malignancies other than breast cancer and are described further in other chapters. Likewise, risk-reduction strategies for malignancies other than breast cancer are described elsewhere. NCCN criteria for testing for breast cancer susceptibility genes are summarized in Table 38–4.

Pathogenic mutations in other high- and moderate-penetrance genes have also been associated with an increased risk of breast cancer; however, data guiding management for these patients are much less robust compared with those on BRCA mutations. Mutations in *TP53*, which causes Li Fraumeni syndrome, and *PTEN*, causing Cowden syndrome, are considered to be highly penetrant. However, there are limited data on breast cancer risk-reduction strategies with these mutations and clinical management is primarily based on data extrapolated from patients with BRCA mutations, with considerations regarding competing risks of other malignancies.[62,143] An important concern in patients with *TP53* mutations is the need for avoidance of radiation when formulating breast cancer treatment plans.[62,143] Other moderately to highly penetrant genes associated with increased breast cancer risk include *PALB2*, *ATM*, *CHEK2*, *CDH1*, *NBN*, *STK11*, and *NF1*.[62,143] Again, the evidence to guide risk management strategies in these patients is lacking. The list of breast cancer susceptibility genes, associated risks, and recommended management is constantly changing as new data become available.

Screening

The NCCN guidelines recommend intensified breast cancer screening in women with BRCA mutations, including encouragement of breast awareness at 18 years of age or older, clinical breast examination one to two times per year at 25 years of age or older, yearly breast MRI at 25 to 29 years of age, and the addition of annual mammography with consideration of tomosynthesis at

Table 38–4 Genetic Testing Criteria for Breast Cancer Susceptibility Genes[a]

Personal History of Breast Cancer
45 years
50 years: second breast cancer diagnosis; unknown/limited family history; breast cancer in a close relative[b]
60 years: triple-negative breast cancer
Any Age: Male breast cancer; Ashkenazi Jewish ancestry; breast cancer at <50 years or ovarian, pancreatic, or prostate cancer[0] in >1 close relative[b]; >3 breast cancer diagnoses in patient and/or close relative[b]
Personal History of Other Cancer
Ovarian cancer, epithelial
Pancreatic cancer, exocrine
Prostate cancer[c]
Family history of cancer
Criteria above in a first- or second-degree relative
>5% probability of *BRCA1/2* pathogenic mutation[d]
Family history of pathogenic/likely pathogenic mutation

[a]Based on National Comprehensive Cancer Network Genetic/Familial High-Risk Assessment Guidelines.[62]
[b]First-, second-, and third-degree blood relatives on the same side of the family.
[c]Metastatic or intraductal prostate cancer and some high-grade prostate cancers.
[d]Based on prior probability models (such as Tyrer-Cuzick, BRCApro, Penn II).

30 to 75 years; recommendations are similar for women with other high-penetrance genes.[62] In women with moderate-penetrance gene mutations, annual mammography is generally initiated when the estimated risk of breast cancer within 5 years is higher than 1%, and screening with breast MRI starting when risk is higher than 2.2%.[62] Recommendations often require individualization based on family history, including the age of diagnosis and gene mutation variants.

When deciding on appropriate screening and prevention strategies for individual patients with pathogenic mutations, it is important to discuss the risks and benefits with the patient and consider multiple factors, including the patient's age, life expectancy, comorbid medical conditions, and quality of life preferences.

Chemoprevention

The benefit of tamoxifen for risk reduction among women with *BRCA1/BRCA2* mutations is based on limited data. The P1 breast cancer prevention trial randomly assigned patients to tamoxifen or placebo for breast cancer chemoprevention. A subgroup analysis of mutation carriers among the 288 patients in whom breast cancer developed was performed, but only 19 patients (6.6%) tested positive for deleterious *BRCA1* or *BRCA2* mutations.[146] Of the *BRCA1* mutation carriers (n = 8), 5 patients were randomly assigned to tamoxifen and three to placebo (RR 1.67, 95% CI 0.32–10.7). However, among the *BRCA2* mutation carriers (n = 11), three received tamoxifen and eight received placebo (RR 0.38, 95% CI 0.06–1.56). In this very small subset of patients, tamoxifen reduced breast cancer incidence only in *BRCA2* carriers; the 62% risk reduction was similar to that observed for ER+ breast cancer when all women in the study are considered. The findings may be related to the higher incidence of ER+ breast cancer in *BRCA2* carriers compared with *BRCA1*. Cumulative data reveal that 76% of breast cancers were ER+ in patients with *BRCA2* mutations, compared with 17% in *BRCA1* mutation carriers.[146]

The Hereditary Breast Cancer Clinical Study Group performed a matched case-control study of 1504 women with *BRCA1* or *BRCA2*. Tamoxifen was used in 331 (22%) of the women and was associated with decreased CBC in both *BRCA1* (OR 0.58, 95% CI 0.39–0.85) and *BRCA2* (OR 0.39, 95% CI 0.19–0.83) mutation carriers.[147] The impact of tamoxifen duration was also assessed. Interestingly, the strongest protective effect was observed in women who received 1 year or more of tamoxifen (OR 0.37, 95% CI 0.20–0.69; P = .001), followed by 1 to 4 years (OR 0.53, 95% CI 0.32–0.87; P = .01), and was nonsignificant in women who received 4 years or more of tamoxifen (OR 0.83, 95% CI 0.44–1.55; P = .55).[147] The authors concluded that a short-term course of tamoxifen for primary prevention might be as effective as a conventional 5-year treatment course in BRCA mutation carriers. Of caution, the data on tamoxifen duration were determined through interviews with study participants, in which accuracy and reporting of data is subject to bias.

Available data in women with BRCA mutations are insufficient to determine the most effective chemoprevention strategy, optimal duration of use, and the appropriate age to begin therapy. For patients who prefer to avoid prophylactic mastectomy, it is reasonable to offer primary prevention with a regimen similar to patients at high risk of breast cancer without a mutation.

Prophylactic Mastectomies

Women with BRCA mutations should be counseled regarding the potential role of prophylactic mastectomy in reducing the future risk of breast cancer. Regardless of the specific surgical procedure chosen, a small amount of residual breast tissue remains after prophylactic mastectomy, and so does not achieve 100% efficacy in preventing subsequent breast cancer. Although discussion of surgical options for the individual patient is recommended, recent data suggest that nipple-sparing prophylactic mastectomy may be an appropriate option based on limited follow-up.[143,148]

A retrospective study examined prophylactic mastectomy efficacy among women at increased risk of breast cancer. In the moderate-risk group, 4 breast cancers were diagnosed, compared with 37.4 predicted by the Gail model, an 89.5% risk reduction. In the high-risk group, 214 women who underwent bilateral prophylactic mastectomies (BPMs) were compared with their sisters who did not. At a median follow-up of 14 years, the incidence of breast cancer in the women who underwent surgery was 1.4% and was 38.7% in their sisters.[149] The investigators then genotyped 176 of the women who had BPM and 26 were found to carry germline mutations in *BRCA1* or *BRCA2*; breast cancer developed in none over a median follow-up of 13 years.[150]

A case-control study performed by the PROSE study group followed 483 women with *BRCA* mutations, of whom 105 underwent BPM and 378 did not, serving as matched controls. At a mean follow-up of 6.4 years, 1.9% of women in the surgery group were diagnosed with breast cancer, compared with 48.7% in the control group, a more than 90% risk reduction.[151]

Although randomized studies are not feasible, BPM results in significant benefit in these and other studies.[152,153] A meta-analysis including 2555 women without prior cancer revealed significant reduction in breast cancer risk with BPM (RR 0.114, 95% CI 0.041–0.317).[154] Benefit was observed both in patients with *BRCA1* (RR 0.134, 95% CI 0.019–0.937) and *BRCA2* mutations (RR 0.183, 95% CI 0.072–0.468). However, all-cause mortality benefit did not reach statistical significance

(HR 0.226, 95% CI 0.05–1.016). In 1672 women with a history of breast cancer and mastectomy, contralateral prophylactic mastectomy resulted in significant risk reduction in CBC (RR 0.072, 95% CI 0.035–0.148) and improved all-cause mortality (HR 0.226, 95% CI 0.05–0.016).[154] Although the available data are valuable, they are based on nonrandomized studies, and so results may be influenced by selection bias.

At MDACC, women with a known deleterious mutation in either *BRCA1* or *BRCA2* are evaluated and counseled by our genetic counselors and breast surgeons regarding the potential breast cancer risk reduction of BPM or bilateral mastectomies in patients who already carry a diagnosis of breast cancer.

Risk-Reduction Bilateral Salpingo-Oophorectomies

In addition to decreasing the risk of gynecologic cancer among women with a known BRCA mutation, risk-reduction bilateral salpingo-oophorectomy (RRSO) may decrease the risk of breast cancer developing; however, the risk for primary peritoneal cancer remains. A large, prospective, multicenter study followed 1079 women 30 years of age or older with deleterious *BRCA* mutations who chose RRSO or surveillance.[155] Of patients assessable for breast cancer, RRSO reduced the risk of breast cancer in *BRCA2* mutation carriers (HR 0.28, 95% CI 0.08–0.92; P = .036), but not in those with *BRCA1* mutations (HR 0.61, 95% CI 0.30–1.22; P = .16), and was protective against ER+, but not ER– breast cancer. A reduced risk of gynecologic cancer was also observed with RRSO (HR 0.12, 95% CI 0.03–0.41; P = .001); however, the benefit was primarily in *BRCA1* mutation carriers.[155]

A prospective analysis performed by the Hereditary Breast Cancer Clinical Study Group followed 3722 women with BRCA mutations for a mean of 5.6 years. RRSO significantly reduced the risk of breast cancer only in the subgroup of patients with *BRCA2* mutation who were younger than 50 years old (HR 0.18, 95% CI 0.05–0.63; P = .007) and was especially successful in preventing ER+ breast cancers (HR 0.10, 95% CI 0.01–0.82; P = .03).[156] In contrast, another large prospective cohort study revealed that RRSO was associated with a lower risk of first breast cancer diagnosis in both *BRCA1* and *BRCA2* mutation carriers; however, in women with *BRCA1* mutations, the benefit was primarily seen in those younger than 50 years old. RRSO also significantly improved all-cause mortality, breast cancer–specific mortality, and ovarian cancer–specific mortality.[153]

Results from a meta-analysis of 10 studies in *BRCA-mutation* carriers showed that RRSO was associated with a decreased risk of breast cancer (HR 0.49, 95% CI 0.37–0.65), with similar risk reduction in the *BRCA1* and *BRCA2* subgroups. Reduction in *BRCA*-associated gynecologic cancers with HR 0.21 (95% CI 0.12–0.39) was also observed.[157] Another meta-analysis revealed similar improvements in breast cancer risk with RRSO (RR 0.552, 95% CI 0.448–0.682).[154] In women without a prior history of breast cancer, RRSO significantly improved all-cause mortality (HR 0.349, 95% CI 0.190–0.639) but not breast cancer–specific mortality (HR 0.27, 95% CI 0.05–1.33). However, both all-cause mortality (HR 0.432, 95% CI 0.318–0.588) and breast cancer–specific mortality (HR 0.337, 95% CI 0.190–0.598) were improved in women with prior breast cancer.[154]

Our patients with germline BRCA mutations are counseled by qualified professionals on the risks and benefits of RRSO. Although the procedure decreases the risk of malignancy, fertility is clearly impaired. It is important to counsel premenopausal patients regarding the physiologic changes that may be associated with premature menopause, including bone loss and psychosocial changes, such as changes in mood and sexual function.

MD ANDERSON PRACTICE TIPS

- Diagnostic imaging to evaluate for distant metastasis in the pregnant woman with breast cancer can include: MRI of the thoracic/lumbar spine without contrast, liver ultrasonography, and chest radiograph with fetal shielding.
- In men, estradiol is not completely suppressed with AIs, and therefore the addition of a gonadotropin-releasing hormone analogue is favored with aromatase inhibitor therapy.
- HRT is discouraged in women with a history of breast cancer; other pharmacologic therapies for symptoms of estrogen deficiency are preferred.
- Adjuvant ET is not indicated for patients with DCIS who have had bilateral mastectomies, and benefit is limited to chemoprevention to reduce contralateral breast cancer risk in patients with ipsilateral mastectomy.
- High-dose chemotherapy with stem cell/bone marrow support is not recommended for treatment of breast cancer.
- Although risk-reduction salpingo-oophorectomy decreases the risk of gynecologic malignancy in women with BRCA mutations, the procedure may also reduce breast cancer risk, especially in younger women.

KEY CONCEPTS

- Over the past decade, there has been increasing recognition that epithelial ovarian cancers (EOCs) represent a heterogeneous group of malignancies secondary to distinct pathogenic pathways and molecular alterations associated with the development of different histologic subtypes. Although some types are thought to arise from the ovarian surface epithelium, the fallopian tube is the likely origin of high-grade serous cancer. This understanding heralded the practice of risk-reducing salpingo-oophorectomy in women at high risk for development of ovarian cancer
- Stage of disease at the time of diagnosis is an important prognostic indicator. Five-year survival rates among women with localized, regional, and distant disease at the time of diagnosis are 92%, 72%, and 27%, respectively. Early-stage ovarian cancer is discovered in fewer than 30% of patients.
- In advanced EOC, surgery and chemotherapy are both used in initial management; however, there remains debate regarding the sequence of these interventions. Historically, patients have been candidates for neoadjuvant chemotherapy if they have multiple medical comorbidities, poor performance status, or extensive disease on imaging that is not felt to be amenable to upfront surgery. Despite this, there is no current consensus regarding which patients should have upfront cytoreduction or neoadjuvant chemotherapy.
- High risk of recurrent disease after treatment of advanced-stage EOC has prompted an intensive search for maintenance strategies, and poly (adenosine diphosphate [ADP]-ribose) polymerase inhibitors have been found to be particularly efficacious in this setting. Recent trials have yielded multiple indications: olaparib for patients with germline or somatic *BRCA1/2* mutations, niraparib for all-comers, and the combination of olaparib and bevacizumab for those with homologous-recombination deficiency.
- Over the last 5 years, a number of trials have assessed the efficacy of programmed cell death protein 1/programmed cell death ligand 1 immune checkpoint inhibitors in patients with recurrent EOC. The efficacy results can be summarized as an observed response rate of 10% to 15%, with another 20% to 40% of patients experiencing stable disease.
- Malignant ovarian germ cell tumors (MOGCTs) recapitulate normal embryonic and extraembryonic cells and structures and are derived from the primitive germ cells of the embryonic gonad. The MOGCTs comprise 2% to 3% of all ovarian malignancies, and they usually develop in girls, adolescents, and women of reproductive age. Advances in chemotherapy have yielded cure in the vast majority of patients with these tumors, and modifications in surgical technique have allowed fertility preservation in most patients.

EPITHELIAL OVARIAN CANCER

Epidemiology

Ovarian cancer is the second most common cancer of the female genital tract in developed countries, with approximately 21,750 cases expected in the United States in 2020.[1] Epithelial tumors comprise 95% of ovarian cancers, and the most common histologic subtype is high-grade serous carcinoma, followed by endometrioid, clear cell, and mucinous tumors. Ovarian cancer remains the number one cause of death from gynecologic cancers in the United States, accounting for 13,940 deaths expected this year.

Among women, ovarian cancer is the fifth most common cancer-related cause of death in the United States.[1] The lifetime risk of a woman in the United States developing ovarian cancer is approximately 1 in 70 (1.37%).[2] Incidence rates are higher among White women compared with Black, Hispanic, or Asian American women in the United States, although the differences are narrowing. In most parts of Europe and North America, the incidence of ovarian cancer was constant during the decades before the 1990s. However, incidence rates have been falling on average 2.3% each year over the last 10 years. In addition, death rates have been falling on average 2.3% each year from 2007 through 2016.[2]

This cancer is predominantly a cancer of the perimenopausal and the postmenopausal period, with 80% to 90% of cases occurring after the age of 40 years. The incidence is higher in older women, and the median age at diagnosis is 63 years.[2]

Mortality

Ovarian cancer accounts for 5.4% of the deaths from cancer that occur in women between 60 and 79 years of age.[1] Prognosis among women with ovarian cancer is dependent on the stage of disease at the time of diagnosis. Five-year survival rates among women with localized, regional, and distant disease at the time of diagnosis are 92%, 72%, and 27%, respectively.[1] Relative survival rates for ovarian cancer have improved substantially over the last decade by an average of 2.3% per year, and the modern 5-year survival estimate is 47.6%.[2] A large study leveraging the Surveillance, Epidemiology, and End Results (SEER) database showed that among 35,868 patients, age above 70 years, marital status, Black race, and higher stage were strongly associated with worse 3-year mortality, but these characteristics had a declining impact the longer patients survived.[3] An additional study using SEER data demonstrated that compared with non-Hispanic White women, non-Hispanic Black women were at a 28% increased risk of death, and Hispanic women had equivalent survival to non-Hispanic White women, with Asian women experiencing the lowest risk of mortality.[4] Between 1995 and 2004, non-Hispanic Black women had a 31% increase in mortality compared with White women. This disparity remained consistent between the years 2005 and 2015, whereas there was a 6% reduction in the risk of mortality among White women.[4] It has been hypothesized that poorer survival in Black women may be mediated by lack of access to appropriate guideline-adherent care, with multiple studies revealing that Black women are less likely to receive surgery[4–6] and chemotherapy[5–7] for ovarian cancer.

Etiology

Over the past decade, there has been increasing recognition that epithelial ovarian cancers (EOCs) represent a heterogeneous group of malignancies. This heterogeneity is the product of distinct pathogenic pathways and molecular alterations associated with the development of different histologic subtypes. Specifically, serous malignancies are now further subdivided into two separate groups: high-grade serous carcinomas (HGSCs) and low-grade serous carcinomas (LGSCs).[8]

Historically, HGSC was thought to arise from the ovarian surface epithelium because it is often associated with ovarian masses.[9] However, over the past two decades, advancement in knowledge defined the fallopian tube as the likely origin of HGSC. The understanding that HGSC is often characterized by *TP53* mutations and subsequent defects in DNA repair mechanisms via loss of *BRCA* gene function[10] heralded the practice of risk-reducing salpingo-oophorectomy (RRSO) in women at high risk for developing ovarian cancer (such as those with *BRCA 1* and *BRCA 2* germline mutations). In women undergoing RRSO, it is now standard-of-care practice to section and extensively examine the fimbriated end of the fallopian tubes (SEE-FIM protocol). Even if overt malignancy is not present, this examination may reveal areas of marked cytologic atypia and disorganized growth within the fimbria. These aberrations have been called serous tubal intraepithelial carcinoma or tubal dysplasia and are characterized by cytologic atypia, positive p53 immunostaining (which correlates with mutations in the *TP53* gene), abnormal proliferation (as evident by Ki67 staining), and DNA damage (Fig. 39–1).[8–13] Older studies found the risk of occult tubal carcinoma in high-risk patients undergoing RRSO to be approximately 5% to 10%.[14–16] A recent systematic review of 27 studies found that the pooled prevalence was lower at 1.19%, though this study included women at risk based on family history alone in addition to women with germline *BRCA* mutations.[17] The discovery of fallopian tube carcinoma in the absence of ovarian carcinoma led to the hypothesis that precursor lesions for HGSC arise in the fallopian tube and share identical *TP53* mutations.[18]

Based on their distinct molecular features and clinicopathologic characteristics, other carcinogenesis models have been proposed for endometrioid, clear cell, mucinous, and low-grade serous ovarian cancers. Endometrioid and clear cell tumors have an epidemiologic link with endometriosis,[19] and there is accumulating evidence that they may arise via activation of *KRAS*, and *PI3K,* and inactivation of *PTEN* and *ARID1A*,[20] though the rate of malignant transformation is low[21] and endometriosis is not considered a precursor lesion. The origin of the rare mucinous ovarian tumors

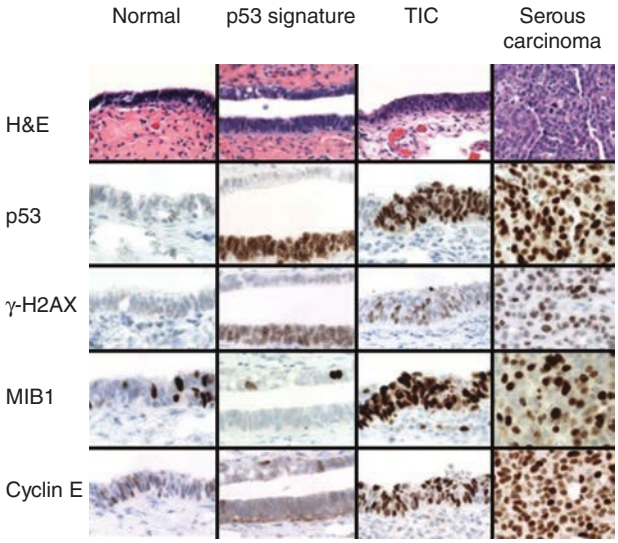

FIGURE 39–1 Overview of co-localization of p53, γ-H2AX, MIB1, and cyclin E in normal mucosa, p53 signature, tubal intraepithelial carcinoma, and serous carcinoma. H&E, hematoxylin and eosin. (Reproduced with permission from Lee Y, Miron A, Drapkin R, et al. A candidate precursor to serous carcinoma that originates in the distal fallopian tube, *J Pathol* 2007 Jan;211(1):26-35.)

is not fully elucidated, possibly because in the past many "mucinous ovarian cancers" were misdiagnosed metastases of gastrointestinal origin.[22] A study using genetic analysis found evidence for a stepwise progression from borderline precursors initiated by a KRAS or CDKN2A event to high-grade invasive Müllerian ovarian cancer driven by *TP53* mutation and copy number aberrations.[23] LGSCs are characterized by KRAS and BRAF mutations,[8] absence of TP53 mutations, and lack of a known precursor in the fallopian tube. They are thought to arise from ectopic cortical inclusion cysts and a stepwise progression from benign lesion to borderline neoplasm to LGSC has been described. This remains a controversial area with ongoing research efforts focusing on understanding the pathophysiology of these differing EOC subtypes.

Risk Factors

Numerous studies have attempted to demonstrate possible links between the risk of developing ovarian cancer and environmental, dietary, reproductive, endocrine, viral, and hereditary factors. These factors are summarized in Table 39–1.

The strongest risk factor for ovarian cancer is a genetic predisposition. A contemporary prospective study of 9856 women with *BRCA1* and *BRCA2* mutations demonstrated a 46% (95% CI 35–53) and 17% (95% CI 11–25) cumulative lifetime risk[24] of developing ovarian cancer, respectively, which is 18 to 36 times higher than that of the general population. Similar to *BRCA1* and *BRCA2* mutations, variants in other genes in the Fanconi anemia pathway have been implicated in the development of EOC, such as *RAD51C*, *RAD51D*, *PALB2*, and *BARD1*. Notably, these genes are less penetrant than variants in *BRCA* genes.[25] A smaller proportion of cases of familial ovarian cancer are associated with mutations in mismatch repair genes (*MLH1*, *MSH2*, *MHS6*, *PMS2*) related to Lynch syndrome. Patients with Lynch syndrome can demonstrate varying lifetime risk of ovarian cancer depending on the mutated gene. Patients with germline mutations in *MLH1* and *MSH2* seem to be at the highest risk for ovarian cancer compared with patients with

Table 39–1 Risk Factors for Developing Ovarian Cancer

Increased	Decreased	Indeterminate
Hereditary Family history of ovarian cancer Personal history of breast cancer *BRCA1* or *BRCA2* mutation Lynch syndrome Other gene mutations: *BRIP1* *RAD51C* *RAD51D*	*Reproductive* Multiparity Breastfeeding	Fertility drugs Exercise Cigarette smoking
Reproductive Advanced age Nulligravity Infertility	*Hormonal* Oral contraceptives Progestins	
Hormonal Early menarche Late age at natural menopause Hormone replacement therapy Estrogen Androgens	*Surgery* Hysterectomy Tubal ligation	
Inflammatory Endometriosis Pelvic inflammatory disease		
Lifestyle Obesity

MSH6 and *PMS2* mutations. Ovarian cancer risk can range from 5% to 20% in patients with MLH1 mutations, 10% to 38% in patients with MSH2 mutations, and 1% to 11% in patients with MSH6 mutations. More data are needed to determine ovarian cancer risk in patients with PMS2 mutations.[26–30] Identifying women at risk for development of ovarian cancer from a heritable cause is currently the only successful method for ovarian cancer prevention. Thus, National Comprehensive Cancer Network (NCCN) guidelines have recommended genetic testing for patients with a history of ovarian cancer since at least 2010, not only to determine their risk for developing concurrent malignancies and identify treatment options, but also to identify family members who may be at risk and could benefit from preventive measures.

Other factors associated with an increased risk of ovarian cancer include age, early menarche, late menopause, and obesity.[31–33] Protective factors that have been shown to reduce the risk of ovarian cancer include the use of oral contraceptives, multiparity, breastfeeding, hysterectomy, and tubal ligation.[34] Other factors, including exercise, infertility treatment, and use of postmenopausal hormone replacement therapy, have not been definitively shown to alter a woman's risk of development of ovarian cancer.

Screening

Stage I ovarian cancer is associated with excellent survival; however, more than two-thirds of patients are diagnosed with stage III or IV disease. These observations have provided a compelling rationale in support of screening for early-stage disease. The most commonly used screening strategies include a combination of serum cancer antigen 125 (CA 125) levels and pelvic sonography. Although several large trials have demonstrated that screening can detect cancer in asymptomatic women, there are concerns regarding the poor positive predictive value for these strategies and lack of proven survival benefit. In fact, screening average-risk women can cause potential harm. With the low prevalence of ovarian cancer, there is a high risk of obtaining false-positive results with patients possibly undergoing unnecessary surgical evaluation, risk from surgery and anesthesia, psychological stress, and associated cost. The findings of four key trials are summarized in Table 39–2.[35–40] The United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) evaluated more than 200,000 postmenopausal average-risk women and randomly assigned them to (1) multimodal screening (utilizing the Risk of Ovarian Cancer time series algorithm to interpret CA 125 with transvaginal ultrasound), (2) annual transvaginal ultrasound screening, or (3) no screening in a 1:1:2 ratio. There was no significant reduction in ovarian cancer–related mortality in their primary analysis.[40] As of this writing, the US Preventive Services Task Force as well as the American College of Obstetricians and Gynecologists and the Society of Gynecologic Oncology recommend against screening for ovarian cancer in asymptomatic women of average risk.

The Molecular Landscape of Epithelial Ovarian Cancer

Molecular Biology

Although the different subtypes of EOC possess unique molecular aberrations (Table 39–3) and transcriptional signatures, their morphologic features resemble the specialized epithelia of the reproductive tract that derive from the Müllerian ducts.

As noted, accumulating evidence points to the distal fallopian tube epithelium as the tissue of origin for most HGSCs. The most common molecular alterations in serous carcinomas are mutations in *TP53*, which are nearly ubiquitous. The Cancer Genome Atlas project has also significantly advanced our understanding of other molecular and genetic alterations in HGSC. In addition to the expected *TP53* mutations in 96% of tumors, low-prevalence, recurrent somatic mutations in *NF1*, *BRCA1*, *BRCA2*, *RB1*, and *CDK12* were also observed. Serous carcinomas are also characterized by a high degree of chromosomal instability (gene copy number amplifications and deletions), and both total and regional instability are associated with tumor grade and altered patient outcomes.[41] Somatic copy number analysis performed as part of The Cancer Genome Atlas also confirmed 8 and 22 chromosomal regions of recurrent gain and loss, respectively. Five of the gains and 18 of the losses occurred in more than half of the tumors. Although such aberrant areas of DNA frequently carry multiple genes, it is presently thought that only a limited number of genes are "key drivers" of the process. These key drivers are thought to be the most critical markers and potential treatment targets. Candidate drivers at areas of copy number gain and loss are frequently proposed. For example, it has been suggested that 45% of HGSCs harbor altered phosphatidylinositol 3-kinase (PI3K)/RAS signaling mediated by multiple copy number alterations, including *PTEN* deletion and *PIK3CA*, *KRAS*, *AKT1*, and *AKT2* amplification. LGSCs have been found to have alterations in the mitogen-activated protein kinase pathway. Approximately 20% to 40% of LGSC tumors have a *KRAS* mutation, although a smaller proportion of tumors demonstrate mutations in *BRAF*, accounting for 5% of LGSCs.[42]

Clear cell and endometrioid cancers are epidemiologically and molecularly linked to endometriosis. Frequent somatic mutations of *PIK3CA* and ARID1A

Table 39–2 Summary of Major Trials in Ovarian Cancer Screening

Study Name Recruitment Years	RCT	Location	No. of Women	Screening Method	Aim	Outcome	Limitations/Strengths
Kentucky study[39]	No	Kentucky, USA	37,293 screened	Annual TVS	5-year OC survival	Screened (74.8±6.6%) vs Unscreened (53.7±2.3%) $P < .001$ Hard to interpret true effects of screening on disease mortality in non-RCT	Single center Unscreened controls were diagnosed with OC in the center but not part of the study Lead time effect Healthy volunteer effect
SCSOCS[38] 1985–1999	Yes	Shizuoka, Japan 212 hospitals	82,487 total (41,688 screened) (40,799 control)	Annual CA 125 (>35 U/mL) Annual TVS	Early stage I/II diagnosis	Screened (63%) vs control (38%) $P = .23$	—
PLCO[37] 1993–2001	Yes	USA 10 sites	78,216 total (34,253 screened) (34,304 usual care)	Annual CA 125 (>35 U/mL) (6 years) Annual TVS (first 4 years)	All-cause mortality: for invasive EOC, tubal and peritoneal cancer	12.4-year risk ratio (1.18, 95% CI 0.91–1.54) 14.7-year risk ratio (1.01, 95% CI 0.97–1.05)	High surgical complication rate (15%) Lack of stage shift (22.2%)
UKCTOS[40] 2001–2005	Yes	UK 13 sites	202,638 total (50,639 USS) (50,640 MMS) (101,359 control)	MMS	Mortality reduction: for invasive EOC, tubal and peritoneal cancer Early stage I/II diagnosis	**Primary analysis:** Mortality reduction over years 0–14 was: MMS 15% (95% CI –3 to 20; $P = .10$) USS 11% (–7 to 27; $P = .21$) **Analysis excluding prevalent cases:** Overall mortality reduction 20% (–2 to 40; $P = .021$) with reduction of 8% (–27 to 43) over years 0–7 And 28% (–3 to 49) mortality reduction over years 7–14 in favor of MMS Stage I/II shift with MMS of 36.1% stage I/II vs control 23.9%, but not with USS ($P = .0001$)	Screening group had higher worry and lower pleasure scores when >2 TVS performed vs no TVS Good PPV of 4.4 surgeries per cancer detected
NROSS[a] 2001–2011	No	USA 7 sites	4051 total	MMS	Specificity and PPV of OC screening in PM	PPV of 40% (95% CI 12.2–73.8)	—

Table 39–3 Current Concepts Regarding the Origins and Molecular Pathology of Epithelial Ovarian Cancer

Histology	Precursor	Molecular Features
Low-grade serous carcinoma	Cystadenoma–borderline tumor–carcinoma sequence	Mutations in *KRAS* and/or *BRAF*
High-grade serous carcinoma	"De novo" in epithelial inclusion cysts	*p53* mutation and *BRCA1* dysfunction (usually promoter methylation) *PIK3CA*[b] amplification (25%-40%)
Low-grade endometrioid carcinoma	Endometriosis and endometrial-like hyperplasia[a]	Mutations in *CTNNB1* (B-catenin gene) and *PTEN* with microsatellite instability
High-grade endometrioid carcinoma	Epithelial inclusion glands/cysts	*p53* mutation and *BRCA1* dysfunction (usually promoter methylation) *PIK3CA* mutation
Mucinous carcinoma	Cystadenoma–borderline tumor–carcinoma sequence	Mutations in *KRAS*; *p53* mutation associated with transition from borderline tumor to carcinoma.
Clear cell carcinoma	Endometriosis	*PTEN* mutation/loss of heterozygosity *PIK3CA* mutation

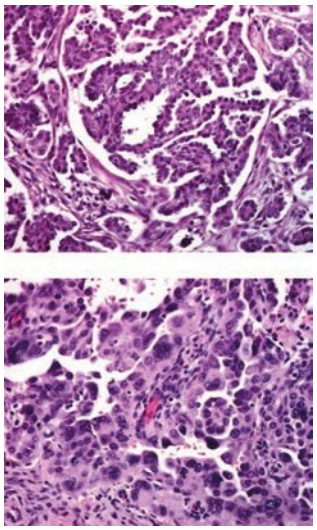
[a]Endometriosis and adjacent low-grade endometrioid carcinoma share common genetic events, such as loss of heterozygosity at the same loci involving the same allele (eg, PTEN). In contrast, high-grade and poorly differentiated endometrioid carcinomas are similar to high-grade serous carcinomas.
[b]*PIK3CA* is the gene at chromosome 3q26 that specifically encodes the p110α subunit of the phosphatidylinositol-3-kinase (PI3K) protein.

(AT-rich interactive domain-containing protein 1A) have been documented in tumors associated with endometriosis.[43,44] Common genetic abnormalities identified in endometrioid ovarian carcinomas include somatic mutations of *CTNNB1* and *PTEN*.[45]

Cytokines and Growth Factors

Several cytokines and growth factors have been studied in ovarian carcinogenesis. Although a detailed review of growth factor pathways targeted in ovarian cancer is beyond the scope of this chapter, we will highlight a few of interest.

Levels of interleukin 10 (IL-10) and interleukin 6 (IL-6) are particularly elevated in ovarian cancer ascites. Endogenously produced IL-6 can protect tumor cells from natural killer cell–mediated killing, and IL-6 expression by immunohistochemistry is associated with poor prognosis.[46] Furthermore, IL-6 has been identified as an etiologic paracrine factor in paraneoplastic thrombocytosis and associated poor prognosis in ovarian cancer.[47] When compared with high-grade serous tumors, ovarian clear cell carcinomas are associated with higher circulating levels of IL-6.[48]



The vascular endothelial growth factor (VEGF) signaling cascade is mediated through a partially redundant set of ligands and receptors, which have emerged as promising targets for antiangiogenic cancer therapy. The VEGF ligand family consists of seven ligands: VEGF A–E, placenta growth factor 1 (PlGF1), and PlGF2. The receptor tyrosine kinases involved in this signaling cascade include VEGF receptor type 1 (VEGFR1), VEGFR2, and VEGFR3. VEGF ligands are overexpressed in EOC cells, although the receptors are present mainly on the tumor endothelial cells.[49] VEGF is a key mediator of angiogenesis, which is stimulated by hypoxia. Bevacizumab, a monoclonal anti–VEGF-A antibody, is the prototypical member of this class and has become a common addition to standard cytotoxic agents in the upfront, platinum-sensitive, and platinum-resistant settings.

Prognostic Factors

Prognostic factors are tumor-related characteristics that determine the biologic behavior and risk of death from the disease; their predictive value may change during the course of treatment and thereafter.

Factors associated with poor prognosis in advanced ovarian cancer (stage III or IV) fall into two subgroups (as determined by multivariate analysis in clinical trials and observational studies):

1. *Variables before systemic treatment predictive of survival:* age, stage at diagnosis, performance status, residual tumor volume after cytoreductive surgery, BRCA status, and tumor histology.
2. *Variables at the time of relapse predictive of time to progression:* less than 6 months from last chemotherapy (platinum-resistant disease), poorer performance status, mucinous histology, larger number of sites of disease, best previous response to chemotherapy, and serum CA 125 levels.

Low-grade serous carcinoma of the ovary is characterized by relative uniformity of the cells and up to 12 mitoses per 10 high-power fields. Courtesy of Anais Malpica, MD.

High-grade serous carcinoma of the ovary is characterized by pleomorphism; there is marked nuclear atypia and >12 mitoses per 10 high-power fields. Courtesy of Anais Malpica, MD.

FIGURE 39–2 **Low-grade and high-grade serous carcinoma. (Used with permission from Anais Malpica, MD.)**

Stage

Stage is a dominant prognostic factor in ovarian cancer. The main prognostic factors in early-stage ovarian cancer (stages I–IIA) are International Federation of Gynecology and Obstetrics (FIGO) stage, histologic grade, histologic type, and patient's age. Early-stage ovarian cancer is discovered in fewer than 30% of patients. In such cases, the 5-year survival is good, ranging from 51% to 98%.[1–3]

Cancer Antigen 125

Cancer antigen 125 is a high-molecular-weight glycoprotein that is elevated in 80% of EOCs.[50] There is no definitive evidence that pretherapeutic CA 125 levels correlate with survival in EOC[51]; however, there has been evidence that the kinetics of an individual's CA 125 level during treatment may be related to the best response to treatment as well as survival.[52]

Residual Disease

It is logical to assume that the extent of postoperative residual tumor volume is affected by both the biology and the history of the disease, as well as the radicality, emphasis, and effort involved in the tumor-reductive surgery. What remains controversial is the relative contribution of these factors to the prognostic significance of residual disease. On one hand, the tumors that are more aggressive and disseminated are more difficult to resect and therefore associated with larger residual disease. Therefore, the preoperative tumor burden may be more predictive of outcome than the amount of residual disease after surgery. Other features—such as the type of chemotherapy, the intrinsic chemosensitivity of the tumor, and the presence of other biological variables—may be as important as, or even more important than, the extent of the surgery. Proponents of the importance of maximal surgical effort point to a wealth of retrospective data and the evolution of "optimal cytoreductive surgery" from less than 2 cm to R0 (no visible residual disease) as evidence for the importance of the surgical result.[53]

Histologic Subtypes

Serous Carcinoma

Serous carcinoma is the most common histologic subtype of EOC, and this subtype can further be divided into HGSCs and LGSCs.[54] In 2004, Malpica and colleagues at MDACC developed a two-tier grading system in serous carcinomas based on nuclear atypia and mitotic rate to distinguish high-grade from low-grade tumors (Fig. 39–2).[55] This system has since been validated and adopted by the gynecologic oncology community to define these two diseases.

High-Grade Serous Carcinoma

HGSCs account for 70% to 80% of all ovarian cancers and are the most common type of EOC. HGSCs may present with varying architectural patterns, but the defining characteristic of these tumors is high mitotic activity (>12 mitoses per 10 high-power fields [HPFs]) and the presence of multinucleated cells.[56]

Low-Grade Serous Carcinoma

Low-grade serous carcinoma accounts for 6% to 10% of serous ovarian cancers and 5% to 8% of all ovarian

cancers. These tumors are now thought to arise from borderline tumors and have distinct molecular aberrations and clinical behavior when compared with their high-grade counterparts. Low-grade serous tumors have low mitotic activity (<12 mitoses per 10 HPFs) and are distinguished from borderline tumors based on destructive invasion of more than 5 mm. Consistent with their distinct pathophysiology and tumor biology, LGSCs are more resistant to chemotherapy and are associated with significantly higher rates of platinum-resistant disease.[57]

Mucinous Carcinoma

In older publications, the proportion of mucinous ovarian cancers is as high as 30%. However, there is now increased recognition that many such tumors, on careful evaluation, are thought to represent metastases from the gastrointestinal tract. A contemporary estimate of the prevalence of primary ovarian mucinous carcinoma is approximately 3%. Primary ovarian origin is favored by unilaterality, size greater than 12 cm (large), smooth external surface, and association with other ovarian pathology. Conversely, metastases tend to be bilateral, measure less than 10 cm in size, exhibit surface involvement, and demonstrate colloid and signet ring morphology. True mucinous ovarian tumors are low-grade malignancies that have a low propensity for metastatic spread and are usually diagnosed as unilateral stage IA tumors even though they may reach a large size (Fig. 39–3).[58] Newer studies have also dispelled the notion that pseudomyxoma peritonei is commonly secondary to an ovarian mucinous carcinoma. It is now recognized that pseudomyxoma peritonei is almost always associated with an appendiceal mucinous lesion.[59]

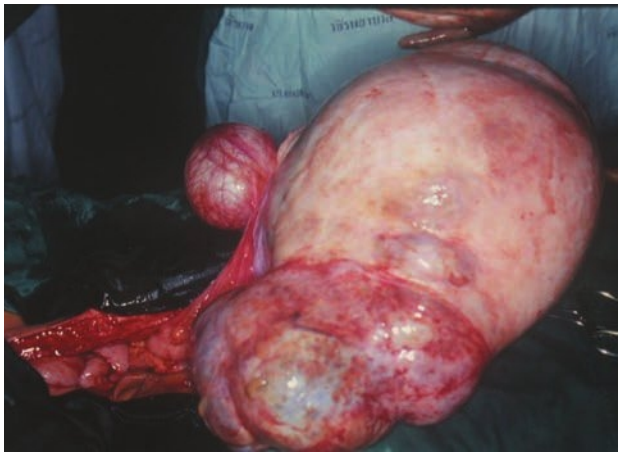


FIGURE 39–3 Operative removal of mucinous ovarian tumor.

Endometrioid Adenocarcinoma

Overall, 10% of epithelial ovarian tumors are of endometrioid histology and resemble endometrial adenocarcinoma. Endometrioid ovarian and endometrial malignancies can occur simultaneously as synchronous primary tumors in as many as 25% of cases in patients younger than 45 years of age.[60] Identification of multifocal disease is important because patients with metastatic disease from the uterus to the ovaries have a 5-year survival rate of 30% to 40%. Those with synchronous multifocal disease have a 5-year survival rate of 70% to 80%. Concurrent endometriosis is present in 10% of cases. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be seen.

Clear Cell Carcinoma

Clear cell carcinomas comprise 5% to 10% of ovarian cancers and, like endometrioid tumors, may be associated with endometriosis or endometrial cancer. Some studies indicate that clear cell carcinoma may be resistant to standard carboplatin-paclitaxel–based chemotherapy regimens. However, other investigators have shown that when the pathology was carefully reviewed by a gynecologic pathologist, only suboptimal cytoreduction and spread of disease were associated with a significantly increased risk of platinum resistance.[61]

Transitional Cell Carcinoma

Transitional cell carcinomas were previously thought to represent malignant Brenner tumors; however, recent studies have shown that they are molecularly similar to HGSCs. These tumors are now classified as a subtype of HGSC.[62]

Undifferentiated Carcinoma

Undifferentiated carcinomas are thought to represent the most poorly differentiated HGSCs rather than a separate entity.[63]

Histologic Grading

Previously, a three-tier grading system was used in the diagnosis of EOC; however, there was no consensus on the definition of this system. More recently, two-tier grading systems (high grade vs low grade) have been shown to have better prognostic and interobserver variability.[64]

Staging

Accurate staging is critical to the success of surgery and adjuvant therapy. The staging of ovarian cancer

Table 39–4 FIGO Staging for Ovarian Cancer

FIGO		TNM
0	Primary tumor cannot be assessed	TX
	No evidence of primary tumor	T0
I	Tumor confined to ovaries	T1
IA	Tumor limited to one ovary, capsule intact	T1a
	No tumor on ovarian surface	
	No malignant cells in the ascites or peritoneal washings	
IB	Tumor limited to both ovaries, capsules intact	T1b
	No tumor on ovarian surface	
	No malignant cells in the ascites or peritoneal washings	
IC IC1 IC2 IC3	Tumor limited to one or both ovaries Surgical spill Rupture before surgery, tumor on ovarian surface Positive malignant cells in the ascites, or positive peritoneal washings	T1c
II	Tumor involves one or both ovaries with pelvic extension	T2
IIA	Extension and/or implants in uterus and/or tubes	T2a
IIB	Extension to other pelvic organ	T2b
III	Tumor involves peritoneal metastasis outside the pelvis and/or regional lymph node metastasis	T3
IIIA1(i) IIIA1(ii) IIIA2 IIIB	Positive retroperitoneal nodes only ≤10 mm Positive retroperitoneal nodes only >10 mm Microscopic, extrapelvic (above the brim) peritoneal involvement ± positive retroperitoneal lymph nodes Macroscopic, extrapelvic, peritoneal metastasis ≤2 cm ± positive retroperitoneal lymph nodes; includes extension to capsule of liver/spleen	T1, T2, T3aN1 T3a/T3aN1 T3b/T3bN1
IIIC	Macroscopic, extrapelvic, peritoneal metastasis >2 cm ± positive retroperitoneal lymph nodes; includes extension to capsule of liver/spleen	T3c/T3cN1
IVA IVB	Pleural effusion with positive cytology Hepatic and/or splenic parenchymal metastasis, metastasis to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside the abdominal cavity)	M1

Other major recommendations are as follows:
- Histologic type including grading should be designated at staging.
- Primary site (ovary, fallopian tube, or peritoneum) should be designated where possible.
- Tumors that may otherwise qualify for stage I but involved with dense adhesions justify upgrading to stage II if tumor cells are histologically proven to be present in the adhesions.

is based on the gross and pathologic findings of the initial surgical evaluation. The FIGO classification uses the sites and extent of the disease, including capsule rupture and ascites, to categorize ovarian cancer into four stages. This is summarized in Table 39–4.

Diagnosis

Symptoms of ovarian cancer are nonspecific and include early satiety, bloating, constipation, and weight loss. It is not uncommon for patients to have been referred for a gastrointestinal evaluation before the correct diagnosis is reached. Objective signs of ovarian carcinoma are also nonspecific and can include a pelvic mass, ascites, carcinomatosis, possible pleural effusion(s), and occasionally supraclavicular lymphadenopathy.

Management

In general, the initial management and staging of EOC is surgical. In early-stage ovarian cancer, comprehensive staging allows for proper triage to adjuvant therapy. When comprehensive staging is performed, a substantial number of patients initially believed to have disease confined to the pelvis will be staged upward.[65]

In advanced EOC, surgery and chemotherapy are both utilized in initial management; however, there remains debate regarding the sequence of these interventions. Historically, patients have been candidates for neoadjuvant chemotherapy if they have multiple medical comorbidities, poor performance status, or extensive disease on imaging that is not felt to be

amenable to upfront surgery. Despite this, there is no current consensus regarding which patients should have upfront cytoreduction or neoadjuvant chemotherapy (NACT).

The current approach at MDACC is for patients with suspected advanced ovarian cancer who are medically fit for surgery and are without distant metastatic disease (based on computed tomographic [CT] imaging) to undergo a preoperative laparoscopic assessment.

This laparoscopic evaluation provides the following: surgicopathologic diagnosis, assessment of metastatic disease burden and likelihood of complete resection (modified Fagotti score),[66] and research tissue acquisition. Our laparoscopic triage is accomplished by scoring made by two independent and blinded surgeons. Patients scoring less than 10 undergo primary cytoreduction. Those with scores of 10 or more undergo NACT (consisting of 3 or 4 cycles of carboplatin and paclitaxel), followed by consideration of interval cytoreductive surgery and three additional cycles of chemotherapy (with or without maintenance therapy).[67] An outline of our treatment algorithm is shown in Fig. 39–4.

In addition to a preoperative evaluation with lab testing, imaging, and office examination, the NCCN now recommends genetic testing for all newly diagnosed high-grade serous ovarian cancers.

Primary Cytoreductive Surgery

A staging laparotomy involves the following steps:

1. Midline vertical incision
2. Evacuation and cytologic analysis of ascites
3. Inspection and palpation of all peritoneal (intraperitoneal and retroperitoneal) surfaces, including the subdiaphragmatic areas
4. Total abdominal hysterectomy and bilateral salpingo-oophorectomy
5. Omentectomy with debulking to no gross residual disease
6. If disease is limited to the ovaries, staging includes bilateral pelvic and para-aortic lymph node sampling, and multiple biopsies including the paracolonic gutters, cul-de-sac, lateral pelvic walls, vesicouterine reflection, subdiaphragmatic sites, and intra-abdominal areas
7. Appendectomy if a mucinous tumor is found

The goal of primary cytoreductive surgery (PCS) is to remove all visible tumor as the amount of residual disease is inversely correlated with patient survival. Currently, an optimal tumor-reductive surgery is defined as no residual nodules greater than 1 cm in size. More recent studies have tried to refine the definition of *optimal* cytoreductive surgery by distinguishing patients with no visible residual disease. Patients who undergo complete gross resection of all visible disease have improved overall survival (OS), even compared with patients with less than 1 cm of residual disease.

Several retrospective studies have suggested that primary surgery with optimal cytoreduction is more effective than NACT for women with advanced-stage EOC, with improved progression-free survival (PFS) and OS. However, three phase 3 randomized clinical trials found that NACT does not result in inferior OS compared with primary surgery.[68–70] These trials have been criticized because many women who received PCS had more than 1 cm of residual disease after surgery, the survival durations were shorter than expected, and a significant proportion of women received single-agent carboplatin instead of the traditional platinum-based doublet. Despite these concerns, the use of NACT for advanced ovarian cancer has been increasing in the United States in recent years.

Among patients who receive NACT, it may be possible to further reduce morbidity by performing interval cytoreductive surgery using minimally invasive surgical techniques. However, although preliminary data have been promising, it is unknown whether minimally invasive interval cytoreductive surgery delivers oncologic outcomes that are comparable with those achieved in open surgery.

Adjuvant Therapy

Chemotherapy

Early-Stage Disease

Though women with surgically treated early-stage EOC in general have excellent rates of survival, studies have defined a subset of patients with early-stage disease who are at increased risk of relapse ranging from 25% to 45%.[71] These high-risk features include:

1. Stage IC (tumor confined to the ovary with positive peritoneal washings) or II disease
2. Clear cell histology of any stage
3. High-grade tumor

To investigate whether adjuvant therapy after cytoreduction is warranted for early-stage disease, the ACTION (Adjuvant Chemotherapy in Ovarian Neoplasms) trial randomly assigned 448 patients to platinum-based chemotherapy or observation. Overall, adjuvant chemotherapy improved recurrence-free survival (RFS; 70% vs 62%). Although there was no survival advantage in patients who underwent optimal surgical staging, adjuvant chemotherapy after incomplete surgical staging led to a significant improvement in RFS (65% vs 56%) and cancer-specific survival (80% vs 69%).[72] This was also demonstrated in a meta-analysis of five randomized trials.[73] Thus, patients with early-stage disease without high-risk features who undergo complete

[1]Paclitaxel, hormonal therapy, or biologic therapy
[2]Symptomatic or radiologic

FIGURE 39–4 (*Cont.*)

surgical staging likely do not benefit from postsurgical chemotherapy. Those with high-risk features, however, should be considered for adjuvant therapy. Two meta-analyses have shown that adjuvant chemotherapy improved both RFS and OS in patients with early-stage disease.[73,74] Subgroup analysis demonstrated that adjuvant therapy decreased the risk of death by 52% compared with observation in women with high-risk features (hazard ratio [HR] 0.48, 95% CI 0.32–0.72), but not in women without high-risk features.[73]

For early-stage EOC with high-risk features, treatment strategies are largely extrapolated from regimens with demonstrated efficacy in advanced disease. Thus, these patients often receive a platinum doublet such as carboplatin plus paclitaxel, though retrospective data indicate that single-agent carboplatin may be equally efficacious.[74] In addition, there is no consensus on the optimal number of adjuvant chemotherapy cycles. GOG 157 randomly assigned 457 patients with stage IA grade 3, stage IB grade 3, stage IC, and completely resected stage II ovarian epithelial cancer to six versus three cycles of carboplatin (7.5 area under the curve [AUC] over 30 min) and paclitaxel (175 mg/m^2 over 3 hours) every 21 days.[75] In the standard 3-cycle arm, the estimated probability of cancer recurring within 5 years was 27%, compared with 19% in the 6-cycle arm. The recurrence rate for 6 cycles was 24% lower, though this did not reach statistical significance (HR 0.761; 95% CI 0.51–1.13; $P = .18$). In addition, patients receiving six cycles of chemotherapy had significantly higher rates of grade 3 or 4 neurotoxicity, severe anemia, and neutropenia. It was concluded that the addition of three cycles to the standard three cycles did not significantly alter the rate of recurrence in patients with early-stage EOC.[75] It is notable that this study had 85% power to detect a 50% reduction in recurrence rate, and this optimistic assumption may have left the study underpowered to detect a smaller yet clinically important difference. Moreover, there may be subgroups that benefit from six cycles of chemotherapy. Chan and colleagues conducted an exploratory analysis of GOG 157 and found that the 5-year RFS of patients with serous tumors receiving six cycles was 82.7% compared with 60.4% in those receiving 3 cycles ($P = .007$). This effect was not seen in patients with nonserous cancers. Five-year OS in patients with serous cancer demonstrated a similar trend: 85.6% versus 73.2% in those receiving six versus three cycles, respectively.[76] Thus, it is reasonable to offer six cycles of adjuvant chemotherapy to patients with apparent early-stage HGSC.

Advanced-Stage Disease

Timing of Chemotherapy Initiation

Approximately 75% of women will have stage III or IV disease at diagnosis.[1,2] As mentioned previously, the sequence of chemotherapy and surgery is determined by patient fitness for surgery as well as volume and location of disease. Postoperatively, it is recommended to initiate chemotherapy within a month of surgery, though data are limited. An ad-hoc analysis of GOG 218, a phase 3 randomized placebo-controlled trial investigating the use of bevacizumab in EOC, demonstrated that in patients with stage IV disease who underwent complete surgical resection, chemotherapy initiation beyond 25 days (95% CI 16.6–49.9) was associated with an increased risk of death.[77] Prospective studies have demonstrated similar results in patients with residual disease,[78] and in those receiving postoperative chemotherapy in the neoadjuvant setting.[79] It is important to note that in the absence of randomized data, it is not known whether the detriment in survival is secondary to the delay in chemotherapy or the complications and comorbidities potentially leading to that delay.

Regimens

Carboplatin and paclitaxel remain the gold standard drugs in adjuvant treatment of EOC. Carboplatin is preferred to cisplatin given that multiple phase 3 randomized trials showed comparable efficacy with better tolerability and quality of life.[80,81] The effect of incorporating additional cytotoxic agents (gemcitabine, liposomal doxorubicin, topotecan) in combination with carboplatin and paclitaxel was evaluated in GOG 182. This randomized 4-arm trial showed equivalent PFS and OS in all the arms and a better toxicity profile in the carboplatin-and-paclitaxel-alone arm.[82]

The FDA approved frontline and maintenance bevacizumab for advanced ovarian cancer on June 13, 2018, though only modest benefit has been demonstrated. The addition of bevacizumab to chemotherapy during concurrent treatment and maintenance was tested in GOG 218 and ICON 7.[83,84] Both studies showed that the addition of bevacizumab resulted in a modest improvement in PFS, but without an improvement in OS. In GOG 218, only 19% of patients completed all planned treatments given progressive disease, and a PFS advantage was only seen for patients receiving bevacizumab both concurrently and after chemotherapy (HR 0.72, 95% CI 0.63–0.82). In ICON7, more than 90% of patients completed their treatment and almost two-thirds completed the maintenance phase, but the PFS benefit was 24 versus 22 months without an improvement in OS. Incidence of serious bowel toxicity (perforation or fistulas) and hypertension were about 2% and 23%, respectively.[79] Given the significant costs of bevacizumab and the lack of OS improvement, cost-effectiveness analysis has shown that bevacizumab as part of frontline therapy in ovarian cancer is not cost-effective when administered to all patients.[85] However, there is a

subgroup of patients that likely benefit from the addition of bevacizumab. In a post hoc analysis of GOG 218, Ferriss and colleagues found that patients with ascites who were treated with bevacizumab had significantly improved PFS (10.4 vs 15.2 months, HR 0.71, 95% CI 0.62–0.81; $P < .001$) and OS (39.9 vs 43.3 months, HR 0.82, 95% CI 0.70–0.96; $P = .014$).[86] In the final OS analysis of GOG 218, Tewari and colleagues reported a 10-month survival advantage in stage IV disease with the addition of bevacizumab (HR 0.75, 95% CI 0.59–0.95).[87] This finding was recapitulated in a subgroup analysis of ICON-7, where a predefined poor prognosis group (patients with stage IV, nonoptimally cytoreduced stage III, and inoperable stage III disease) experienced improved OS (34.5 vs 39.3 months) with the addition of bevacizumab to chemotherapy.[88] Thus, in patients with poor prognosis (as defined by ICON7), we recommend considering the addition of bevacizumab to standard chemotherapy.

It is important to note that patients with *BRCA 1* and *2* mutations derive a substantial benefit from the poly (adenosine diphosphate [ADP]-ribose) polymerase (PARP) inhibitor, olaparib, as maintenance therapy as demonstrated by both the phase 3 SOLO-1 trial (olaparib vs placebo maintenance in patients with BRCA mutations) and the phase 3 PAOLA-1 trial (discussed further in the maintenance section). The phase 3 PAOLA-1 trial evaluated maintenance therapy with olaparib versus placebo in patients receiving standard chemotherapy plus bevacizumab (continued as maintenance) and found PFS benefit in patients with a *BRCA* mutation (as well as patients with homologous-recombination deficiency [HRD]).[89] This study did not have an olaparib-only maintenance arm, so the additional benefit of bevacizumab to olaparib maintenance in these patients is unknown.

Recently, PARP inhibitors have been studied in combination with chemotherapy followed by maintenance in patients with newly diagnosed HGSC. A phase 3 trial randomly assigned 1140 patients (receiving adjuvant or neoadjuvant treatment) to receive: (1) chemotherapy plus placebo followed by placebo maintenance, (2) chemotherapy plus the PARP inhibitor veliparib followed by placebo maintenance, or (3) chemotherapy plus veliparib followed by veliparib maintenance. Coleman and colleagues demonstrated a significant PFS advantage in the overall study population (23.5 vs 17.3 months, HR 0.68) in favor of veliparib throughout. This was most pronounced in 200 patients with *BRCA* mutations (34.7 vs 22.0 months, HR 0.44), and 421 patients with HRD (31.9 vs 20.5 months, HR 0.57).[90] It is unclear whether there is benefit from the addition of veliparib to chemotherapy in the absence of veliparib maintenance.

Intraperitoneal Chemotherapy

Given the predilection for ovarian cancer to spread within the peritoneal cavity and the higher concentration of platinum and taxane achieved with intraperitoneal chemotherapy administration, there is a compelling rationale for use of intraperitoneal chemotherapy in patients with advanced-stage disease. Three randomized trials have revealed improved PFS and OS in patients receiving intraperitoneal chemotherapy in the adjuvant setting.[91–93] Although all three trials have been criticized, the results of GOG 172, which revealed a 16-month OS benefit in the intraperitoneal arm (intravenous [IV] paclitaxel/intraperitoneal [IP] cisplatin and IP paclitaxel), led the National Cancer Institute to issue a Clinical Announcement recommending that women with stage III ovarian cancer who undergo optimal surgical cytoreduction be considered for intraperitoneal chemotherapy. However, in the IV/IP arm of this study, fewer than half of the patients were able to complete the six prescribed cycles secondary to excessive toxicity.[91] Furthermore, despite the clear survival benefit, fewer than 50% of patients at NCCN centers received IP/IV chemotherapy between 2003 and 2012,[94] possibly secondary to difficulty with administering the inpatient IV/IP protocol. In hopes of arriving at a more feasible outpatient intraperitoneal regimen, GOG 252 was conducted to compare the GOG 172–derived outpatient regimen (with IP cisplatin) to a dose-dense IV therapy arm; and an IV/IP arm with paclitaxel IV and carboplatin IP; with bevacizumab included in all three arms. After 84.8 month of follow-up in 1560 optimally cytoreduced patients, neither of the IV/IP regimens led to improved PFS but were associated with worse toxicity.[95] The use of dose-dense paclitaxel, the addition of bevacizumab, the decreased dose of cisplatin (from 100 mg/m^2 to 75 mg/m^2), and 28% crossover limit the conclusions from GOG 252. Given that this was the largest study involving IP chemotherapy and it was definitively negative, many have concluded that there is no role for IP chemotherapy in advanced ovarian cancer.[96]

There has been growing interest in hyperthermic intraperitoneal chemotherapy (HIPEC), a treatment strategy initially used in colorectal cancer. Recently, van Driel and colleagues randomly assigned 245 patients with stage III EOC to HIPEC with cisplatin during the time of interval cytoreductive surgery versus surgery alone and found both a PFS (14.2 vs 10.7 months) and an OS (45.7 vs 33.9 months) benefit with the addition of HIPEC.[97] On the other hand, a randomized study by Lim and colleagues[98] showed no benefit from HIPEC. In the setting of multiple limitations of the van Driel study, there has not been a universal change in practice, and HIPEC is not considered standard of care for first-line therapy of ovarian cancer in many centers.

Carboplatin and Dose-Dense (Weekly) Paclitaxel

Weekly dose-dense paclitaxel initially gained popularity in the last decade with preclinical evidence suggesting increased apoptosis of tumor cells, improved drug delivery, and reduction of angiogenesis with this strategy.[99] This was followed by the promising results of the Japanese GOG protocol (JGOG 3016) demonstrating significant survival benefit with this dosing schedule. JGOG 3016 compared the administration of carboplatin (AUC = 6) with paclitaxel (180 mg/m^2) every 3 weeks versus weekly (80 mg/m^2 on days 1, 8, and 15 of a 21-day cycle). This study was the first phase 3 trial to evaluate this regimen and demonstrated significant improvement in both median PFS and OS in the weekly paclitaxel regimen (PFS 18.2 vs 17.5 months; OS 100.5 vs 62.2 months).[100,101] There is question surrounding the generalizability of this trial given that OS in the control arm (62.2 months) was much longer than in any of the platinum-era GOG or European trials, even with the inclusion of patients who underwent suboptimal cytoreductive surgery. Unfortunately, these favorable results have not been replicated in subsequent phase 3 studies.

In a similar design, the GOG group compared carboplatin (AUC = 6) with either weekly paclitaxel (80 mg/m^2) versus paclitaxel every 3 weeks (175 mg/m^2) as adjuvant treatment in patients with stage II–IV EOC after both optimal and suboptimal cytoreductive surgery. However, unlike JGOG 3016, this study allowed the use of bevacizumab (15 mg/kg every 3 weeks), which may have had an impact on the results. Notably, in the intention-to-treat analysis, there was no difference in PFS for either the weekly or every-3-week paclitaxel group. In a subgroup analysis, patients who had not received bevacizumab demonstrated significant improvement in PFS (by 3.9 months) with weekly paclitaxel. This suggests that perhaps dose-dense weekly paclitaxel is only beneficial when anti-angiogenic therapy is not used.[102]

The Multicenter Italian Trials in Ovarian cancer study (MITO-7) compared weekly carboplatin (AUC = 2) and weekly paclitaxel (60 mg/m^2) to conventional therapy with carboplatin (AUC = 6) with paclitaxel (175 mg/m^2) every 3 weeks. Again, there was no significant PFS benefit for either group. Patients treated with the weekly dosing regimen experienced less severe toxicities with less neutropenia, thrombocytopenia, and neuropathy, making this a reasonable option for patients with poor performance status.[103]

In a trial by the International Collaborative Ovarian Neoplasm group (ICON 8 trial), 1566 women in Europe with stage IC–IV EOC after PCS or before neoadjuvant chemotherapy were randomly assigned to one of three groups: (1) carboplatin (AUC 5 or 6) and paclitaxel 175 mg/m^2 every 3 weeks; (2) carboplatin (AUC 5 or 6) every 3 weeks with weekly paclitaxel (80 mg/m^2); or (3) weekly carboplatin (AUC 2) and weekly paclitaxel (80 mg/m^2). There was no improvement in median PFS with either weekly regimen over standard dosing.[104]

GOG 252 also evaluated weekly paclitaxel dosing, but instead used it as the control arm in an attempted evaluation of intraperitoneal chemotherapy. As noted in the previous section, there was no significant PFS benefit observed with intraperitoneal chemotherapy over weekly paclitaxel dosing. In addition, bevacizumab was included in all arms in this trial, again possibly clouding the interpretation of these results.[95,96]

Although four of five phase 3 randomized controlled trials do not demonstrate a benefit of dose-dense paclitaxel, the results of JGOG 3016 are compelling and should not be ignored. It is possible that with the ethnic differences among the populations involved, there could also be genetic differences in processing paclitaxel that are not fully understood. Even so, we do not currently feel there is sufficient evidence to support the standard use of weekly paclitaxel in the adjuvant setting and are not incorporating this into our practice at MDACC.

Alternative Chemotherapeutic Agents

Docetaxel (Taxotere) is a semisynthetic compound structurally related to paclitaxel. Although the toxicity profiles are similar between the two drugs, docetaxel seems to be associated with less neuropathy and more myelosuppression. Prolonged treatment with docetaxel can also increase skin and nail toxicity as well as cause fluid retention and significant edema. In addition, docetaxel is prepared without the cremophor EL diluent used in the preparation of paclitaxel. Cremophor is felt to be responsible for many cases of paclitaxel hypersensitivity. A trial conducted by the Scottish Gynaecological Cancer Trials Group included 1077 patients with FIGO stage IC–IV EOC who were randomly assigned to receive carboplatin in combination with either paclitaxel or docetaxel. The median PFS for both arms was approximately 15 months.[105] The authors concluded that the docetaxel combination appears to be a viable alternative to the paclitaxel combination as first-line chemotherapy in EOC with similar efficacy and different side effect profile.

Maintenance Therapy

High risk of recurrent disease after treatment of advanced-stage EOC has prompted an intensive search for therapeutic strategies that can be implemented after standard-of-care therapy to improve patient outcomes. More than 12 phase 3 trials have been undertaken in this setting, including extension of frontline

agents, administration of short-duration non–cross-resistant chemotherapy, high-dose chemotherapy, whole-abdominal or intraperitoneal radiotherapy, immunotherapy, vaccine therapy, and biologic therapy; however, none have shown an OS advantage against various controls (usually no treatment).[106] The S9701/GOG178 phase 3 trial that administered paclitaxel IV for 12 months (vs 3 months) after an initial response to first-line chemotherapy showed improved PFS. However, the design of the trial (with PFS as the primary end point) led to early closure and lack of data on the effect of this consolidation strategy on OS. This improvement in PFS was associated with significant neurotoxicity, and this strategy has not been widely adopted in routine clinical practice.[107] The chemotherapy regimens utilized at MDACC are outlined in Fig. 39–5.

Conversely, remarkable advancements have been made in the upfront management of patients with germline or somatic *BRCA1* or *2* mutations. The SOLO-1 study demonstrated significant benefit with maintenance olaparib in this patient population. This study was a phase 3 trial evaluating maintenance olaparib in patients with a germline or somatic *BRCA1/2* mutation and newly diagnosed advanced EOC (HGSC or endometrioid) who had a partial or complete response to platinum-based chemotherapy. After 41 months of follow-up, the rate of freedom from disease progression or death was significantly lower with olaparib than with placebo at 3 years (60% vs 27%, HR 0.3, 95% CI 0.23–0.41; $P < .001$).[108] In December of 2018, the FDA expanded approval of olaparib to include this indication and it has become widely adopted in this setting.

Results of three additional clinical trials—PRIMA, PAOLA-1, and VELIA—have been published, also demonstrating benefit of maintenance PARP inhibitor in the upfront setting. PRIMA evaluated 733 patients randomly assigned to niraparib versus placebo after response to platinum-based chemotherapy. In patients with homologous-recombination deficiency, PFS was significantly improved with niraparib maintenance (21.9 vs 10.4 months). Even in the overall population, the PFS was improved with niraparib (13.8 vs 8.2 months).[109] In April 2020, the FDA approved the use of niraparib for maintenance treatment of EOC regardless of biomarker status. In the VELIA trial, a different PARP inhibitor (veliparib) was evaluated. As previously discussed, patients were randomly assigned to one of three arms: (1) first-line chemotherapy with carboplatin, paclitaxel, and veliparib followed by veliparib maintenance therapy; (2) chemotherapy and veliparib followed by placebo maintenance; and (3) chemotherapy and placebo followed by placebo maintenance. Veliparib with chemotherapy followed by maintenance veliparib seemed to derive the greatest survival benefit. Although patients with BRCA mutations seemed to benefit most (PFS 34.7 vs 22.0 months), the HRD cohort and the intention-to-treat population both benefited as well (PFS 31.9 vs 20.5 months and 23.5 vs 17.3 months, respectively).[90] Lastly, PAOLA-1 evaluated maintenance olaparib in the frontline setting in combination with bevacizumab. PFS was significantly improved when olaparib was added to bevacizumab in the maintenance setting with PFS of 22.1 months versus 16.6 months in the overall population.[89]

Follow-up and Treatment of Recurrent Disease

Despite multimodality therapy, 75% to 80% of women with advanced-stage EOC will have disease recurrence. Regular follow-up with CA 125 tumor marker level can detect disease recurrence.[110,111] In women with previously treated EOC that is in clinical remission, the NCCN has recommended assessment of serum CA 125 concentration at every follow-up visit if this concentration was raised at initial diagnosis. After documentation of CA 125 increase in such women, the median time to a clinical relapse of EOC is 2 to 6 months. There is, however, controversy over the benefit of early treatment versus later treatment. The results of a large study showed no survival benefit from early treatment on the basis of rising serum CA 125 concentration alone without clinical evidence of recurrence. With these findings, the authors questioned the value of routine measurement of CA 125 in the follow-up of patients with EOC.[111] It has also been suggested that smaller tumors are more often responsive to treatment, but this does not eliminate the lead-time bias. Others claim that larger tumors have an inferior primary response and grow rapidly. Recurrent ovarian cancer is a mortal disease but—in the absence of data showing that treatment improves quality of life—this does not justify haste in treating patients with recurrence. At MDACC, we follow patients with CA 125 levels in surveillance but in general do not treat patients based solely on a rising value (see Fig. 39–4).

Unfortunately, although chemotherapy can produce meaningful responses in the recurrent setting, it is not curative. The treatment of recurrent EOC is stratified by the amount of time from completion of primary platinum-based chemotherapy. Patients whose disease recurs with a PFS of 6 months or longer are defined as having platinum-sensitive disease. Patients whose disease recurs in less than 6 months from primary chemotherapy are classified as having platinum-resistant disease. Patients whose disease progresses on primary chemotherapy have tumors classified as platinum refractory and have a poor prognosis.[112] A list of treatment regimens utilized at MDACC in platinum-sensitive and platinum-resistant disease can be found in Fig. 39–5.

Systemic Therapy for EOC	
Adjuvant	**IV/IP Paclitaxel cisplatin:** Paclitaxel 135 mg/m2 IV continuous infusion Day 1; Cisplatin 75-100 mg/m2 IP Day 2 after IV paclitaxel; Paclitaxel 60 mg/m2 IP day 8 Repeat every 21 days x 6 cycles **Paclitaxel 175/carboplatin:** Paclitaxel 175 mg/m2 IV followed by carboplatin AUC 5-6 IV Day 1 Repeat every 21 days x 3-6 cycles* **Paclitaxel weekly/carboplatin every 3 weeks:** Dose-dense paclitaxel 80mg/m2 IV Days 1, 8, 15 followed by carboplatin AUC 5-6 Day 1 Repeat every 21 days x 6 cycles **Docetaxel/carboplatin:** Docetaxel 60-75 mg/m2 IV followed by carboplatin AUC 5-6 IV Day 1 Repeat every 21 days x 3-6 cycles* **Carboplatin/PLD:** Carboplatin AUC 5 IV + PLD 30 mg/m2 IV Repeat every 28 days for 3-6 cycles* **Paclitaxel/carboplatin/bevacizumab + maintenance bevacizumab (GOG-218)** Paclitaxel 175 mg/m2 IV followed by carboplatin AUC 6, and bevacizumab 15 mg/kg IV Day 1 Repeat every 21 days x 6 cycles Starting Day 1 of cycle 2, bevacizumab 15 mg/kg every 21 days for up to 22 cycles
Neoadjuvant	Paclitaxel 175/carboplatin (as above) x 3-6 cycles Paclitaxel weekly/carboplatin every 3 weeks (as above) x 3-6 cycles Docetaxel/carboplatin (as above) x 3-6 cycles Carboplatin/PLD (as above) x 3-6 cycles Paclitaxel/carboplatin/bevacizumab + maintenance bevacizumab (GOG-218, or ICON-7), consider holding bevacizumab on the cycle prior to surgery
Maintenance after Frontline	Bevacizumab as above Olaparib (if BRCA 1/2 germline/somatic mutation) Niraparib Bevacizumab/olaparib (if BRCA 1/2 germline/somatic mutation or HRD)
Platinum-Sensitive Recurrence	**Preferred, combination:** Carboplatin/gemcitabine +/- bevacizumab Carboplatin/PLD +/- bevacizumab Carboplatin/paclitaxel +/- bevacizumab Cisplatin/gemcitabine **Preferred, single agents:** Bevacizumab Niraparib (three or more prior chemotherapy lines, BRCA 1/2 germline/somatic mutation or HRD) Olaparib (three or more prior lines of chemotherapy, BRCA 1/2 germline mutation) Rucaparib (two or more prior lines of chemotherapy, BRCA 1/2 germline/somatic mutation)
Maintenance after Platinum-Sensitive Recurrence	Bevacizumab (if prior regimen contained bevacizumab) Niraparib (two or more prior line of platinum-based therapy) Olaparib (two or more prior line of platinum-based therapy) Rucaparib (two or more prior line of platinum-based therapy)
Platinum-Resistant Recurrence**	**Preferred:** Cyclophosphamide/bevacizumab Docetaxel Etoposide Gemcitabine PLD +/- bevacizumab Paclitaxel (weekly) +/- bevacizumab Topotecan +/- bevacizumab Bevacizumab Niraparib (three or more prior chemotherapy lines, BRCA 1/2 germline/somatic mutation or HRD) Olaparib (three or more prior lines of chemotherapy, BRCA 1/2 germline mutation) Rucaparib (two or more prior lines of chemotherapy, BRCA 1/2 germline/somatic mutation)

* For stage I disease: 6 cycles is recommended for high-grade serous; 3-6 cycles for all other ovarian cancer types. For stage II–IV disease: 6 cycles is recommended
IP: Intraperitoneal
AUC: Area under the curve
PLD: Pegylated liposomal doxorubicin
** Encourage clinical trial participation

Treatment of Platinum-Sensitive Disease

As mentioned, patients who have a treatment-free interval of 6 months or greater before recurrence are more likely to respond to repeat platinum treatment. Therefore, as long as patients continue to respond to platinum and have more than a 6-month interval between each treatment, it seems reasonable to continue treatment with platinum, either as a single agent or in a combination regimen (see Fig. 39–5). When selecting single-agent versus combination therapy, it is important to consider the patient's performance status, comorbidities, and toxicities with prior therapies. If combination therapy is elected, then the choice of combination regimen should also take these factors into account to optimize outcome and minimize overlapping toxicities.

Carboplatin and Paclitaxel

Two phase 3 trials have shown the benefit of carboplatin and paclitaxel in the setting of platinum-sensitive recurrence, and the results were published together. The ICON4 and AGO-OVAR-2.2 studies randomly assigned 802 patients to receive conventional single-agent platinum-based chemotherapy or platinum plus paclitaxel. The combination regimen was associated with improved OS (29 vs 24 months, HR 0.82, 95% CI 0.69–0.97; P = .023). There were higher rates of neuropathy and alopecia in the platinum-plus-paclitaxel treatment group but a lower rate of myelosuppression.[113] Although this is only one of two studies to date that has documented an improvement in OS in this setting, one critique of this study is that a large proportion of patients (30%) were not previously treated with taxane therapy, which may have led to an improved response in this patient population.

Carboplatin and Pegylated Liposomal Doxorubicin

The combination of carboplatin and pegylated liposomal doxorubicin was compared with carboplatin and paclitaxel in the Caelyx in Platinum-Sensitive EOC (CALYPSO) trial. Designed as a noninferiority trial with a primary end point of PFS, the experimental arm of carboplatin and pegylated liposomal doxorubicin was determined to be noninferior (P < .001). An analysis of superiority to the carboplatin-and-paclitaxel arm was also significant (median 11.3 vs 9.4 months, HR 0.82, 95% CI 0.72–0.94; P = .005); however, there was no difference in OS (30.7 vs 33 months). The combination of carboplatin plus liposomal doxorubicin led to fewer cases of severe neutropenia, fewer episodes of mild myalgias/arthralgias, and less neuropathy, but it did lead to more cases of severe thrombocytopenia, nausea/vomiting, hand-foot syndrome, and mucositis. Interestingly, this combination also led to fewer episodes of carboplatin hypersensitivity reactions.[114]

Carboplatin and Gemcitabine

A phase 3 trial was performed by the Gynecologic Cancer InterGroup (GCIG) to evaluate carboplatin alone versus carboplatin plus gemcitabine in patients with platinum-sensitive disease. Treatment with the combination regimen showed an improved PFS (8.6 vs 5.8 months), but no improvement in OS. Not surprisingly, there were more toxicities seen in the combination arm, with increased neutropenia and thrombocytopenia.[115]

Targeted Therapies

To date, among targeted therapies, only bevacizumab (OCEANS and GOG-0213) and trebananib (TRINOVA 1, discussed later in treatment of platinum-resistant disease) have been assessed in a phase 3 effort. The OCEANS trial was a randomized phase 3 trial that evaluated carboplatin plus gemcitabine with or without the addition of bevacizumab. Patients received the assigned treatment for 6 to 10 cycles and were then continued on bevacizumab or placebo maintenance until progression. The addition of bevacizumab led to an improved PFS (12.4 vs 8.4 months) with an improved objective response rate (78.5% vs 57.4%; P < .001). However, with a median follow-up of 57 months, OS did not significantly differ between the two arms (33.6 vs 32.9 months; HR 0.96, 95% CI 0.77–1.18; P = .65). As seen with other antiangiogenesis studies, the addition of bevacizumab led to higher rates of hypertension and proteinuria.[116]

GOG-0213 was designed with OS as the primary end point for each of its two primary objectives. The first was to assess the impact of bevacizumab given concomitantly with paclitaxel and carboplatin, as well as in maintenance, among women with one prior line of treatment.[117] The second objective was to evaluate the impact of secondary cytoreduction. In the analysis of the first objective, the experimental arm showed a significant improvement in PFS (13.8 vs 10.4 months, HR 0.63, 95% CI 0.53–0.74; P < .001), as well as a significant improvement in objective response (78% vs 59%, P < .001), including a near doubling of the complete response rate (32% vs 18%). More importantly, bevacizumab given concomitantly with chemotherapy and in maintenance improved OS (42.2 vs 37.3 months, unadjusted HR 0.83, 95% CI 0.68–1.005; P = .056; adjusted HR 0.82, 95% CI 0.68–0.996; P = .045). Adjustment was made based on prespecified stratification variables (platinum-free interval and participation in secondary cytoreduction). Based on the OCEANS

trial and GOG-0213, the FDA approved bevacizumab in combination with chemotherapy for women with platinum-sensitive recurrent EOC in late 2016.

In an effort to compare regimens for platinum-sensitive disease, a randomized phase 3 trial was performed that assigned patients to either (1) carboplatin (AUC 4, day 1) plus gemcitabine (1000 mg/m,^{2} days 1 and 8) plus bevacizumab (15 mg/kg day 1) every 3 weeks; or (2) carboplatin (AUC 5, day 1) plus pegylated liposomal doxorubicin (30 mg/m,^{2} day 1) plus bevacizumab (10 mg/kg, days 1 and 15), both followed by maintenance bevacizumab (15 mg/kg every 3 weeks in both groups) until disease progression or unacceptable toxicity. Median PFS was 13.3 months (95% CI 11.7–14.2) in the experimental group (carboplatin-pegylated liposomal doxorubicin-bevacizumab) versus 11.6 months (95% CI 11.0–12.7) in the standard group (carboplatin-gemcitabine-bevacizumab) (HR 0.81, 95% CI 0.68–0.96; p = .012). This trial demonstrated superior efficacy of the more widely used platinum-based regimen (carboplatin plus pegylated liposomal doxorubicin) plus bevacizumab, suggesting that this is the new standard regimen for patients with recurrent platinum-sensitive ovarian cancer.[118]

Poly-ADP Ribose Inhibitors

The inhibition of DNA repair pathways is another strategy that has led to the development of new active agents in women with EOC. Cells with reduced BRCA protein function are inefficient in the repair of double-stranded DNA breaks by homologous recombination. Consequently, such cells must rely on other pathways to repair DNA damage, in particular the PARP pathway, which detects single-stranded breaks and activates a number of effector proteins to initiate repair. PARP plays an essential part in the repair of single-stranded DNA breaks through the base-excision-repair pathway, and it has been proposed that PARP keeps low-fidelity nonhomologous-end-joining DNA repair machinery in check. Inhibition of PARPs leads to the accumulation of single-stranded breaks, which leads to accumulation of DNA double-strand breaks in those deficient cells. Although germline mutations in the *BRCA1* and *BRCA2* genes are present in only about 15% of high-grade serous EOC, studies have estimated that approximately 50% of high-grade serous EOCs have HR deficiency.[119]

Three of the most commonly used PARP inhibitors (olaparib, niraparib, and rucaparib) have been evaluated in the maintenance setting with platinum-sensitive disease, and as treatment for patients with *BRCA1/2* germline mutations and recurrent disease. (As discussed in a prior section, olaparib and niraparib have also been evaluated in the maintenance setting after upfront adjuvant chemotherapy.)

Olaparib

Treatment

Study 42, a single-arm trial that evaluated olaparib as treatment for patients with recurrent, platinum-resistant EOC and a germline *BRCA1/2* mutation, included patients who received olaparib until disease progression or toxicity. The overall response rate (ORR) was 31.1% and the median PFS and OS were 7 months and 16.6 months, respectively. In a subgroup analysis of 137 patients with three or more prior lines of chemotherapy, olaparib was similarly effective, with an ORR of 34%.[120] On the basis of these data, the FDA granted accelerated approval in 2014 for single-agent olaparib in women with germline BRCA mutations with ovarian cancer for treatment after 3 or more prior therapies.

Maintenance

Study 19, a randomized, double-blind, placebo-controlled, phase 2 study of the use of olaparib as maintenance therapy in the setting of recurrent, platinum-sensitive EOC, enrolled patients regardless of *BRCA* mutation status who had received two or more prior lines of chemotherapy, with a partial response or complete response to the last platinum-based chemotherapy.[121] Those who received olaparib exhibited a significant improvement in PFS (8.4 vs 4.8 months, HR 0.35, 95% CI 0.25–0.49; $P < .001$). A preplanned analysis of this study by retrospective determination of *BRCA* status revealed that PFS was significantly improved in the olaparib group compared with the placebo group among the patients with germline or tumor *BRCA* mutations (HR 0.18, 95% CI 0.10–0.31; $P < .001$).

The subsequent SOLO-2 study, a randomized, double-blind, placebo-controlled phase 3 trial, was developed to assess the efficacy of olaparib maintenance therapy in patients with platinum-sensitive recurrent EOC harboring a *BRCA1/2* mutation who had a complete or partial response to most recent platinum-based therapy and had received at least two previous lines of chemotherapy. Randomization was stratified by response to previous platinum chemotherapy (complete *vs* partial) and length of platinum-free interval (6–12 *vs* ≥12 months). Patients in the experimental arm (olaparib maintenance) had a significantly prolonged median PFS of 19.1 versus 5.5 months in the placebo group (HR 0.30, 95% CI 0.22–0.41; $P < .001$).[122] The FDA granted additional approval for the use of olaparib on August 2017 as maintenance therapy for women with recurrent EOC (with and without *BRCA* mutations) who have achieved a complete or partial response to platinum-based chemotherapy.

Niraparib

Treatment

Niraparib was investigated as monotherapy as a fourth or later line of therapy in the QUADRA trial. This

trial was a multicenter, open-label, single-arm, phase 2 study evaluating niraparib in women with relapsed HGSC who had received three or more previous chemotherapy regimens. The primary objective was ORR in patients with HRD-positive tumors (regardless of BRCA status) and sensitive to their last platinum-based therapy. In this group, there was a 28% response rate. This led to the FDA approval in October 2019 of niraparib for patients with advanced HRD-positive ovarian, fallopian tube, or primary peritoneal cancer who had received three or more prior chemotherapy regimens.

Maintenance

The pivotal phase 3 ENGOT-OV16/NOVA trial of niraparib maintenance therapy enrolled patients with recurrent ovarian cancer with either a partial or complete response to platinum-based chemotherapy and normalization of CA 125. They were categorized by germline *BRCA* mutation status (203 carried a germline *BRCA* mutation [gBRCA] and 350 were not germline *BRCA* carriers [non-gBRCA]). They were then randomly assigned in a 2:1 ratio to receive niraparib (300 mg daily) maintenance versus placebo. Assessment of somatic HRD was made by performing the MyChoice™ assay (Myriad Genetics, Inc.) on submitted tumor samples. Among germline *BRCA* mutation carriers, there was a significant prolongation in PFS in the experimental group relative to placebo (median 21.0 vs 5.5 months, HR 0.27, 95% CI 0.017–0.41; $P < .001$). There was also a benefit in patients without a germline *BRCA* mutation (median 9.3 vs 3.3 months, HR 0.45, 95% CI 0.34–0.61; $P < .001$) and in a prespecified analysis of the HRD-positive subgroup of the non–germline *BRCA* mutation group (median 12.9 vs 3.8 months, HR 0.38, 95% CI 0.24–0.59; $P < .001$). Patients with HRD-negative tumors also had prolonged PFS with niraparib relative to placebo (median 6.9 vs 3.8 months, HR 0.58, 95% CI 0.36–0.92; $P = .02$).[123] In March 2017, the FDA approved niraparib as the first PARP inhibitor for routine administration as a second-line maintenance strategy (after a response to platinum-based treatment) without requiring the use of a molecular biomarker (either *BRCA* mutation or HRD-positive).

Rucaparib

Treatment

ARIEL2 is an international two-part phase 2 trial conducted to assess rucaparib sensitivity in three prospectively defined subgroups and to develop a diagnostic test to identify, through fresh and archival tumor biopsies, a biomarker of HRD. The objective of part 1 was to identify molecular predictors of rucaparib sensitivity in patients with platinum-sensitive recurrent high-grade EOC, including tumors without a germline or somatic *BRCA* mutation.[124] Of the 204 patients who received rucaparib, 192 patients could be classified into one of the three predefined HRD subgroups based on tumor mutational analysis: BRCA mutant (deleterious germline or somatic, $n = 40$); BRCA wild-type and LOH high (LOH high group, $n = 82$); or BRCA wild-type and LOH low (LOH low group, $n = 70$). The median PFS was: *BRCA*-mutant (12.8 months; 95% CI 9.0–14.7), LOH high group (5.7 months; 95% CI 5.3–7.6), and LOH low group (5.2 months; 95% CI 3.6–5.5). PFS was significantly longer in the *BRCA*-mutant subgroup (HR 0.27, 95% CI 0.16–0.44; $P < .001$) and LOH high subgroup (HR 0.62, 95% CI 0.42–0.90; $P = .01$) than in the LOH low subgroup. These results suggest that assessment of tumor LOH can be used to identify patients with *BRCA* wild-type platinum-sensitive EOC who might benefit from rucaparib. In December 2016, the FDA granted accelerated approval to rucaparib for the treatment of patients with deleterious *BRCA*-mutant (germline and/or somatic)–associated advanced EOC who have been treated with two or more chemotherapies.

Maintenance

ARIEL3 is a phase 3 randomized, double-blind, placebo-controlled trial that included patients with platinum-sensitive high-grade serous or endometrioid ovarian carcinoma. All patients received at least two previous platinum-based chemotherapy regimens and achieved complete or partial response to their last platinum-based regimen. Patients were stratified by LOH status, progression-free interval after the penultimate platinum-based regimen, and best response to the most recent platinum-based regimen. Consistent with the SOLO2 and NOVA trials, ARIEL3 revealed a strong effect of rucaparib in the enrolled women. The primary efficacy analysis evaluated three prospectively defined molecular subgroups in a step-down manner: (1) *BRCA*-mutant; (2) HRD-positive; and (3) the intent-to-treat population, or all patients treated in this study. Among patients with a *BRCA*-mutant carcinoma, there was a significant prolongation of PFS in the rucaparib group relative to placebo (16.6 vs 5.4 months, HR 0.23, 95% CI 0.16–0.34; $P < .001$) and in patients with HRD cancers (13.6 vs 5.4 months; $P < .001$). In the intention-to-treat population, PFS was 10.8 months versus 5.4 months (rucaparib vs placebo) ($P < .001$). Unique to ARIEL3, objective response data were collected from patients entering the trial with a partial response in each of the cohorts. In the subgroup of patients with measurable disease at study entry with a *BRCA*-mutant carcinoma, exploratory analysis showed that the rucaparib group achieved higher rates of confirmed RECIST response compared with placebo (38% vs 9%). In HRD-positive patients, the objective response was also higher in the rucaparib group (27% vs 7%).[125] Based on

ARIEL 3, rucaparib was approved by the FDA in April 2018 for maintenance therapy in patients with ovarian cancer that responded to platinum-based chemotherapy. As with olaparib and niraparib, documentation of *BRCA* status or LOH is not needed under this label.

Treatment of Platinum-Resistant Disease

There are several treatment options for the treatment of platinum-resistant recurrent EOC. In general, single-agent treatment regimens are utilized in this patient population to minimize adverse effects, given incurable disease. Although there are several options, no one therapy has been shown to be superior to others as first-line treatment for platinum-resistant disease. A Cochrane review of three of the most commonly used agents (paclitaxel, pegylated liposomal doxorubicin, and topotecan) showed similar efficacy. Thus, choice of first-line therapy is driven by side effect profiles of each of the therapies.

Liposomal Doxorubicin

A pegylated liposomal formulation of doxorubicin was first tested in patients with platinum-refractory disease; the resulting response rate was approximately 26%. Compared with topotecan in a phase 3 setting, liposomal doxorubicin was associated with lower toxicities, including lower rates of grade 3/4 neutropenia and thrombocytopenia, but with equivalent efficacy, with similar response rate (20% vs 17%) and time to progression (22 vs 20 weeks).[126] Based on the data from Gordon et al, the drug was FDA approved for use in ovarian cancer.

Gemcitabine

In a phase 3 study comparing gemcitabine and liposomal doxorubicin, both drugs had similar ORR (6.1% vs 8.3%), PFS (3.6 vs 3.1 months), and OS (12.7 vs 13.5 months).[127] Gemcitabine has been frequently studied in combination with cisplatin. The response rates ranged from 40% to 70%. However, the small number of patients treated as well as their heterogeneity disallows any further conclusion. Furthermore, it is difficult to justify the use of combination chemotherapy in patients without evidence that responses correlated with improvements in quality of life.

Weekly Paclitaxel

Paclitaxel is part of the backbone of treatment for advanced ovarian cancer. Several studies have shown activity of paclitaxel in platinum-resistant patients; however, a proportion of these studies were performed before the incorporation of paclitaxel in primary adjuvant therapy. Most recently, weekly paclitaxel produced a 21% response rate in patients with platinum-resistant disease. Not surprisingly, the main toxicity associated with this regimen is peripheral neuropathy.[128]

Topotecan

Compared with paclitaxel in patients with refractory ovarian cancer, topotecan was found to produce a response rate of 20% versus 13% in patients who received paclitaxel. This resulted in its approval for use by the FDA. In patients with relapsed platinum-resistant ovarian cancer, the ORR to treatment with topotecan ranged from 5% to 18%. The proportion of these patients who achieved stable disease was 17%. In phase 3 studies, topotecan was shown to have an efficacy equal to both paclitaxel and liposomal doxorubicin as second-line therapy in patients with relapsed ovarian cancer.[129]

Etoposide

Etoposide, a topoisomerase II inhibitor, has the advantage of being administered as an oral agent. In patients with platinum-refractory disease who were given 100-mg doses of etoposide orally for 14 days every 21 days, the response rate was about 26%. Lower doses of etoposide, at 50 mg/day, produced similar response rates, ranging from 10% to 27%. The combination of cyclophosphamide and bevacizumab has also been shown to be active in this patient population. A phase 2 trial showed partial response in 24% of patients, with 56% of patients predicted to be alive and progression-free at 6 months.

Bevacizumab

The phase 3 AURELIA study evaluated bevacizumab in addition to single-agent chemotherapy in platinum-resistant ovarian cancer. Patients with disease that progressed less than 6 months after completing adjuvant therapy were eligible, but platinum-refractory patients were excluded. The patients received the treating physician's choice of liposomal doxorubicin, weekly paclitaxel, or topotecan and were then randomly assigned to receive chemotherapy alone or chemotherapy plus bevacizumab. Patients who received bevacizumab had an improved response rate (31% vs 13%) and a reduction in the risk of disease progression (6.7 vs 3.4 months). There was no difference in OS; however, patients were allowed to cross over to receive bevacizumab after disease progression on chemotherapy alone, which may mask the survival advantage.[130] Based on the results of this trial, bevacizumab is now FDA approved for use in combination with chemotherapy for the treatment of platinum-resistant recurrent EOC. Patient-reported outcomes, a secondary end point of AURELIA, showed for the first time in platinum-resistant EOC that treatment can improve symptoms. Bevacizumab improved abdominal/gastrointestinal symptoms, as demonstrated by a significantly higher

proportion of patients achieving the predefined 15% improvement in abdominal/gastrointestinal symptoms using a responder-analysis approach. Effects on a broader range of quality-of-life concerns either favored the bevacizumab group or were no different.

In the TRINOVA 1 study, patients with recurrent EOC who had been treated with three or fewer previous regimens and had a platinum-free interval of 12 months or less (nearly 50% of patients in each arm were considered platinum-resistant), were randomly assigned to receive trebananib (an anti-angiogenic agent acting by neutralizing angiopoietin [Ang] 1 and 2 and preventing interaction with their target tie2 receptors) with paclitaxel versus single-agent paclitaxel. Median follow-up was 18 months, and the primary end point was PFS. The experimental arm had a significant advantage in PFS (7.2 vs 5.4 months, HR 0.66, 95% CI 0.57–0.77; $P < .001$). Although all patients exhibited some improvement in this end point, the subgroup with ascites benefited the most (HR 0.72, 95% CI 0.85–0.93; $P < .01$).[19] Median OS was not significantly improved with trebananib versus placebo (19.3 vs 18.3 months; HR 0.95, 95% CI 0.81–1.11; $P = .52$) in the intent-to-treat population.[131]

Immunotherapy

Over the last 5 years, a number of trials have assessed the efficacy of programmed death protein 1/programmed death ligand 1 (PD-1/PD-L1) immune checkpoint inhibitors in patients with recurrent EOC.[132–138] Although a detailed analysis of these trials is beyond the scope of this chapter, the efficacy results can be summarized as an observed response rate of 10% to 15%, with another 20% to 40% of patients experiencing stable disease. Furthermore, the results in trials that preselected patients based on tumor PD-L1 expression (eg, as with the KEYNOTE-028 study of pembrolizumab) has not been appreciably better, suggesting that PD L1 expression is not a discriminating predictor of response.[134] In the KEYNOTE-100 study, patients with advanced, recurrent ovarian cancer were stratified based on the number of prior lines of systemic therapy and treatment-free interval and were treated with pembrolizumab. However, this study found no significant differences in response or disease control rates based on the aforementioned stratification.[135]

Combination Therapy: Immune-Chemotherapy

Given the strength of the immunosuppressive tumor microenvironment and modest response to single-agent immune checkpoint inhibitor therapies, interest has grown to use combination therapy in ovarian cancer. Wenham and colleagues presented their preliminary findings at the 2018 International Gynecologic Cancer Society Meeting, describing platinum-resistant recurrent ovarian cancer patients having been treated with weekly paclitaxel and pembrolizumab (NCT02440425).[137] In the 37 evaluable patients, the ORR was 51.4% (all partial responses) with disease control rate (DCR) of 86.5%. The 6-month PFS rate was 64.5% and median PFS was 7.6 months with a median OS of 13.4 months.

The JAVELIN trials have investigated the use of avelumab in EOC. In the JAVELIN Ovarian 200 trial, patients with platinum-resistant/refractory ovarian cancer were randomly assigned to receive avelumab alone, pegylated liposomal doxorubicin alone, or both (NCT02580058).[138] Avelumab monotherapy was associated with the worst PFS and OS, and there was no additional benefit with the combination of avelumab to pegylated liposomal doxorubicin.[138]

Combination Therapy: Immune-Targeted therapy

Preclinical studies support a potential synergy between immune checkpoint inhibitors and PARP inhibitors, as well as VEGF targeting drugs. One of the first clinical studies in this area was a phase 1 study by Lee and colleagues, aimed at determining the safety and efficacy of durvalumab (anti–PD-L1) in combination with either olaparib or cediranib (multiple tyrosine kinase inhibitor that targets VEGF receptors 1–3).[139] Although the number of patients with ovarian cancer was small, an ORR in who received durvalumab and olaparib was 20% (two partial responses) with a DCR of 90%. Durable responses in this treatment group were not explained by homologous-recombination DNA repair pathway defects and none of the patients had germline BRCA mutations (two patients with somatic *BRCA* mutations had stable disease). This study included only six evaluable patients who received durvalumab and intermittent cediranib, and three of the six had partial responses. The combination of durvalumab and olaparib in a highly favorable patient population (patients with germline *BRCA* mutations with platinum-sensitive ovarian cancer) was investigated in the MEDIOLA study; (NCT02734004).[140] An ORR of 63% with a DCR of 81% at 12 weeks was observed. In contrast, the TOPACIO/KEYNOTE-162 trial examined the combination of niraparib and pembrolizumab in a population of patients with recurrent, platinum-resistant ovarian cancer who were unselected because of *BRCA* mutations.[141] In the 60 evaluable patients with ovarian cancer, the ORR was 18% with a DCR of 65%.

In another VEGF-PD1–targeting study, the combination of nivolumab and bevacizumab resulted in an ORR of 26.3% in a mixed population of patients with platinum-sensitive and platinum-resistant ovarian cancer.[142]

Combination Therapy: Immune-Immunotherapy

The preliminary results of the phase 2 NRG-GY003 trial (NCT02498600) were reported at the 2018

International Gynecologic Cancer Society Meeting; in that study, 100 patients with recurrent ovarian cancer were randomly assigned to receive either nivolumab alone or nivolumab/ipilimumab followed by maintenance nivolumab. This study revealed a higher ORR in the combination group compared with the nivolumab monotherapy group (31.4% vs 12.2%, respectively; $P = .034$).[143] This came at a cost of higher (but manageable) toxicity in the combination group.

In summary, although there is currently no approved immune checkpoint inhibitor therapy for patients with ovarian cancer, there are a plethora of ongoing studies investigating immune checkpoint inhibitors in combination with other chemotherapy, targeted, and immunologic agents. There is hope that this intense investigation will lead to an approved combination in the coming years.

Secondary Cytoreduction for Recurrent Disease

The two most consistent factors associated with favorable outcome in patients undergoing secondary cytoreductive surgery are time to first recurrence and postoperative residual disease. Therefore, secondary cytoreduction was traditionally reserved for patients with isolated, resectable, and platinum-sensitive disease. The conflicting results of the GOG 213, DESKTOP III, and SOC-1 trials (presented at the virtual American Society of Clinical Oncology [ASCO] meeting in 2020) should be considered to determine the utility of surgery in this setting.

In GOG 213, 485 women with investigator-determined resectable, platinum-sensitive recurrent EOC were randomly assigned 1:1 (stratified by platinum-free interval and chemotherapy) to secondary cytoreduction followed by chemotherapy or chemotherapy alone. Surgical candidacy was predicated on the likelihood to achieve no visible residual tumor (R0). The overall R0 rate in this trial was 67%. OS, the primary end point, was 53.6 months for those in the surgery group versus 65.7 months in the chemotherapy-only group (HR 1.28, 95% CI 0.92–1.79). One patient died of complications from secondary cytoreduction. Given the less than 0.1% chance of meeting superiority with mature survival data (expected at 250 events) the Data and Safety Monitoring Committee recommended releasing the trial results early.[144]

The final analysis of DESKTOP III was reported at the virtual 2020 ASCO Annual Meeting.[145] In this study, patients with EOC and first relapse after six or more months of platinum-free interval were eligible if they presented with a positive AGO score (PS ECOG 0, ascites ≤500 mL, and complete resection at initial surgery) and were randomly assigned to second-line chemotherapy alone versus secondary cytoreductive surgery followed by chemotherapy. Chemotherapy regimens were selected according to the institutional standard. Complete resection was achieved in 74.2% of the patients randomly assigned to surgery. The PFS in women who were randomly assigned to undergo surgery followed by chemotherapy was 18.4 months compared with 14 months in women who were randomly assigned to receive only second-line chemotherapy (HR 0.66, 95% CI 0.55–0.82; $P < .001$). Women randomly assigned to surgery also experienced an improved OS compared with control (53.7 vs 46 months; HR 0.75, 95% CI 0.58–0.96; $P = .02$). In addition, the OS benefit was highest in patients with complete resection (61.9 months; HR 0.57, 95% CI 0.43–0.76).

Finally, the results of SOC-1 were also presented at the virtual ASCO 2020 meeting.[146] In this study, patients with their first relapse after six or more months of platinum-free interval were eligible if they had an iMODEL score of less than or equal to 4.7 and the primary investigators agreed that the tumor could be completely resected based on PET-CT image results. The iMODEL score is comprised of stage, residual disease after primary surgery, length of progression-free interval, performance status, CA 125 level, and ascites at recurrence. This study randomly assigned 182 patients to receive secondary cytoreductive surgery followed by chemotherapy and 175 to receive chemotherapy alone, and had PFS and OS as coprimary end points. In the intention-to-treat population, 72.5% achieved complete cytoreduction to R0. The median PFS in those assigned to surgery was 17.4 months versus 11.9 months in those assigned to control (HR 0.58, 95% CI 0.45–0.74; $P < .001$). Immature OS analysis, however, demonstrated no significant difference between the groups (58.1 vs 53.9 months, HR 0.82, 95% CI 0.57–1.19).

Although the manuscripts for DESKTOP III and SOC-1 have yet to be published, we can summarize that two studies show a PFS benefit (DESKTOP III, SOC-1), one shows an OS benefit (DESKTOPIII), and one shows no benefit (GOG-213) with the addition of secondary cytoreduction to chemotherapy for recurrence. There are important differences in patient characteristics in these studies that should be considered. First, both DESKTOP III and SOC-1 used triage algorithms for patient selection that resulted in higher complete gross resection rates (~75%) than investigator-assessment in GOG 213 (67%). In addition, in GOG 213, 84% of the patients received bevacizumab compared with 23% of participants in DESKTOP III, and 1% in SOC-1. Finally, the control arm in GOG 213 experienced improved OS (65.7 months) compared with DESKTOP III (46 months) and SOC-1 (53.9 months). It is unclear whether the use of bevacizumab mediates the improved survival in the control arm of GOG 213. It is important to note that all the studies caution that suboptimal resection is no better than

chemotherapy alone and may be worse, and future studies are required to clarify patient selection criteria. In addition, the impact of novel agents and maintenance strategies on outcomes after secondary cytoreduction are to be further explored.

Low-Grade Serous Ovarian Carcinoma

Primary Management

Historically, all EOCs have been included together in clinical trials, which has led to a one-size-fits-all strategy for treatment. As with HGSC, the mainstay of treatment for LGSC involves comprehensive surgical staging followed by adjuvant platinum-based chemotherapy. Also like HGSC, maximal cytoreductive effort is important, because decreasing residual disease after PCS is associated with increasing survival. This was demonstrated in an ancillary analysis of a subset of patients with LGSC (n = 189) from GOG protocol 182, a phase 3, randomized, controlled trial of paclitaxel and carboplatin versus triplet or sequential doublet combinations in patients with EOC or primary peritoneal carcinoma. In this analysis, OS was significantly prolonged with cytoreductive surgery to no gross residual disease (96.9 months) versus optimal to less than 1 cm residual disease (44.5 months) and greater than 1 cm residual disease (42.0 months).[147]

Unfortunately, LGSC is relatively chemoresistant when compared with HGSC.[148,149] Despite this, carboplatin and paclitaxel remain first-line adjuvant therapy in advanced disease. However, hormonal therapies have had promising results in the adjuvant and maintenance settings.[150,151] Fader and colleagues performed a retrospective study of 27 patients with LGSC who underwent PCS followed by adjuvant hormonal therapy rather than standard platinum-based chemotherapy.[150] They found that after a median follow-up of 41 months, only 22% of patients had disease recurrence. Gershenson and colleagues have also demonstrated promising results of hormonal therapy in the maintenance setting. In a retrospective analysis of 203 patients with LGSOC, PFS was improved with maintenance hormonal therapy over observation (64.9 vs 26.4 months).[151] The NCCN has now included the use of hormonal therapy as an option for both adjuvant and maintenance treatment in stage 1C–IV disease (category 2B recommendation). A randomized phase 3 trial (NCT04095364) of paclitaxel/carboplatin followed by maintenance letrozole versus letrozole monotherapy as adjuvant treatment after cytoreductive surgery in patients with LGSC has recently started enrolling patients. It is hoped the results of this trial will provide more definitive guidance surrounding management of this disease in the upfront setting.

As noted above, LGSC has also shown relative chemoresistance in the neoadjuvant setting. Schmeler and colleagues retrospectively analyzed 25 women at a single institution who underwent neoadjuvant chemotherapy for advanced low-grade serous ovarian cancer. In this study, only one patient had a complete response, 21 (88%) had stable disease, and two (8%) had progressive disease.[148] Hormonal therapy is under investigation in this space as well. Specifically, a phase 2 trial evaluating fulvestrant and palbociclib as neoadjuvant treatment has recently started enrolling patients at MDACC (NCT03531645).

Management of Recurrent Disease

Recurrent LGSC can be treated with surgery, chemotherapy, hormone therapy, and targeted therapies, including MEK inhibitors. Although GOG 213 did not demonstrate improvement in OS in patients with platinum-sensitive recurrent ovarian cancer who received surgery and chemotherapy versus chemotherapy alone, only 7 (3%) of these patients had LGSC. In a retrospective review of recurrent LGSC, 78% of patients who had secondary cytoreduction had no gross residual disease at the conclusion of surgery, which translated into an improved PFS compared with patients who were left with gross residual disease.[152] Therefore, secondary cytoreductive surgery may be a reasonable approach in this histology.

Similar to the neoadjuvant setting, LGSC is also chemoresistant in the recurrent setting, with a response rate of less than 4%; however, 60% of patients did have stable disease in one study.[149] Numerous hormonal agents have been used in the treatment of recurrent LGSC, with response rates that are only slightly improved compared with chemotherapy. Retrospective series have shown an ORR of 9%; however, similar to chemotherapy, 62% of patients achieved stable disease.[149] In addition, hormonal treatments are usually more tolerable to patients, likely leading to improved quality of life.

Alternatives to chemotherapy and hormonal therapy are under investigation. Given the frequency of *KRAS* and *BRAF* mutations in this histologic subtype, a single-arm phase 2 trial of selumetinib, a MEK 1/2 inhibitor, was performed in recurrent LGSC. The objective response rate was 15%, and 65% of patients had stable disease. Interestingly, there was no correlation between *KRAS* and *BRAF* mutational status and response to the study drug. A different MEK inhibitor, binimetinib (MEK162) was evaluated and compared with physician's choice of liposomal doxorubicin, paclitaxel, or topotecan in the MILO study in women with recurrent or persistent LGSC (NCT01849874). Unfortunately, in the interim analysis, the PFS hazard

ratio crossed the predefined futility boundary, and the study was closed early. More promising results have been reported for a recent phase 2/3 clinical trial (NRG-GOG 0281), which compared treatment using the MEK inhibitor trametinib to the physician's choice of standard-of-care treatment for women with recurrent or progressive LGSC. Results indicated improved PFS (13.0 vs 7.2 months), ORR (26.2 vs 6.2%), and response duration (13.6 vs 5.88 months) favoring trametinib. As of this writing, the results of this trial are not yet published, but they were presented at the European Society for Medical Oncology Congress in September of 2019. This could represent a new standard-of-care treatment option for women with recurrent LGSC.

Future directions will likely continue to steer away from standard cytotoxic chemotherapy regimens and trend toward combination targeted and hormonal therapies. Strategies under development include PARP inhibitors combined with MEK inhibitors as well as cyclin-dependent kinase 4/6 inhibitors with hormonal therapies. For example, GOG 3026 (NCT03673124) is evaluating response to treatment with ribociclib and letrozole in patients with recurrent or progressive LGSC and is currently recruiting.

MALIGNANT GERM CELL TUMORS

Malignant ovarian germ cell tumors (MOGCTs) recapitulate normal embryonic and extraembryonic cells and structures and are derived from the primitive germ cells of the embryonic gonad. The MOGCTs comprise 2% to 3% of all ovarian malignancies, and they usually develop in girls, adolescents, and women of reproductive age. Advances in chemotherapy have yielded cure in the vast majority of patients with these tumors, and modifications in surgical technique have allowed fertility preservation in most patients.[153] These tumors should always be considered in the differential diagnosis in a young woman with a solid ovarian mass, as the median age of diagnosis is 16 to 20 years (range 6–60), and the highest incidence occurs in 15- to 19-year-old girls.

The current classification of ovarian germ cell tumors includes both benign and malignant neoplasms. Most benign ovarian germ cell tumors are mature teratomas. MOGCTs include primitive germ cell tumors, biphasic or triphasic teratomas, and monodermal teratomas (Table 39–5). Immature teratomas should be extensively sampled to determine the amount of immature neural, nonneural, and yolk sac elements and thereby malignant potential. Although we continue to report grading criteria for immature teratomas using a three-tier system, we agree that a biphasic system may allow for greater consistency.

Table 39–5 World Health Organization Classification of Ovarian Germ Cell Tumors

Primitive Germ Cell Tumors	Biphasic or Triphasic Teratoma	Monodermal Teratoma and Somatic-Type Tumors
Dysgerminoma	Immature teratoma (grades 1–3)	Thyroid (struma ovarii)
Endodermal sinus tumor (yolk sac tumor)	Mature teratoma (solid, cystic, or fetiform teratoma)	Carcinoid
Embryonal carcinoma		Neuroectodermal
Polyembryona		Carcinoma
Nongestational choriocarcinoma		Melanocytic
Mixed germ cell tumor		Sarcoma
		Sebaceous
		Pituitary type

Etiology

The etiology of MOGCT is related to gonadal dysgenesis in a minority of patients. Patients with a mosaic variant of Turner syndrome including a Y chromosome may develop gonadoblastoma.[154] Patients with complete gonadal dysgenesis who have a 46, XY genotype and a female phenotype (Swyer syndrome) have up to a 30% risk of developing MOGCT, especially dysgerminomas, and prophylactic removal of both gonads is indicated if the diagnosis is made.[155]

Diagnosis

The diagnosis of MOGCT may be suspected based on the young age of the patient with a solid, palpable ovarian mass, but histologic confirmation is required for the diagnosis. Eighty-five percent of patients present with abdominopelvic pain associated with a palpable mass. Other presenting symptoms and signs include abdominal distention, fever, ascites, and vaginal bleeding. Ten percent of patients present with acute abdominal pain associated with rupture, hemorrhage, or torsion of the mass. Isosexual pseudoprecocity may be caused by β-chorionic gonadotrophin production by the tumor.[156] Evaluation of the pelvic mass in the young patient may be aided by transvaginal ultrasound and magnetic resonance imaging. Supradiaphragmatic disease or pure choriocarcinoma is an indication for magnetic resonance imaging of the brain.[156]

Tumor markers may be especially helpful in MOGCT to suggest individual tumor histology, provide prognostic information, and provide a basis to

Table 39–6 Tumors Markers Helpful in MOGCT

Tumor	AFP	β-HCG	Lactic Dehydrogenase
Pure dysgerminoma	Normal	May be elevated	Elevated
Endodermal sinus tumor	Elevated	Normal	May be elevated
Embryonal carcinoma	Elevated	Elevated	Elevated
Choriocarcinoma	Normal	Elevated	Normal
Immature teratoma	May be elevated	Normal	Normal

follow the response of the disease to therapy (Table 39–6). When MOGCT is suspected, these markers should be measured preoperatively. A karyotype should be performed if gonadal dysgenesis is suspected, because bilateral oophorectomy is indicated if the diagnosis is confirmed. The appropriate minimum diagnostic evaluation for the young woman with a suspicious adnexal mass should include routine blood studies, serum tumor marker analysis, chest radiography, and imaging of the abdomen and pelvis.[156]

Management

Surgery is the mainstay of diagnosis and initial treatment of MOGCT. Laparotomy has been the standard of care, but minimally invasive surgery appears to be feasible when the tumor can be removed intact and complete staging can be performed.[157] Patients who have completed childbearing should undergo total hysterectomy and bilateral salpingo-oophorectomy. However, most patients with MOGCT are of reproductive age, and because outcomes with conservative surgery are comparable to that of hysterectomy with bilateral salpingo-oophorectomy, fertility-sparing surgery should be considered in every patient of reproductive age. Whenever possible, the normal-appearing contralateral adnexa and uterus should be conserved. If both ovaries are grossly involved, bilateral salpingo-oophorectomy may be warranted, but this is the exception rather than the rule. Some discussion has centered on ovarian preservation with postoperative chemotherapy to treat this chemosensitive residual disease, thus allowing fertility preservation even with advanced disease or bilateral ovarian involvement. Even if both ovaries are removed, the uterus may be preserved to allow assisted reproduction with a donor egg.

Several treatment conundrums are encountered not infrequently. If a MOGCT is diagnosed postoperatively after an ovarian cystectomy for disease thought to be benign, subsequent removal of the remaining ovarian tissue may be avoided. Excellent survival has been reported in this setting, although most patients did receive adjuvant chemotherapy.[158] In addition, occasionally patients might present with widespread bulky abdominopelvic disease, and aggressive debulking surgery is followed by rapid tumor regrowth. Although not yet considered standard, neoadjuvant chemotherapy after percutaneous biopsy has been increasingly used to allow for less morbid, more effective fertility-sparing interval cytoreductive surgery.[159]

Staging for MOGCT follows FIGO staging for EOC (see Table 39–4). However, the extent of comprehensive surgical staging is controversial. Comprehensive surgical staging has traditionally been performed in adult patients, including peritoneal cytology, biopsies, omentectomy, bilateral pelvic and para-aortic lymphadenectomy, and removal of any suspicious tissue. In the pediatric setting, staging is typically limited to pelvic washing, tumor removal, and biopsy of suspicious implants. Although proponents of limited staging cite the exquisite sensitivity of MOGCT to chemotherapy, there may be some benefit to complete surgical staging. At our institution, we have performed comprehensive staging to either support the administration of chemotherapy up front in patients with nodal involvement or avoid chemotherapy in fully staged patients without metastatic disease. Regardless, patients with nondysgerminomatous MOGCT should receive chemotherapy unless they have stage 1A disease after comprehensive surgical staging. Surveillance in low-risk patients has been proposed, and studies are ongoing.

Adjuvant Therapy

Although patients with stage I dysgerminoma and stage IA grade 1 immature teratoma may be safely observed after surgery without chemotherapy, combination chemotherapy with three to four courses of bleomycin, etoposide, and cisplatin (BEP) results in the cure of most other patients with MOGCT (Table 39–7). Patients with completely resected disease usually receive three cycles of BEP, although patients with macroscopic residual disease receive four cycles, sometimes omitting bleomycin from cycle 4. Care should be taken to evaluate for bleomycin-related pulmonary toxicity, with periodic lung auscultation, chest radiography, and pulmonary function testing if the patient

Table 39–7 Regimen for Administration of Bleomycin, Etoposide, and Cisplatin (BEP)

After prehydration and premedications:
Cisplatin: 20 mg/m^2 per day in 1 L normal saline with 50 g mannitol IV over 4 hours on days 1–5
Etoposide: 100 mg/m^2 per day in 1 L 5% dextrose in normal saline IV over 2 hours on days 1–5
Bleomycin: 20 U/m^2 in 250 mL normal saline over 24 hours on day 1
OR
Bleomycin: 10 U/d on days 1–3
OR
Bleomycin: 10 U/d on days 1, 8, and 15 (United States)
OR
Bleomycin: 30,000 IU weekly for 12 weeks, with the fourth course consisting of EP alone (Europe/United Kingdom)[a]

[a]Maximum total bleomycin dose not to exceed 270 mg. Regimen repeated every 21 days.

experiences symptoms. Rales, pulmonary consolidation, or a 30% decrease in the diffusion capacity of carbon monoxide prompts deletion of bleomycin from the regimen.[153] Radiation therapy is effective in the treatment of dysgerminoma but is rarely used because of the impact on ovarian function and subsequent fertility.

Although most patients are cured, worse outcomes are related to advanced stage, yolk sac (endodermal sinus) tumor histology, incomplete surgical resection, and advanced age.[160] Patients with high-risk disease or who do not respond to BEP rapidly may be considered for alternate therapies, including paclitaxel combined with BEP (T-BEP) or dose-dense BEP.[153]

Follow-Up

After treatment, patients receive imaging of the chest, abdomen, and pelvis and evaluation of tumor markers. Subsequently, they are monitored every 3 months for the first year, every 4 months for the second year, and every 6 months for years 3 to 5. We do not obtain routine imaging, although in high-risk patients, transvaginal ultrasound may follow and initial abdominopelvic imaging may be obtained.

Treatment of Recurrent Disease

In the small percentage of patients who are thought to have a recurrence, evaluation must include repeat imaging of the chest, abdomen, and pelvis and evaluation of tumor markers, and a biopsy must confirm the diagnosis of recurrent disease because immature teratomas can recur with only mature benign elements (growing teratoma syndrome) or with benign gliosis. Both of these entities are benign and do not automatically require chemotherapy or surgical resection. In the event of true recurrence, surgical resection should be considered, and appropriate salvage chemotherapy should be considered. More than half of patients who have a recurrence after 6 weeks after initial therapy (platinum-sensitive) can achieve cure with VeIP (vinblastine, ifosfamide, and cisplatin) or TIP (paclitaxel, ifosfamide, and cisplatin); high-dose chemotherapy may also be administered.[153] Patients whose disease progresses during treatment or who have a recurrence within 4 to 6 weeks (platinum-resistant) are not curable; standard-dose VeIP may be administered, and in the event of response, high-dose etoposide and carboplatin with stem cell rescue may be given.[153] Other agents with activity include ifosfamide, taxanes, and gemcitabine.

Reproductive Outcomes

Reproductive outcomes after surgical or chemotherapeutic treatment for MOGCT are excellent, with little effect on menstrual cycling, reproductive function, conception, or childbirth. Chemotherapy-induced infertility appears to occur in 18% or less of patients treated with BEP and is unrelated to cisplatin dose. Eighty percent of women resume normal menstrual function. Long-term quality of life and psychosocial outcomes of survivors of MOGCT are also excellent.

SEX CORD STROMAL TUMORS

Sex cord stromal tumors (SCSTs) of the ovary comprise 7% of all ovarian malignancies and have an annual incidence rate of 0.20 per 100,000 women.[161] These tumors can occur in females of all ages, but most occur in peri- and postmenopausal women. Some histologic subtypes, such as juvenile granulosa cell tumors (GCTs) and Sertoli-Leydig cell tumors (SLCTs) have a propensity to develop in adolescents; all histologic subtypes may develop in women of reproductive age. Overall, many of these tumors tend to be indolent, progressing slowly over decades.

Sex cord stromal tumors are a heterogeneous group of tumors classified in Table 39–8.[162] The GCTs are the most common (90% of all malignant ovarian SCSTs) and consist of adult (95% of cases) and juvenile (5% of cases) forms, which differ in their histologic appearance, age of onset, and natural history. Juvenile GCTs usually affect adolescent females, may present with precocious puberty, may be associated with breast cancer, and have high mitotic activity. Adult GCTs tend to occur in older women, produce estrogen, may be associated with endometrial hyperplasia or cancer, and are often quite indolent.[162] SLCTs arise from mesenchyme and sex cords, which

Table 39–8 Classification of Ovarian Sex Cord Stromal Tumors

Steroid Cell Tumors
Stromal luteoma Leydig cell tumor Steroid cell tumor, not otherwise specified

recapitulate testicular development and may include various proportions of Sertoli and Leydig elements. Pure Sertoli cell tumors and pure Leydig cell tumors are benign, although tumors with Sertoli and Leydig cell components demonstrate degrees of malignant behavior and are classified based on differentiation. The benign differentiated form typically produces androgens; intermediate differentiated forms have immature Sertoli cells; and poorly differentiated forms with sarcomatoid or retiform patterns tend to be more aggressive. Gynandroblastomas are rare, tend to be virilizing, and are usually benign, but large tumors occurring in women aged 30 to 50 years may exhibit malignant behavior. A sex cord tumor with annular tubules (SCTAT) may be associated with Peutz-Jeghers syndrome.

Etiology

The etiology for all SCSTs is unknown. However, a somatic cytosine-to-guanine point mutation in the *FOXL2 403* gene has been identified as pathognomonic for adult GCT formation (but not juvenile GCT).[163] In addition, mutations in *DICER1* appear to be present in some patients with SLCTs and in patients with pleuropulmonary blastoma; children with SLCTs may be screened for *DICER1* mutations and thereby undergo early treatment for pleuropulmonary blastoma, a potentially lifesaving intervention.[164] The SCTATs may be associated with Peutz-Jeghers syndrome and potentially linked to *STK11* mutations in these patients.

Diagnosis

Most patients with SCSTs present with pelvic pain, pelvic pressure, and menstrual irregularities, including precocious puberty, menometrorrhagia, or postmenopausal bleeding.[162] Although these tumors cannot be diagnosed without histologic confirmation of surgical findings, preoperative studies such as pelvic ultrasonography and analysis of certain tumor markers may suggest the diagnosis of SCST. When suspected, preoperative CT of the abdomen and pelvis is warranted. Preoperative laboratory testing should include analysis for serum human chorionic gonadotrophin and routine laboratory testing.

Serum markers may be useful in the preoperative diagnosis of SCST when suspected or in establishing a baseline level with which to follow the tumor status of the patient during treatment and surveillance. Inhibin A, inhibin B, and anti-Müllerian hormone (AMH) are useful markers, and AMH may be highly specific for GCT in postmenopausal women or women whose ovaries have been removed.

Management

Surgery remains the cornerstone of diagnosis and treatment for patients with SCSTs. Although surgery has historically been performed via laparotomy, minimally invasive surgery appears to be safe and feasible for initial limited surgery and staging as well as restaging in many patients with SCSTs, as long as the tumor can be removed intact without contamination of the peritoneal cavity, using a specimen bag for removal.[162] Staging procedures include examination of the entire abdominopelvic cavity; peritoneal washings; infracolic omentectomy; and biopsy of any suspicious lesions of the diaphragmatic peritoneum, paracolic gutters, and pelvic peritoneum. Lymphadenectomy can be omitted in the absence of suspicious lymph nodes given that lymph node metastases are quite uncommon in this histology.[162,165] Although postmenopausal women and women who have completed childbearing should undergo total hysterectomy and bilateral salpingo-oophorectomy, young women and women of reproductive age who have not completed childbearing may undergo conservative surgery to preserve fertility regardless of stage. This is demonstrated by a multiinstitutional study from the United States[166] and a recent population-based study from Sweden where the 5-year OS for patients undergoing fertility-sparing surgery was 100% with a PFS of 98%.[167] In patients with adult GCTs, retrospective studies[168,169] have demonstrated that fertility-sparing surgery does not appreciably affect

survival outcomes, with the notable exception of FIGO stage IC. It is important to note that fertility-sparing surgery refers to removal of the entire involved adnexa as well as surgical staging. There is no role for ovarian cystectomy in definitive surgical treatment.[170] Evaluation of the endometrium should be a part of any surgery for SCSTs because 55% of patients with GCTs have endometrial hyperplasia and 4% to 20% have endometrial adenocarcinoma.[170] The FIGO staging for SCST is the same as that for EOCs (see Table 39–4).[162]

Adjuvant Therapy

Patients with stage IA and IB SCSTs do not require adjuvant therapy after surgery. Therapy for patients with stage IC disease is controversial and may include chemotherapy or hormonal therapy for patients with a high mitotic index. Patients with stage I SLCTs who have poorly differentiated tumors or heterologous elements should be treated with adjuvant chemotherapy. Any patient with advanced-stage (II or above) SCSTs should receive treatment with chemotherapy.[162] The type of chemotherapy administered has historically been 3 to 4 cycles of BEP, but retrospective reports suggest that taxanes, especially when administered with platinum-based chemotherapy, have efficacy and less toxicity than BEP.[170,172] The GOG is currently comparing these two regimens in advanced-stage upfront, and recurrent chemo-naïve SCST patients.

Follow-Up

Most patients with SCST are cured, but 20% have a recurrence; these patients may succumb to their disease.[162] Tumor stage, tumor rupture, age over 50 years, and tumor size are reported prognostic factors.[173] The SCSTs tend to have an indolent nature with a propensity for late recurrence. Therefore, patients require long-term surveillance. Our strategy is to follow patients every 3 months for the first year, every 4 months for the second year, every 6 months for years 3 to 5, and then annually. At each visit, history, physical examination including pelvic examination, and tumor marker values (inhibin A, inhibin B, AMH, and sometimes CA 125) are obtained; imaging is reserved for patients with new symptoms, signs, or elevated marker values.

Treatment of Recurrent Disease

Patients who have a recurrence require a biopsy to confirm the initial recurrence. These patients may benefit from surgical resection in the event of limited resectable recurrent disease. Radiotherapy may also be an option. Treatment with hormonal agents may induce response or long-term stable disease. Chemotherapy using BEP or taxane-platinum combinations may be useful. Most recently, bevacizumab has been shown to be an active agent in the recurrent setting.[174]

MD ANDERSON PRACTICE TIPS

- The current approach at MDACC for patients with suspected advanced ovarian cancer who are medically fit for surgery and are without distant metastatic disease is to undergo a preoperative laparoscopic assessment to assess the likelihood of complete resection (modified Fagotti score). Our laparoscopic triage is accomplished by scoring made by two independent and blinded surgeons. Patients scoring less than 10 undergo primary cytoreduction. Those with scores of 10 or more undergo neoadjuvant chemotherapy followed by consideration of interval cytoreductive surgery and three additional cycles of chemotherapy.
- Based on the results of four of five phase 3 randomized controlled trials, we do not currently feel there is sufficient evidence to support the standard use of weekly paclitaxel in the adjuvant setting and are not incorporating this into our practice.
- In patients with newly diagnosed advanced ovarian cancer and poor prognosis, we recommend considering the addition of bevacizumab to standard chemotherapy.
- We follow patients with CA 125 levels in surveillance but in general do not treat patients based solely on a rising value.
- Identifying women at risk for development of ovarian cancer from a heritable cause is currently the only successful method for ovarian cancer prevention. We recommend genetic testing for patients with a history of ovarian cancer, not only to determine their risk for developing concurrent malignancies and identify treatment options, but also to identify family members who may be at risk and could benefit from preventive measures
- Low-grade serous carcinoma is relatively chemoresistant when compared with high-grade serous carcinoma. Despite this, carboplatin and paclitaxel remain first-line adjuvant therapy in advanced disease. However, hormonal therapies and targeted therapies have had promising results in the adjuvant and maintenance settings.

40 Tumors of the Uterine Corpus

Michaela A. Onstad
Shannon N. Westin
Karen H. Lu

KEY CONCEPTS

- For women with early-stage, intermediate-risk endometrial cancer, there is no evidence that adjuvant therapy improves overall survival. For women with *low-intermediate-risk disease*, observation is favored. For women with *high-intermediate-risk disease*, vaginal cuff brachytherapy is favored.
- Women with high-risk disease have either serous or clear cell adenocarcinoma (any stage) or have pathologic stage III disease with extrauterine involvement. Adjuvant treatment may involve radiation, chemotherapy, or a combination of the two modalities, based on histology, stage, and other factors
- Recurrent or metastatic endometrial cancer is associated with a poor prognosis. Clinical trial GOG 209 supports the use of carboplatin and paclitaxel in this setting.
- Immunotherapy may be considered as second-line treatment for recurrent/metastatic endometrial cancer. Pembrolizumab has a response rate (RR) of 53% for women with mismatch repair–deficient tumors. The combination of pembrolizumab with the tyrosine kinase inhibitor lenvatinib has a RR of 38% among women with microsatellite stable tumors.
- Targeted therapies with demonstrated efficacy in second-line treatment include single-agent bevacizumab (GOG229E), and the combination of the mTOR inhibitor everolimus with letrozole.
- Endocrine therapy may also be used to treat metastatic/recurrent endometrial cancer. It tends to be well tolerated with relatively minor side effects, and has modest RRs, ranging from 11% to 24%. Characteristics that improve the likelihood that a patient will have a favorable response to hormone therapy include having a low tumor grade (1 or 2), endometrioid histology, the presence of estrogen and progesterone receptors, having a longer disease-free interval, and being asymptomatic or minimally symptomatic.

EPITHELIAL UTERINE TUMORS

Epidemiology

Endometrial cancer is the most common gynecologic malignancy, and the fourth most common cancer among women in the United States, affecting 1% to 2% of US women.[1] Approximately 75% of women diagnosed with endometrial cancer are diagnosed at an early stage and have a 5-year overall survival (OS) of 74% to 91%.2 For women with stage III or IV disease, 5-year OS rates are 57% to 66% and 20% to 26%, respectively.[2] This disease primarily affects women in their postmenopausal and perimenopausal years, with an average age at diagnosis of 61 years,[2] although 5% to 30% of women are under the age of 50 years.[3]

Risk Factors

The main risk factors for endometrial cancer are age, obesity, diabetes, and exposure to excess estrogen without adequate opposition by progesterone. This includes the use of exogenous unopposed estrogen therapy, the use of estrogen agonists (such as tamoxifen), and physiologic states that lead to excess endogenous estrogen. Excess endogenous estrogen can be found in women with obesity, chronic anovulation, early age at menarche, nulliparity, late age of menopause, and in the setting of rare estrogen-secreting tumors.

Obesity is a well-established risk factor for the development of endometrial cancer. A meta-analysis of 19 prospective studies showed that for every 5 kg/m^2

increase in body mass index (BMI), a women's risk of developing endometrial cancer significantly increases.[4] One explanation for these findings is that women who are obese have higher levels of endogenous estrogen because of the conversion of androstenedione into estrone and the aromatization of androgens to estradiol, which occurs in the peripheral adipose tissue. There are additional proposed mechanisms for this association, including alterations in insulin signaling and insulin resistance, alterations in expression of circulating adipokines, as well as alterations in pathways involving inflammation.[5–7] Obesity increases the risk of endometrial cancer in both post- and premenopausal women. In fact, the majority of young, premenopausal women diagnosed with endometrial cancer have a BMI greater than 30.[2]

Lynch syndrome is an autosomal dominant hereditary cancer syndrome characterized by an increased risk in endometrial cancer, colon cancer, and several other malignancies. It is associated with a germline defect in a DNA mismatch repair gene (MutL homolog 1 [*MLH1*], MutS homolog 2 [*MSH2*], MutS homolog 6 [*MSH6*], postmeiotic segregation 2 [*PMS2*]). Women who have Lynch syndrome have a 15% to 66% lifetime risk of developing endometrial cancer, a 15% to 68% lifetime risk of developing colon cancer, and a 1% to 20% lifetime risk of developing ovarian cancer, depending on the specific mutation involved.[8,9]

Diagnosis and Screening

Screening

Except for patients who have been diagnosed with Lynch syndrome, there is insufficient evidence to support routine screening for endometrial cancer in asymptomatic women in the general population, even in those with risk factors such as tamoxifen use, history of unopposed estrogen, obesity, or diabetes. The American Cancer Society currently recommends that all women be informed about the risks and symptoms of endometrial cancer at menopause. Women should alert their physicians of any unexpected bleeding or spotting in the postmenopausal years and abnormal uterine bleeding in the pre- or perimenopausal years.

The American Cancer Society recommends yearly screening with endometrial biopsy beginning at age 35 for women who are known to carry Lynch syndrome–associated mutations, those who have a family member known to carry this mutation, or women from families with an autosomal dominant predisposition to colon cancer in the absence of genetic testing for Lynch syndrome.[10] Prophylactic hysterectomy and salpingo-oophorectomy have been shown to be effective in decreasing the risk of endometrial and ovarian cancers and should be offered to women with Lynch syndrome after childbearing is complete.[11]

Diagnosis

The primary symptom of endometrial cancer is postmenopausal bleeding or abnormal uterine bleeding in pre- or perimenopausal women. A histologic diagnosis is typically obtained by office endometrial sampling or dilation and curettage.

Histopathology

Endometrial Hyperplasia

Women with histologic diagnoses of endometrial hyperplasia often present with postmenopausal bleeding or menometrorrhagia. The risk factors associated with the development of endometrial hyperplasia, including obesity and unopposed estrogen, are similar to those associated with endometrial cancer.[12] The World Health Organization defined endometrial hyperplasia based on two characteristics: (1) simple or complex glandular/stromal architectural pattern, and (2) the presence or absence of nuclear atypia. The presence of nuclear atypia correlates highest with the risk of developing malignancy. In this spectrum, those with simple hyperplasia without atypia are least likely to develop endometrial carcinoma, whereas women with complex hyperplasia with atypia are most likely to develop carcinoma. In a long-term follow-up study conducted by Kurman et al, endometrial carcinoma occurred in simple, complex, simple atypical, and complex atypical hyperplasia in 1%, 3%, 8%, and 29% of cases, respectively.[13] A report from one meta-analysis showing a wider range of risk of cancer progression based on four prospective follow-up studies is summarized in Table 40–1.[14]

Endometrioid Carcinoma

Endometrioid adenocarcinoma is the most common subtype of endometrial cancer, accounting for 75% to 80% of endometrial cancer. Endometrioid adenocarcinomas are graded 1 through 3, based on degrees of differentiation. Grade 1 tumors are well differentiated, composed of glands resembling normal endometrial tissue (Fig. 40–1A). In less-differentiated tumors, glandular formations are less evident or are replaced with solid areas (Fig. 40–1B). The percentage of tumor consisting of these nonsquamous or nonmorular solid areas is the criterion for grading, with grade 1 having a 5% or less solid component, grade 2 having more than 5% but less than or equal to 50%, and grade 3 having greater than 50%. Notably, the presence of nuclear atypia that does not correlate with the architectural features should lead to a one-step upgrade of the tumor.

Table 40–1 Risk of Progression from Endometrial Hyperplasia to Endometrial Cancer

Hyperplastic Type	No. of Cases	Risk of Progression (%)	Mean Risk (%)
Simple hyperplasia	164	0–10	4.3
Complex hyperplasia	193	3–22	16.1[a]
Simple hyperplasia with atypia	27	7.8	7.4[a]
Complex hyperplasia with atypia	151	29–100	47.0

[a]Complex hyperplasia architecture carries a higher risk of progressing to carcinoma than does atypical simple hyperplasia.

Uterine Serous Carcinoma

Uterine serous carcinomas (USCs) are highly aggressive tumors that should be distinguished from other types of uterine carcinoma. Serous carcinomas tend to occur in older women, are usually present in advanced stages, and represent 1% to 5% of cases. Deep myometrial invasion, extensive lymphovascular space invasion (LVSI), and extrauterine spread are common. Intraperitoneal involvement is often observed even when the primary lesion is localized. The histologic features of serous carcinoma resemble those of ovarian or tubal carcinoma. Cytologic atypia is so prominent that serous carcinomas are always graded as poorly differentiated tumors.

Clear Cell Carcinoma

Another aggressive form of uterine carcinoma, clear cell carcinoma, represents 5% to 10% of endometrial cancer cases and is also considered a high-grade tumor. Clear cell carcinoma tends to occur in older women. Morphologically, it resembles clear cell carcinoma arising from other sites (eg, vagina, cervix, ovary), but clear cell carcinoma of the uterine corpus, unlike that of the vagina or cervix, is not associated with intrauterine exposure to diethylstilbestrol. The microscopic appearance varies and can include solid clear cell features; prominent glycogen content; and a glandular, tubulocystic, or papillary pattern. The cells have abundant clear or eosinophilic cytoplasm, sometimes

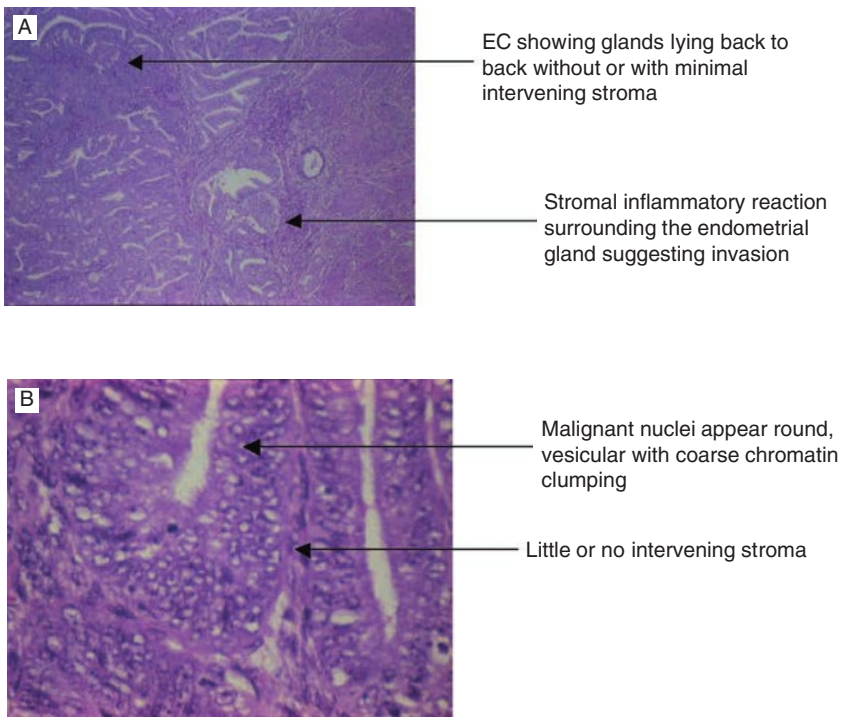

FIGURE 40–1 Endometrioid adenocarcinoma. A. Endometrial cancer with superficial myometrial invasion. The stromal inflammatory reaction surrounding the endometrial gland can aid in the diagnosis in some equivocal cases. B. High-power magnification shows malignant nuclei in the endometrial glands.

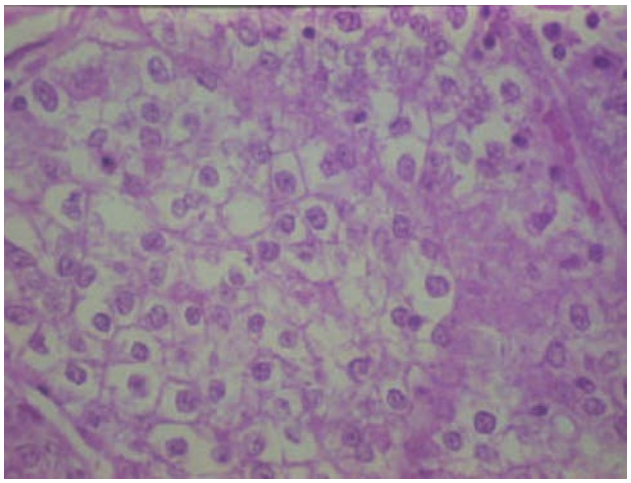

FIGURE 40–2 Clear cell carcinoma: a more aggressive type of endometrial cancer than the usual endometrioid carcinoma. The clear cytoplasmic content is glycogen rather than mucin.

containing periodic acid–Schiff–positive hyaline globules (Fig. 40–2). The nuclei show marked atypia with frequent mitotic figures. The characteristic "hobnail" appearance is seen as cells with scanty cytoplasm and nuclei protruding into the lumen of the gland. At least half of the clear cell carcinomas are admixed with USC; this has contributed to ideas that the poor prognosis associated with clear cell carcinoma is caused by the presence of serous histology.

Mixed-Cell Type

As the name implies, mixed-cell endometrial cancers contain more than one type of tumor. The proportion of the minor component should exceed 10% for a tumor to be designated a mixed-cell type.

Carcinosarcomas

Carcinosarcomas (also called malignant mixed Müllerian tumors [MMMTs]) consist of two components: malignant epithelial and mesenchymal tissue. In homologous carcinosarcomas, the sarcomatous component can be tissue that is normally found in the uterus; endometrial stromal sarcoma (ESS) or leiomyosarcoma are common. The so-called "heterologous" type of carcinosarcoma consists of tissue that does not normally appear in the uterus; rhabdomyosarcoma and chondrosarcoma are two common types.[15–17] Carcinosarcomas are believed to be aggressive carcinomas, rather than true sarcomas.

Staging

In 1988, the International Federation of Gynecology and Obstetrics (FIGO) committee established a surgical staging system for endometrial cancer (FIGO 1988) (Table 40–2). In 2009, this staging system was updated to better stratify patients based on clinically relevant prognostic factors (FIGO 2009, Table 40–3).

Table 40–2 The 1988 FIGO Staging System

Stages	Characteristics
I	Tumor limited to uterus
IA	Confined to endometrium
IB	Invades ≤1/2 the myometrial depth[a]
IC	Invades >1/2 the myometrial depth[a]
II	Cervical extension
IIA	Involves endocervical gland only
IIB	Invades cervical stroma
III	Pelvic structures or intra-abdominal lymph node involvement
IIIA	Invades serosa or adnexa or is peritoneal cytology positive
IIIB	Vaginal metastasis
IIIC	Pelvic or para-aortic lymph node metastasis
IV	Other organ involvement
IVA	Invades bladder or rectal mucosa
IVB	Distant metastasis, including inguinal lymph node involvement

[a]Ideally, width (depth) of myometrial invasion should be measured and recorded with the depth (thickness) of the entire myometrium.

Prognostic Factors

There are clinical and pathologic factors that can be used to predict the behavior of endometrial cancer. Clinical factors include age, ethnicity, and stage of disease. Pathologic factors include histologic type, grade, depth of myometrial invasion, lymphovascular space invasion (LVSI), and spread of tumor outside the uterine cavity, including the retroperitoneal lymph nodes.

Clinical Factors

Studies have shown that outcomes for women with endometrial cancer are more favorable among younger patients. A retrospective study showed that patients younger than 45 years old were statistically more likely to have endometrioid histology, grade I tumors, and stage IA disease, whereas women over age 65 were significantly more likely to have serous histology and grade 3 tumors. A subset analysis of patients older than 75 years old showed an increase in the percentage of patients with aggressive serous histology, higher-grade (grade 3) disease, and advanced-stage disease compared with those younger than 45 years old. Evaluation of patients with endometrioid tumors

Table 40–3 The 2009 FIGO Surgical Staging for Endometrial Carcinoma

Stages	Characteristics
I[a]	Tumor confined to the corpus uteri
IA[a]	No or less than half myometrial invasion
IB[a]	Invasion equal to or more than one-half the myometrium
II[a]	Tumor invades cervical stroma but does not extend beyond the uterusb
III[a]	Local and/or parametrial involvementc
IIIA[a]	Tumor invades serosa and/or adnexaec
IIIB[a]	Vaginal and/or parametrial involvementc
IIIC[a]	Metastases to pelvic and/or para-aortic lymph nodesc
IIIC1[a]	Positive pelvic nodes
IIIC2	Positive para-aortic lymph nodes with or without positive pelvic lymph nodes
IV[a]	Tumor invasion of bladder and/or bowel mucosa and/or distant metastases
IVA[a]	Tumor invasion of bladder and/or bowel mucosa
IVB[a]	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

[a]Either G1, G2, or G3.
[b]Endocervical glandular involvement only should be considered as stage I and no longer as stage II.
[c]Positive cytology has to be reported separately without changing stage.
FIGO, International Federation of Gynecology and Obstetrics.

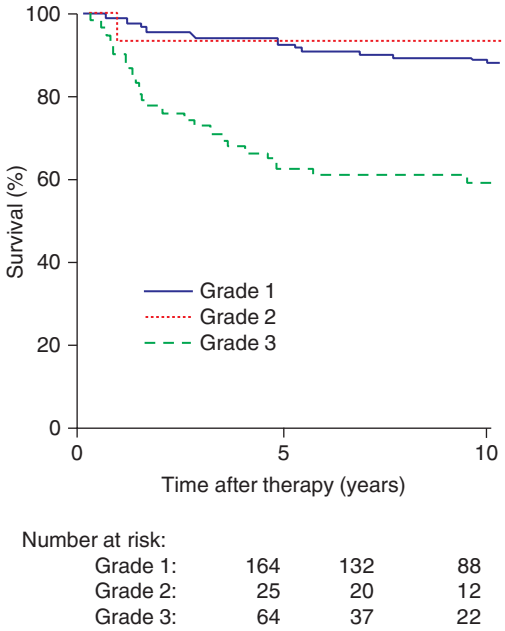

FIGURE 40–3 Tumor grade and survival in endometrial cancer. Use of the two-tier grading system is favored because of less interobserver variability and similar outcome for patients with grade 1 or 2 tumors ($n = 243$). (Reproduced with permission from Scholten AN, Creutzberg CL, Noordijk EM, et al: Longterm outcome in endometrial carcinoma favors a two instead of a three-tiered grading system, *Int J Radiat Oncol Biol Phys* 2002 Mar 15;52(4):1067-1074.)

revealed a similar pattern of deeper myometrial invasion and higher tumor grade as age increased.[18] Other studies have shown that the risks of locoregional relapse and death among patients older than 60 years were twice as high as the risks among those aged 60 years or younger.[19]

Studies in the United States have demonstrated that White women are more likely to be diagnosed with endometrial cancer than Black women. Unfortunately, however, Black women diagnosed with endometrial cancer have a 55% higher mortality risk compared with White women.[20] They tend to be diagnosed at a later stage, with higher-grade tumors, and are more likely to have serous histology. However, after controlling for these factors as well as other comorbid factors, a higher disease-specific mortality rate among Black women still exists.[21]

Pathologic Factors

With regard to histologic subtype, serous carcinoma and clear cell carcinoma are associated with worse prognosis than endometrioid carcinoma. Increasing tumor grade is associated with increased myometrial

Table 40–4 Pathologic Features of Endometrial Carcinoma Grades and Their Association with Depth of Myometrial Invasion

Grade	Pathologic Features	Percentage of Patients with Each Depth of Myometrium Invasion			
		Endometrial Only	Superficial	Middle	Deep
1	5% or less of nonsquamous solid area	24	53	12	10
2	6%–50% of nonsquamous solid area	11	45	24	20
3	>50% of nonsquamous solid area	7	35	16	42

invasion, pelvic and para-aortic node involvement, recurrence, and a poorer OS (Table 40–4, Fig. 40–3).[22]

Lymphovascular space invasion, an independent risk factor for recurrence, is present in about 15% of endometrial cancer cases. Multivariate analyses have shown LVSI to be associated with survival in endometrial cancer regardless of disease stage. Independent of tumor grade or depth of myometrial invasion, LVSI is also associated with risk of pelvic and para-aortic node involvement and thus should lead to consideration of surgical nodal assessment or radiotherapy in patients with unstaged disease.[22]

The depth of myometrial invasion is associated with degree of tumor differentiation, LVSI, lymph node involvement, extrauterine spread, recurrence, and OS (Fig. 40–4, Table 40–5). Adnexal metastasis correlates strongly with metastatic involvement of pelvic and para-aortic nodes; in one study, 32% of patients with adnexal involvement had positive pelvic nodes, as compared with 8% of those without adnexal disease.[22] However, the alternate possibility of simultaneous ovarian and endometrial primaries must be ruled out because the surgical management and prognosis are vastly different. Up to 11% of patients with clinical early-stage disease have lymph node involvement.[22] The risk of para-aortic node involvement increases if the pelvic nodes are positive for tumor.

The current FIGO staging system does not incorporate peritoneal washings because the evidence for their prognostic value is limited. Positive findings on peritoneal cytology are often associated with other unfavorable prognostic factors, such as deep myometrial invasion, cervical extension, and extrauterine spread.

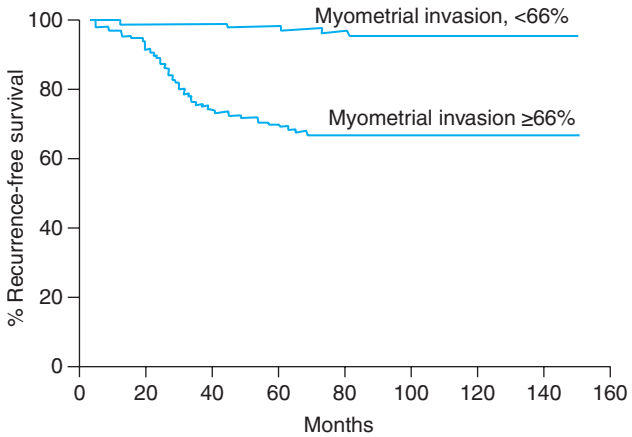

FIGURE 40–4 **Recurrence-free survival rates for 282 patients with stage I endometrial cancer were significantly reduced when the depth of myometrial invasion exceeded two-thirds of the total thickness of the myometrium (P < .001). (Reproduced with permission from Mariani A, Webb MJ, Keeney GL, et al. Surgical stage I endometrial cancer: predictors of distant failure and death, *Gynecol Oncol* 2002 Dec;87(3):274-280.)**

Table 40–5 Association of Lymph Node Metastasis with Other Prognostic Factors in Endometrial Carcinoma

Risk Factors	Percentage of Patients with Positive Pelvic Nodes	Percentage of Patients with Positive Para-aortic Nodes
Histology		
Endometrioid carcinoma	9	5
Others	9	18
Tumor grade		
Grade 1	3	2
Grade 2	9	5
Grade 3	18	11
Depth of myometrial invasion		
None	1	1
Superficial	5	3
Middle	6	1
Deep	25	17
Tumor site		
Fundus	8	4
Isthmus or cervix	16	14
Lymphovascular space invasion		
Absent	7	9
Present	27	19
Peritoneal cytologic findings		
Negative	7	4
Positive	25	19
Extrauterine metastasis		
Absent	7	4
Present	51	23

In particular, USC demonstrates a high rate of positive washings. Even in clinical stage I disease that is confined to the uterus, cytologic findings have been positive in as many as 16% to 17% of cases.[23] However, in at least two studies, the 5-year survival rates for patients with cytologically positive disease but no other risk factors have been higher than 90% (Fig. 40–5).[23]

In conclusion, these prognostic factors correlate with clinical course of disease, recurrence, and risk of death. However, the relative importance of each factor is not always clear because of interrelations and interdependence among them. Results of a multivariate analysis by Zaino and colleagues of factors affecting survival in stages I and II endometrial cancer are summarized in Table 40–6.[24]

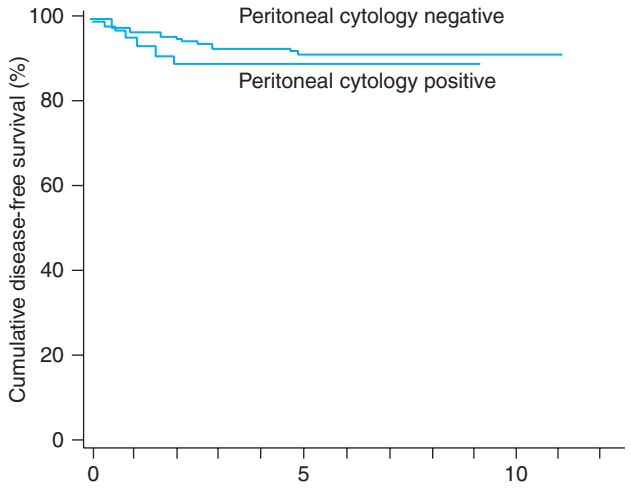

FIGURE 40–5 Five-year survival rates for patients with endometrial cancer confined to the uterus with positive findings on peritoneal cytology (91%) were not different from those with cytonegative findings (95%) (*n* = 280). (Reproduced with permission from Kasamatsu T, Onda T, Katsumata N, et al. Prognostic significance of positive peritoneal cytology in endometrial carcinoma confined to the uterus, *Br J Cancer* 2003 Jan 27;88(2):245-250.)

Evaluation

When evaluating a patient diagnosed with endometrial cancer, in addition to a history and physical examination, chest radiography should be performed, and imaging of the abdomen and pelvis may be considered based on other histologic factors. The measurement of cancer antigen 125 (CA 125) may occasionally be useful (Fig. 40–6).

At MDACC, for patients with disease confined to the uterus, we recommend primary surgery with total hysterectomy and bilateral salpingo-oophorectomy, except in cases with significant medical comorbidities or in patients desiring future fertility (see Fig. 40–6). Lymph node evaluation can be performed using sentinel lymph node mapping techniques or full pelvic and para-aortic lymphadenectomy based on intraoperative evaluation of grade and depth of invasion. Patients with gross cervical involvement may either undergo radical hysterectomy, bilateral salpingo-oophorectomy, with full staging, including pelvic and para-aortic lymph node sampling, or they may undergo primary radiation therapy (see Fig. 40–6). For disease that is not confined to the uterus, surgical debulking is considered (see Fig. 40–6).

Surgery

The standard staging procedure for endometrial cancer includes total hysterectomy, bilateral salpingo-oophorectomy, and assessment of the lymph nodes. In the past, full pelvic and para-aortic lymphadenectomy were performed for all women with presumed stage 1 disease. This was, in part, because of findings of improved survival in several retrospective studies. However, two large randomized, controlled trials of lymphadenectomy in endometrial cancer did not reveal a survival benefit for this surgical procedure. Although no survival benefit was demonstrated, nodal status can inform stage and prognosis, and may direct adjuvant therapy. Thus, indications for performing lymphadenectomy for staging remain controversial.

In the interest of obtaining information on nodal status, while reducing complications and operating room time, sentinel lymph node mapping has been explored as an alternative to full lymphadenectomy in clinical stage I endometrial cancer. Several studies have been reported indicating that this practice has a low false-negative rate when compared with full pelvic and para-aortic lymphadenectomy, in both low-risk and high-risk tumors.[25,26]

In the absence of sentinel lymph node mapping, some surgeons continue to practice routine pelvic or pelvic and para-aortic lymphadenectomy for all patients with endometrial cancer, whereas others perform these procedures only for patients with an increased risk of lymph node metastases based on preoperative and intraoperative assessments. There is a low rate of lymph node metastases in patients with early disease, specifically those with low-grade endometrioid adenocarcinoma with less than 50% invasion of the myometrium. The absence of LVSI and a tumor size of 2 cm or less in diameter also add reassurance that the lymph nodes are not involved.[27] Based on this, intraoperative gross inspection and frozen section of the uterus may be performed to evaluate the extent of uterine disease (see Fig. 40–6) and guide the decision of whether a lymph node dissection will be performed. The preoperative histologic findings and intraoperative pathologic findings that correlate with an increased risk of nodal involvement include grade 3 endometrioid histology; other aggressive histologies, including clear cell, serous or squamous carcinoma; tumor invasion of more than half of the myometrium; tumor size greater than 2 cm; and the presence of extrauterine disease. When these findings are present, there may be a benefit for surgical resection of the pelvic and para-aortic lymph nodes.[22]

Minimally Invasive Approaches

In two reports by the Gynecologic Oncology Group (GOG), laparoscopic surgical methods were compared with conventional laparotomy. The GOG LAP-2 study is the largest randomized trial ever performed in endometrial cancer. In this phase 3 prospective, multi-institutional, randomized study, 2616 patients

Table 40–6 Associations Between Pathologic Prognostic Factors and Relative Risk and Survival Rates

Prognostic Factors	5-Year Survival Rate (%)	Relative Risk of Surgical Stage I–II Tumors[a]

with stage I–IIA uterine cancer were assigned to laparoscopy ($n = 1696$) or laparotomy ($n = 920$). Study end points were morbidity and mortality at 6 weeks, length of hospitalization, failure to complete laparoscopy, site of recurrence, and recurrence-free survival. Consistent with previous studies, laparoscopy required longer operative time but led to fewer postoperative adverse events and shorter hospitalization. The rate of intraoperative complications was similar. One unexpected outcome was that as many as 26% of patients in the laparoscopy arm were converted to laparotomy. Laparoscopic failure was associated with increasing age and BMI.[28]

In a companion report, patients undergoing surgical staging via laparoscopy versus laparotomy were assessed with quality-of-life (QOL) measures. The study's objective was to compare the QOL of patients with endometrial cancer undergoing surgical staging via laparoscopy versus laparotomy. Although patients in the laparoscopy arm had overall better QOL measures at 6 weeks post-surgery, except for better body image in the laparoscopy arm, no difference was detected between the two arms at 6 months.[29]

Robot-assisted surgery, an alternative minimally invasive technique, was evaluated in a systematic review including 36 studies, encompassing 8075 patients undergoing surgery for endometrial cancer. When robot-assisted surgery was compared with laparotomy, it was associated with lower estimated blood loss at time of surgery, lower rates of postoperative complications, and lower rates of conversion to laparotomy. There was no difference in duration of surgery; however, there was a significantly shorter mean length of stay after robot-assisted surgery compared

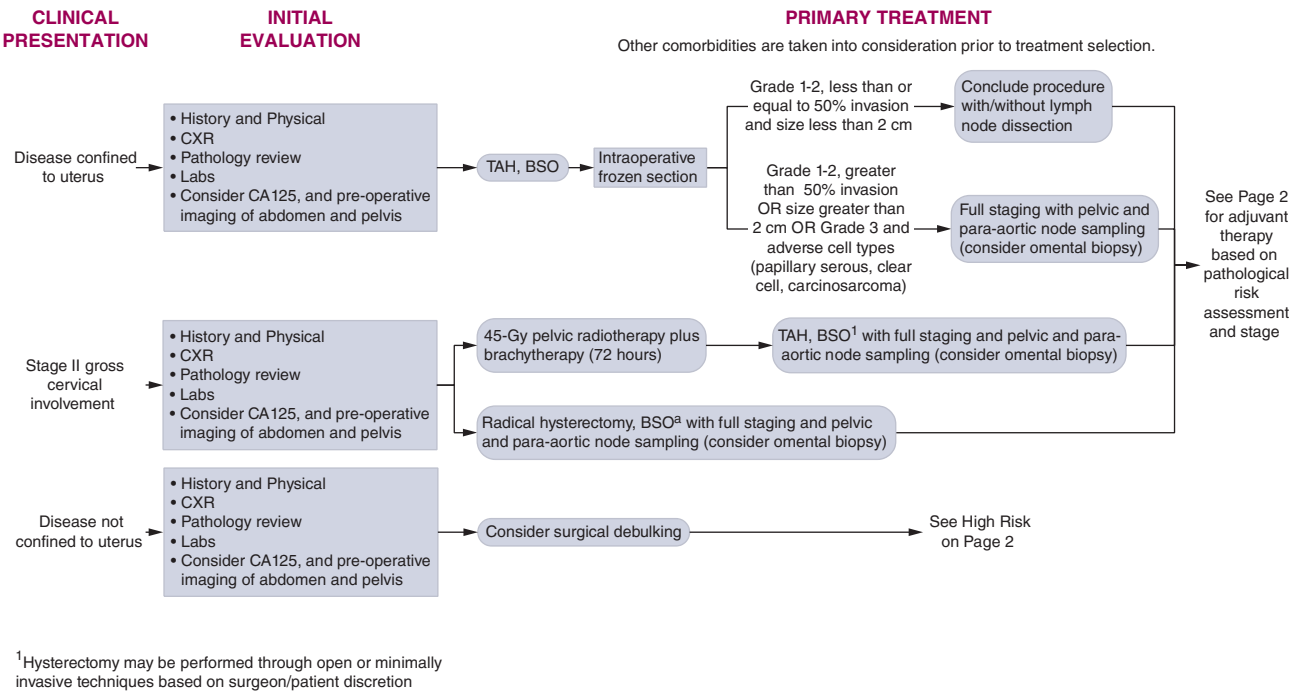

FIGURE 40–6 **MDACC schema for initial evaluation and treatment of patients with endometrial cancer. TAH, total abdominal hysterectomy; BSO, bilateral salpingo-oophorectomy.**

with laparotomy. Cost was noted to be higher with the robotic approach.[30]

The decision to perform open or minimally invasive surgery depends on patient preference, the skill and experience of the surgeon, the availability of the equipment, the size of the uterus, the parity of the patient, and the patient's medical condition. At MDACC, minimally invasive approaches, both laparoscopic and robotic, are the standard of care for the majority of women with endometrial cancer.

Adjuvant Therapy

To determine who is likely to benefit from adjuvant therapy, we stratify patients according to features of the disease and various prognostic factors. Women with grade 1 or 2 endometrioid tumors with no myometrial invasion or LVSI are considered to have *low-risk* disease. Low-risk disease is associated with an excellent prognosis, with 5-year survival approaching 90% and a low risk for recurrence after surgery. Therefore, in general, we do not recommend adjuvant therapy for this group of patients (see Fig. 40–7). Women with stage III–IV disease, regardless of histology or grade, and women with serous carcinoma or clear cell carcinoma at any stage are considered to have *high-risk* disease and typically undergo adjuvant therapy. *Intermediate-risk* disease, therefore, includes women with grade 1–2 endometrioid endometrial cancer confined to the uterus that invades the myometrium or the cervix. The intermediate-risk group can be further stratified based on the presence of specific prognostic factors, including deep myometrial invasion, grade 2 or 3 disease, and the presence of LVSI. Women are considered to have *high-intermediate-risk* disease if they are (1) any age with all three factors, (2) age 50 to 69 with two factors, and (3) age 70 or more years old with one factor. They are otherwise considered to have *low-intermediate-risk* disease.

Low-Risk Disease

As mentioned, most patients with low-risk disease are unlikely to benefit from adjuvant therapy. Therefore, it is not generally recommended for this group.

Intermediate-Risk Disease

As of this writing, there is no evidence that adjuvant therapy improves OS for women with intermediate-risk disease. For women with low-intermediate-risk disease, observation is favored. For women with high-intermediate-risk disease, vaginal cuff brachytherapy is favored.

Women with low-intermediate-risk disease have a good overall prognosis, and there is little benefit to be gained from radiation therapy (Fig. 40–8). In GOG-99, women with early-stage uterine cancer who underwent surgical staging were randomly assigned to undergo adjuvant radiation therapy versus observation. In the

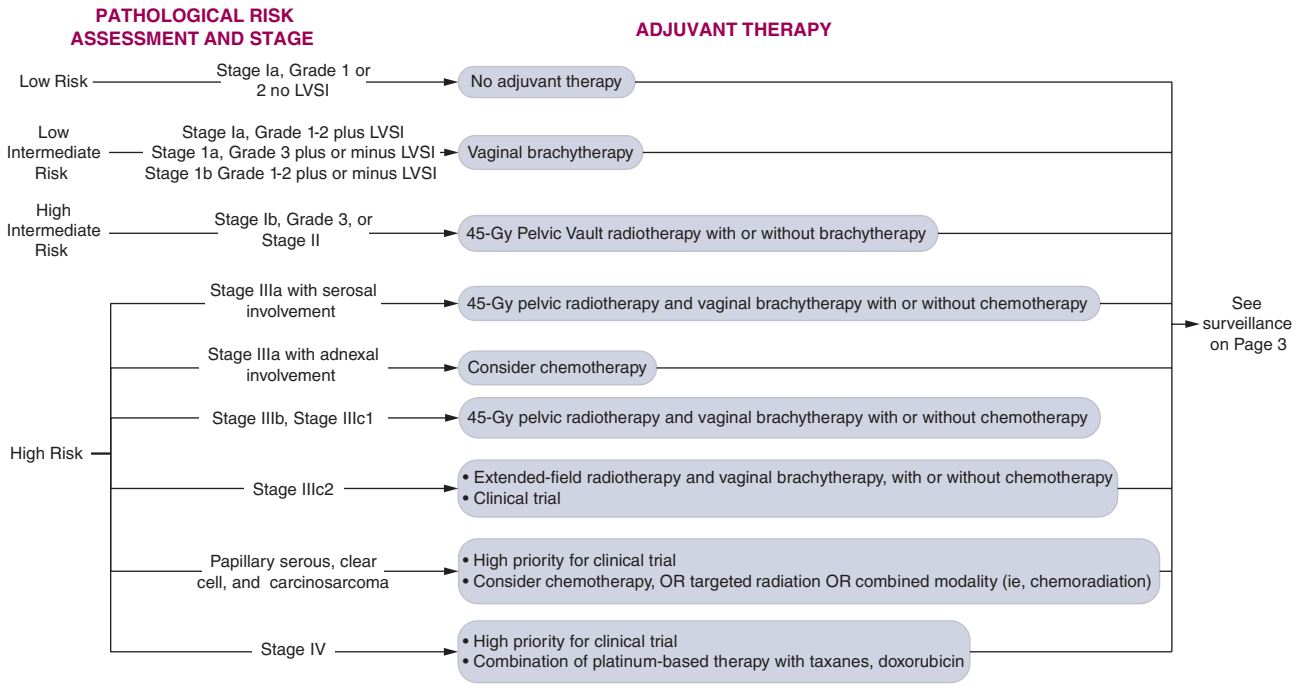

FIGURE 40–7 **MDACC algorithm for adjuvant therapy in endometrial cancer based on postoperative pathologic risk assessment and stage. LVSI, lymphovascular space invasion.**

subgroup analysis of patients who met criteria for low-intermediate-risk disease, those who underwent adjuvant radiation had a lower incidence of recurrence than women who underwent observation, but this was not statistically significant (hazard ratio [HR] 0.46, 95% CI 0.19–1.11). There was no difference in the rate of distant recurrence.[31]

For high-intermediate-risk patients, adjuvant radiation therapy reduces the incidence of pelvic recurrence but does not prolong OS.[32] In GOG 99, women with high-intermediate-risk disease who underwent adjuvant radiation had a reduction in risk of local recurrence compared with those who underwent surveillance (2-year cumulative incidence rate 6% vs 26% in radiation vs no radiation arms; relative HR 0.42). In fact, it was this study that defined the high-intermediate-risk subgroup described previously. The authors concluded that adjunctive radiation in early-stage intermediate-risk endometrial carcinoma decreases the risk of recurrence but should be limited to patients whose risk factors fit a high-intermediate-risk definition. Similarly, the PORTEC-1 (Post-Operative Radiation Therapy in Endometrial Carcinoma) study randomly assigned 714 women with intermediate-risk endometrial cancer after surgical staging to either external beam radiotherapy (46 Gy) or no adjuvant treatment.[32] At 5 years, local recurrence was significantly lower for patients in the experimental arm (4%) versus the control arm (14%).[32] At 10-year follow-up, the local recurrence rates were similar: 5% in the radiotherapy arm versus 14% in the control arm.[33] There was no significant difference in distant recurrence rates at either 5 or 10 years and no OS benefit seen at either time point.

We prefer vaginal cuff brachytherapy alone for most patients with high-intermediate-risk disease because outcomes are equivalent to pelvic radiation. This is based on results from PORTEC-2, which randomly assigned 427 women with high-intermediate-risk disease to vaginal brachytherapy or pelvic radiation. At 45 months, there were no statistically significant differences between the two treatment modalities in terms of locoregional recurrence, distant metastases, or 5-year disease-free survival. Vaginal brachytherapy was associated with a significantly lower rate of side effects, including treatment-related diarrhea and other bowel symptoms.[34,35]

High-Risk Disease

Women with high-risk disease have either serous or clear cell adenocarcinoma (any stage) or have pathologic stage III disease with extrauterine involvement. Treatment may involve radiation, chemotherapy, or a combination of the two modalities, based on histology, stage, and other factors (see Fig. 40–7). A meta-analysis evaluated the use of chemotherapy alone versus radiation alone versus chemoradiation in women with stage III or IV endometrial cancer. Compared with radiation, the use of a combination

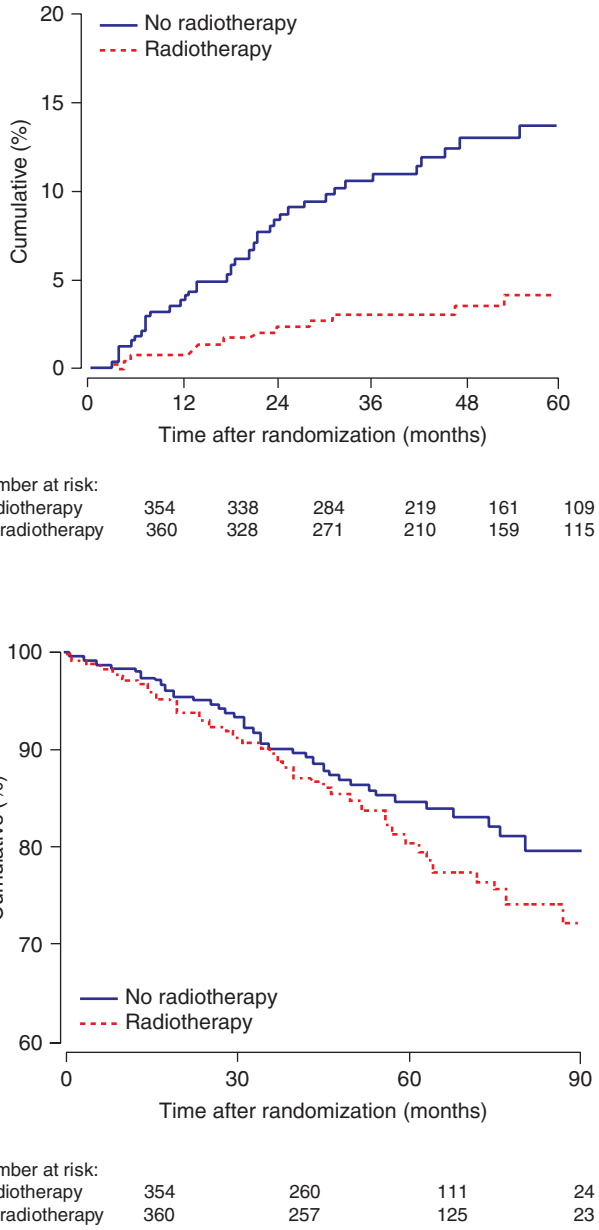

FIGURE 40–8 Pelvic radiotherapy in stage I endometrial cancer. The PORTEC Study Group multicenter randomized trial of 715 patients with stage I endometrial cancer of any type (excluding grade 3 tumors or those with >50% myometrial invasion) showed that pelvic radiotherapy reduced locoregional relapse rates (4% vs 14%, *top panel*) but did not affect 5-year overall survival rates (81% radiotherapy vs 85% observation, *bottom panel*). (Reproduced with permission from Creutzberg CL, van Putten WL, Koper PC, et al. Surgery and postoperative radiotherapy versus surgery alone for patients with stage-1 endometrial carcinoma: multicentre randomized trial. PORTEC Study Group. Post Operative Radiation Therapy in Endometrial Carcinoma, *Lancet* 2000 Apr 22;355(9213):1404-1411.)

platinum-based chemotherapy regimen resulted in a statistically significant improvement in OS (HR 0.75, 95% CI 0.57–0.99) and progression-free survival (PFS) (HR 0.74, 95% CI 0.59–0.92).[36] Two randomized controlled trials recently addressed the role of chemotherapy and radiation for the treatment of high-risk endometrial cancer. GOG258 assessed whether treatment with chemoradiation followed by four cycles of chemotherapy reduced the rate of recurrence or death compared with chemotherapy for six cycles in women with stage III/IVA or stage I/II serous or clear cell cancers.[37] PORTEC3 explored the impact of chemoradiation followed by chemotherapy to radiation therapy alone on OS and failure-free survival in a similar high-risk population (stage I grade 3 with deep myometrial invasion and/or LVSI); stage II/III; or serous/clear cell histology.[38] In GOG258, chemoradiation therapy reduced the rate of local recurrence (vaginal, nodal) compared with chemotherapy alone, whereas distant recurrences were more common in the chemoradiation arm. The addition of radiation to chemotherapy did not significantly improve recurrence-free survival compared with chemotherapy alone (HR 0.9, 95% CI 0.74–1.10).[37] Conversely, PORTEC3 demonstrated improved 5-year failure-free survival in patients treated with chemoradiation therapy compared with radiation alone (75.5% vs 68.9%, HR 0.71, 95% CI 0.53–0.95). However, OS was not significantly improved in the chemoradiation group (HR 0.79, 95% CI 0.57–1.12). Interestingly, among patients with stage III disease, 5-year failure-free survival, HR, and OS were significantly improved in the women treated with chemoradiation.[38] For patients with nodal disease, at MDACC, we typically treat with chemoradiation followed by chemotherapy with four cycles of carboplatin and paclitaxel. The MDACC algorithm further delineates our practice pattern for these patients (see Fig. 40–7).

Recurrent or Metastatic Disease

Women with disease outside the pelvis, either at their initial diagnosis or at the time of recurrence, are considered to have metastatic endometrial cancer. In general, these patients carry a poor prognosis and may benefit from systemic chemotherapy.

The GOG 209 study compared carboplatin plus paclitaxel with the combination of paclitaxel, doxorubicin, and cisplatin (TAP) in 1300 women with chemotherapy-naïve stage III, IV, or recurrent metastatic endometrial cancer. Both regimens were administered every 3 weeks for a total of seven cycles. The data are not yet mature; however, initial findings were presented at the 2012 Society of Gynecologic Oncology Annual Meeting. Compared with TAP, carboplatin plus paclitaxel had a similar overall response rate (RR) (51% in each arm), similar PFS (median of 13 months in

each arm), and similar OS (37 months for carboplatin and paclitaxel vs 40 months for TAP). Importantly, the toxicity in the carboplatin-and-paclitaxel arm was significantly lower than in the TAP arm. Peripheral neurotoxicity was 19% in the carboplatin/paclitaxel arm compared with 26% in patients assigned to receive TAP. Based on this study, carboplatin plus paclitaxel is preferred.[39]

In general, response to second-line chemotherapy in advanced and metastatic disease is low.[40] Thus, research regarding the use of immunotherapy and targeted therapies in this setting has been extensive. Mismatch repair deficiency (MMRd) is found in approximately 30% of all endometrial cancer, representing a key therapeutic opportunity in endometrial cancer.[41] A study of the programmed death-1 inhibitor, pembrolizumab, in MMRd solid tumors (including endometrial cancer) demonstrated impressive activity (RR 53%), which yielded a tissue-agnostic FDA approval.[42] Further study of this agent, in addition to other checkpoint inhibitors such as avelumab, durvalumab, and dostarlimab, have confirmed the activity of these agents in MMRd endometrial cancer.[43–46] Activity of single-agent immunotherapy in microsatellite stable (MSS) tumors has been limited with the exception of dostarlimab, which demonstrated a RR of 21% in this subtype.[44] In 2019, the combination of pembrolizumab with the tyrosine kinase inhibitor, lenvatinib, was granted accelerated approval by the FDA based on a 38% RR in MSS endometrial cancer.[47,48]

Multiple other relevant targeted agents have been explored in endometrial cancer. Single-agent bevacizumab demonstrated clinical activity and was well tolerated in GOG 229E.[49] However, the combination of bevacizumab with cytotoxic chemotherapeutic regimens did not offer survival benefit in two randomized phase 2 studies in advanced and recurrent endometrial cancer.[50,51] Because of the large number of aberrations in the PI3K pathway in endometrial cancer, the use of agents to target this pathway have also been under investigation. A phase 2 trial of the mTOR (mechanistic target of rapamycin) inhibitor everolimus plus letrozole demonstrated a high clinical benefit rate and RR,[52] which led to a subsequent trial comparing everolimus and letrozole with the hormonal regimen of alternating medroxyprogesterone acetate and tamoxifen. Everolimus and letrozole yielded similar RR; however, PFS was improved when compared with the hormonal regimen.[53]

Endocrine Therapy

Progestins have been used to treat advanced endometrial cancer for more than 50 years. These medications tend to be well tolerated with relatively minor side effects, including weight gain, thrombophlebitis, headache, and occasional hypertension. RRs tend to be modest, ranging from 11% to 24%.[54,55] In GOG 121, women with no previous chemotherapy or hormonal treatment were given megestrol acetate (800 mg/d). The overall RR was 24%, with PFS of 2.5 months and OS of 7.6 months.[54] Unlike in breast cancer, there does not appear to be a dose-response effect for progestins in endometrial cancer. In a randomized trial of oral medroxyprogesterone acetate (GOG 81), women who received a low-dose regimen (200 mg/d) actually had a higher RR compared with women who received the high-dose regimen (1000 mg/d).[55]

Certain characteristics improve the likelihood that a patient will have a favorable response to hormone therapy. These include having a low tumor grade (1 or 2), endometrioid histology, the presence of estrogen and progesterone receptors, having a longer disease-free interval, and being asymptomatic or minimally symptomatic.

Tamoxifen has been shown to have some efficacy in this population, with improved rates among women with hormone receptor–positive disease. Interestingly, it has been shown that short-term use of tamoxifen may lead to an increase in progesterone receptors. In GOG 153, women were given a regimen of tamoxifen for 3 weeks, alternating with megestrol acetate for 3 weeks. The overall RR was 27%, with a median PFS of 2.7 months and OS of 14 months.[56] Letrozole and anastrozole are both aromatase inhibitors that have been evaluated in advanced or recurrent endometrial cancer in phase 2 trials. Both agents have shown a RR of less than 10%.[57,58]

Surgery for Relapsed Disease

At MDACC, we evaluate all patients who have experienced an isolated central pelvic recurrence after radiotherapy for radical pelvic surgery or pelvic exenteration; these procedures remain the only potentially curative options that offer the possibility of long-term survival. However, given the high incidence of major postoperative complications, such as urinary/intestinal tract fistulas, pelvic abscesses, septicemia, pulmonary emboli, and cerebrovascular accidents, we consider only selected patients with isolated central recurrences for this treatment.

Postoperative Surveillance

There are no prospective studies to guide frequency of postoperative follow-up. At MDACC, for patients with stage IA, grade 1–2 disease, we schedule office visits every 6 months for the first year and annually during years 2 to 5. For all other patients in surveillance, we schedule office visits every 3 months for year 1, every 4 months for year 2, and every 6 months for years 3 to 5 (Fig. 40–9). At each visit, patients undergo a physical

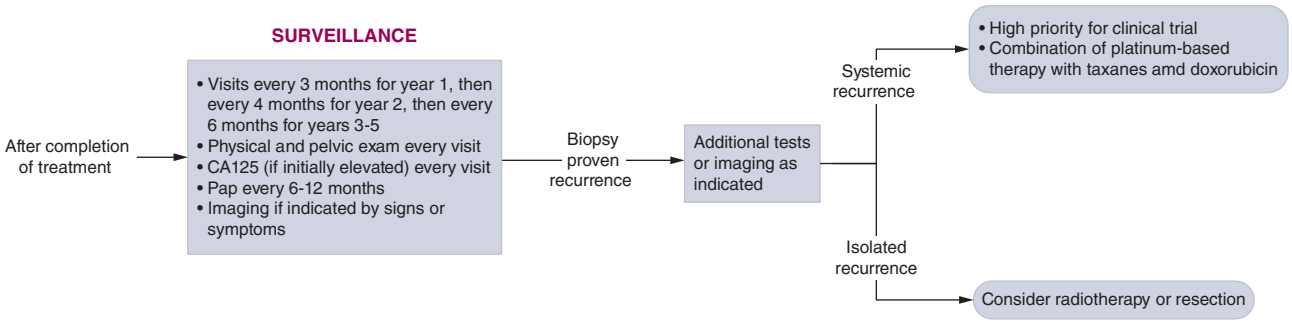

FIGURE 40–9 **Sample surveillance protocol for patients with intermediate- and high-risk disease.**

and pelvic examination. Performing routine vaginal cytology in endometrial cancer survivors is not recommended by the Society of Gynecologic Oncology. This is because multiple studies have suggested that Papanicolaou tests are not as effective in detecting endometrial cancer recurrences compared with physical examination alone[59,60] and are costly and inefficient.[61] In one of these studies, abnormal vaginal cytology had a sensitivity of 40% and specificity of 88% for detecting a vaginal recurrence. The positive predictive value was 7.3% and negative predictive value was 98.4%.[60]

Serum CA 125 level measurements may be helpful for certain patients. In patients with elevated serum CA 125 levels at diagnosis, they can be used as a marker for recurrent disease. In one study, among patients with advanced endometrial cancer who initially had high CA 125 levels, 26% to 58% showed elevated CA 125 at recurrence.[62] The use of serial CA 125 assays is most beneficial in diagnosing recurrence in a high-risk population, although there have been no studies to show that their use improves survival. False elevations may occur after radiation therapy.

Hormone Replacement Therapy After Treatment

The use of estrogen replacement therapy in premenopausal women who have been treated for endometrial cancer is controversial. For young women experiencing vasomotor symptoms, nonhormonal treatment options are considered safe and include selective serotonin reuptake inhibitors, gabapentin, and clonidine. There is also evidence that interventions such as yoga, acupuncture, and cognitive behavioral therapy may be helpful.

For women with low-risk disease who have undergone oophorectomy at the time of surgical staging, estrogen replacement therapy may be considered. In GOG 137, a double-blind, randomized, phase 3 trial, 1236 women with a history of stage I or occult stage II endometrial cancer were enrolled. All enrolled patients had an indication for treatment with estrogen replacement therapy, including hot flashes, vaginal atrophy, increased risk of cardiovascular disease, or an increased risk of osteoporosis, and were randomly assigned to receive estrogen replacement or placebo for 3 years after surgery. This study closed early when the results of the Women's Health Initiative study showed increased overall risks in the estrogen and progestin arm.[63] Based on the results of the Women's Health Initiative study, GOG 137 closed prematurely, and the study was left with insufficient power to detect a difference in patients with intermediate- or high-risk early endometrial cancers. The results of this study are inconclusive. However, the authors noted that in the low-risk population, the absolute recurrence rate was low (2.1%). The relative risk of recurrence/death in the estrogen replacement therapy group was 1.27 compared with the placebo group (80% CI 0.916–1.77).

At MDACC, we approach the use of estrogen replacement therapy on an individual basis. Overall risk of disease recurrence in low-risk patients is low, even in the setting of exogenous estrogen replacement. Therefore, estrogen replacement therapy may be considered for this population on a case-by-case basis. If adjuvant therapy is given after surgery, we recommend a 6- to 12-month waiting period before initiation of hormone replacement therapy.

Carcinosarcomas

Uterine carcinosarcomas account for less than 5% of malignant neoplasms of the uterus.[64] Histologically, they are comprised of both malignant epithelial and mesenchymal elements. These tend to be aggressive tumors and carry a poor overall prognosis. Even when diagnosed at an early stage, 5-year survival rates are dismal, with reports as low as 30% (Fig 40–10).[65]

Epidemiologically, carcinosarcomas usually appear in women aged 60 or older.[64,66] Risk factors are similar to endometrial carcinomas and include obesity, nulliparity, use of exogenous estrogens in the absence of progestin, and tamoxifen. Black women have a twofold higher

incidence of uterine carcinosarcoma compared with non-Hispanic White women. A history of prior pelvic radiation also increases the risk of uterine carcinosarcoma.

Treatment

Surgery

Surgical management of carcinosarcoma, when feasible, includes total abdominal hysterectomy with bilateral salpingo-oophorectomy (BSO) and pelvic and para-aortic lymph node dissection.[67–70] Peritoneal cytology, omentectomy, and peritoneal biopsies are also recommended.[67,71–74] Approximately 20% to 60% of patients will have more advanced disease during surgical staging.[75–77] Among women with stage I–III uterine carcinosarcoma, 5-year OS, disease-free survival, and median survival are significantly improved for patients who undergo lymph node dissection compared with those who do not.[78] With regard to the role of cytoreductive surgery in carcinosarcoma, a series of 44 patients demonstrated increased OS in patients who had a complete cytoreductive surgery versus those that had residual disease (52.3 vs 8.6 months, respectively).[79] Complete cytoreductive surgery should be attempted, when possible, in patients with carcinosarcoma.

Adjuvant Therapy

For stage IA tumors, at MDACC we recommend adjuvant therapy with platinum-based chemotherapy and vaginal cuff brachytherapy (the preferred regimen listed in the National Comprehensive Cancer Network guidelines); however, the ideal treatment strategy remains unclear. A retrospective multi-institutional study of early-stage disease demonstrated improved PFS with adjuvant chemotherapy compared with observation

Because of the overall poor prognosis of these cancers, adjuvant chemotherapy with or without pelvic radiation and/or vaginal cuff brachytherapy is recommended. In early-stage disease, a multi-institutional retrospective cohort study demonstrated improved PFS among women who received chemotherapy compared with those who underwent radiation alone or observation. Unfortunately, there was no impact on OS.[80] Adjuvant radiation therapy decreases local recurrence but does not impact PFS or OS.[78] In advanced-stage disease, a meta-analysis showed improved OS (HR 0.75; 95% CI 0.60–0.94) and reduced disease progression (HR 0.72; 95% CI, 0.58–0.90) with combination chemotherapy versus single-agent ifosfamide.[81–83] More recently, the results of GOG 261 were presented in abstract form. This is a randomized, phase 3 trial comparing carboplatin and paclitaxel versus ifosfamide and paclitaxel among women with stage I–IV persistent or recurrent carcinosarcoma. Median OS was longer for women who underwent carboplatin and paclitaxel (37 vs 29 months) and this combination was found to be noninferior to ifosfamide and paclitaxel and represents the new standard regimen.

FIGURE 40–10 **Gross appearance of a fleshy hemorrhagic polypoid MMMT protruding into the endometrial cavity in a hemiuterus specimen. Such tumors, which typically present with vaginal bleeding, must be distinguished from submucous myoma. Several endometrial tissue biopsies are sometimes needed for diagnosis because of the necrotic and hemorrhagic nature of this tumor.**

NONEPITHELIAL UTERINE TUMORS

Uterine sarcoma is uncommon, accounting for only 3% to 9% of all tumors arising from the uterine corpus.[75,76,84] Most uterine sarcomas originate from mesodermal tissue, although some are derived from specialized Müllerian mesenchyme, such as endometrial stroma, and a few originate from nonspecific or non-Müllerian mesenchyme (eg, smooth or skeletal muscle, vessels, or lymphoid tissue). The three most common types of uterine sarcoma are leiomyosarcoma, ESS, and adenosarcomas. Overall, uterine sarcomas are aggressive tumors with a 5-year OS rate of 17.5% to 54.7%.[84]

Epidemiology

Leiomyosarcoma and ESS usually affect women in their early 50s. Adenosarcomas have been reported in women 14 to 84 years old; the median age at appearance is in the late 50s.[85–87] Although uterine sarcoma differs somewhat from endometrial cancer in its clinical and pathologic characteristics, some risk factors—such as hypertension, diabetes mellitus, and obesity—are common to both. Previous history of pelvic irradiation has been associated with carcinosarcomas and undifferentiated sarcomas, occurring in 2% to

29% of patients so exposed at an interval ranging from 1 to almost 40 years.[88,89] Prior exposure to pelvic radiation, however, is not felt to be associated with leiomyosarcomas.[89] Although the link between estrogen and endometrial cancer is well established, no such clear relationship is evident for estrogen and uterine sarcoma. An association between tamoxifen use and uterine sarcoma was confirmed in a study by Bergman et al, showing increased numbers of uterine sarcomas among women taking tamoxifen and sarcomas constituting about 10% of total malignancies in these cases.[90]

Leiomyosarcoma

Histology

Leiomyosarcomas represent only 1% to 2% of uterine malignancies; however, they are the most common among uterine sarcomas.[75,91,92] Gross features of leiomyosarcoma (Fig. 40-11) are typified by variegation at the cut surface (unlike the whorl-like surface typical of a benign leiomyoma).

Cells are spindle shaped and arranged in fascicles with eosinophilic cytoplasm. The nuclei are usually elongated with rounded ends, appearing hyperchromatic with coarse chromatin and prominent nucleoli. The most important criterion for the diagnosis of leiomyosarcoma is a high mitotic rate, generally exceeding 15 mitotic figures per 10 high-power fields. Other features, such as extrauterine extension, large size, infiltrating border, necrosis, and atypical mitotic figures can also aid in the diagnosis.[84]

Smooth Muscle Tumor of Uncertain Malignant Potential

Uterine smooth muscle tumors with histologic features of necrosis, nuclear atypia, or mitoses that do not meet all diagnostic criteria for leiomyosarcoma fall into the category of smooth muscle tumor of uncertain malignant potential (STUMP).[93] The STUMPs are a group of smooth muscle tumors for which a diagnosis of sarcoma cannot be made because of their uncertain malignant characteristics. Most of these tumors are associated with favorable prognosis, and only follow-up of the patients is recommended.[94] In a study conducted at MDACC of 41 cases of STUMP, the recurrence rate was 7%. One of the three recurrences was a leiomyosarcoma; the others were STUMPs.[95]

Clinical Presentation

Vaginal bleeding is the most common presenting symptom of uterine leiomyosarcomas. Other symptoms, such as back pain, urinary retention or hematuria, gastrointestinal symptoms, or weight loss may indicate an invading or metastasizing tumor.[96–98]

Diagnosis

The definitive diagnosis of leiomyosarcomas is usually made after myomectomy or hysterectomy performed for presumed benign leiomyomas, with the diagnosis based on histologic examination. Methods using pulsed Doppler ultrasonography to preoperatively distinguish between a benign leiomyoma and leiomyosarcoma are reported but not clinically useful.[99] Although useful for detecting extrauterine disease, imaging studies such as computed tomography and magnetic resonance imaging are not specific for diagnosing leiomyosarcomas.[100]

Prognosis and Clinical Course

Leiomyosarcomas are aggressive tumors with high recurrence rates of 50% to 70%, even when diagnosed at early stages.[76] The 5-year OS rate ranges from 15% to 25%, and the 5-year survival rate for patients with stages I and II disease is 40% to 70%.[101,102] Previous

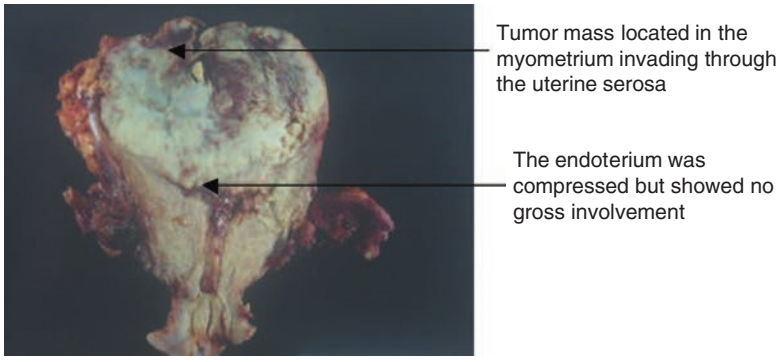

FIGURE 40–11 **Gross appearance of a leiomyosarcoma in the upper uterus. The cut surface shows a grayish-tan tumor with hemorrhage and necrosis, without the whorl-like appearance typical of benign leiomyoma. The mass clearly involves most of the myometrium but not the endometrium.**

studies have reported mitotic index, cellular atypia, vascular invasion, and tumor size to correlate with survival.

Treatment

Surgery

Surgery remains the mainstay of treatment for uterine leiomyosarcoma. For disease confined to the uterus, hysterectomy is recommended. Uterine morcellation should be avoided when there is a preoperative diagnosis of uterine sarcoma or an elevated suspicion for sarcoma. It is not clear if bilateral oophorectomy at the time of surgery affects outcomes in premenopausal women with leiomyosarcoma; therefore, the decision to remove bilateral ovaries should be made on an individual basis. The rate of adnexal masses is low (~3%),[77] and two large retrospective database studies demonstrated no difference in OS between women who underwent oophorectomy and those who did not.[103,104]

The need for lymph node dissection is also controversial. Leiomyosarcoma has a substantially lower risk of nodal involvement than clinical stage I or stage II endometrial cancer with other risk factors. A GOG study of early-stage sarcoma found that nodal metastases were present in only 3.5% of leiomyosarcoma cases, and the pelvic nodes were twice as likely to be involved as the para-aortic nodes.[96] However, the patients in this series underwent lymph node sampling rather than intended dissection, so the reported incidence may be falsely low. Goff et al found lymph node involvement in about 27% of leiomyosarcoma cases, but only in those cases that involved recurrent or disseminated intraperitoneal disease.[96] Two more recent studies identified lymph node metastases in 7% to 11% of patients who underwent lymph node dissection.[103,104] In the series by Kapp et al, the 5-year disease-specific survival rate was 26% in patients who had positive lymph nodes compared with 64% in those who had negative nodes.[104]

Adjuvant Therapy

For early-stage leiomyosarcomas, there has been no clear benefit shown for adjuvant chemotherapy.[105–107] In these patients, surveillance versus referral to a clinical trial are reasonable treatment options. Advanced-stage leiomyosarcomas, on the other hand, have a high risk of recurrence, and individuals so affected are typically offered adjuvant therapy. We work closely with our sarcoma medical oncology colleagues for treatment recommendations. Combination chemotherapy improves RRs over single-agent therapy; however, the impact on PFS and OS has been limited. Various combinations have been investigated, with RRs ranging from 18% to 53%.[106,108–111] The two most common combination regimens used at MDACC are doxorubicin plus ifosfamide or gemcitabine plus docetaxel. Of note, the combination of olaratumab, a platelet-derived growth factor receptor inhibitor, and doxorubicin demonstrated OS benefit in initial investigations compared with doxorubicin alone; however, this was not confirmed in the subsequent confirmatory phase 3 randomized trial.[112,113] Examples of these combination chemotherapies are shown in Table 40–7. Unfortunately, it is not uncommon for these patients to have disease progression after primary chemotherapy. Among single-agent options, the chemotherapy agent trabectedin and the small-molecule inhibitor, pazopanib, are FDA approved for metastatic soft-tissue sarcomas based on favorable impact on PFS.[114,115]

Endometrial Stromal Sarcoma

Histology

Endometrial stromal sarcoma accounts for about 23% of all uterine sarcomas.[64,65] The ESSs originate from endometrial stromal cells that invade the myometrium. Low- and high-grade variants differ in their clinical behavior. Gross features of a low-grade ESS presenting as multiple, small, lobulated tumor masses in the myometrium are shown in Fig. 40–12A.

In fresh specimens, tumor invading the lymphovascular spaces can sometimes be compressed out of the vascular lumen, giving a vermiform appearance. Tumor cells resemble endometrial stromal cells during the proliferative phase of the menstrual cycle and

Table 40–7 Drug Combinations Used to Treat Leiomyosarcomas

Type of Tumor	Drug Regimen	First Author and Year of Study (Reference)	No. of Patients	Intent	Results
Leiomyosarcoma	Dox vs dox + dacarbazine	Omura, 1983[111]	48	Pall	ORR 25% vs 30%
	Dox + ifosfamide	Sutton, 1996[113]	33	Pall	ORR 30.3%
	Eto + hydroxyurea + dacarbazine	Currie, 1996[112]	39	Pall	ORR 18.4%
	Mitomycin C + dox + cisplatin	Edmonson, 2002[114]	23	Pall	ORR 23%
	Gemcitabine + docetaxel	Hensley, 2009[109]	25	Adj	2-year PFS 45%

Adj, adjuvant; dox, doxorubicin; eto, etoposide; ORR, overall response rate; Pall, palliative; PFS, progression-free survival.

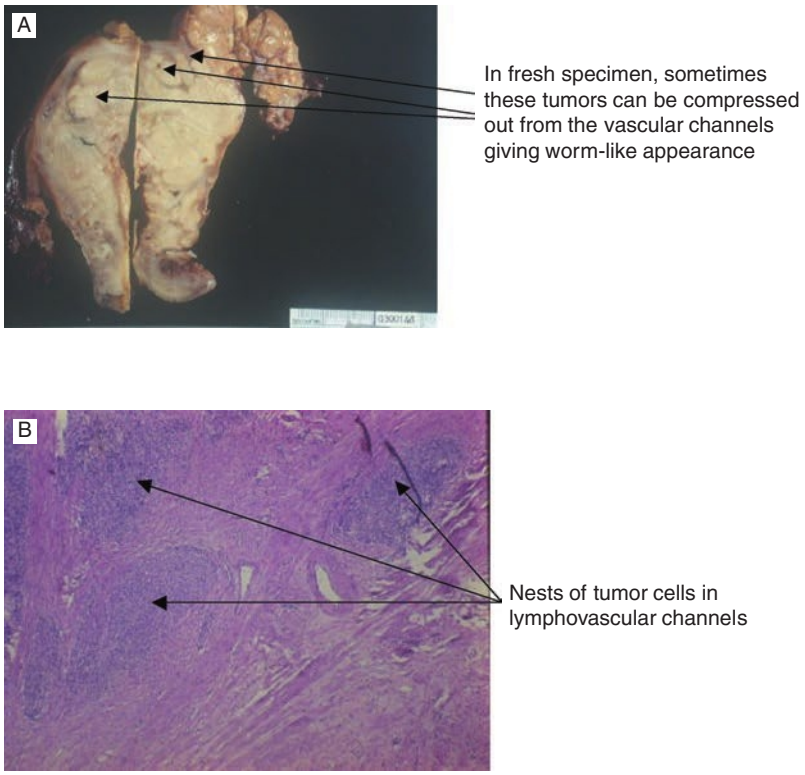

FIGURE 40–12 **A. Gross appearance of an endometrial stromal sarcoma infiltrating most of the myometrium. The lobulated appearance corresponds with the presence of tumor in the lymphovascular spaces, as verified on microscopy in panel B. B. Endometrial stromal sarcoma cells with invasion of the intralymphatic spaces.**

are monotonous and of uniform shape and size.[95] The presence of spiral arteriole-like vessels is a characteristic finding of ESS, as is the propensity of the tumor cells to invade the lymphovascular spaces (Fig. 40-12B).

ESS tumors contain both estrogen and progesterone receptors.[84] In addition, these tumors are generally positive for CD10 and frequently have a t(1;17) chromosomal translocation that expresses a fusion protein composed of JAZF1 and JJAZ1.[84]

Clinical Presentation

Like leiomyosarcomas, vaginal bleeding is the most common presenting symptom. Another common presenting symptom in ESS and adenosarcoma is the appearance of a prolapsed polypoid mass through the cervical os.[96–98]

Prognosis and Clinical Course

Low-grade ESSs are indolent tumors.[116] Generally, patients with ESS have favorable prognoses; however, recurrence can appear late after primary diagnosis and treatment, even in stage I disease.[117,118] The FIGO stage, depth of myometrial invasion, tumor grade, positive margins, and patient characteristics such as age, race, and menopausal status have been reported to be prognostic factors.[64,119–121] Mitotic activity and cytologic atypia were found to be important by some[64,101,122] but not by others.[117,123] Extrauterine and nodal disease is prevalent in ESS.

Treatment

Surgery

Initial treatment for ESS is largely surgical, and hysterectomy with BSO is recommended. ESS is often sensitive to hormones, and patients with intact ovaries may be at a higher risk for recurrence.[124–127] However, there is no consensus on the absolute need for oophorectomy in early-stage ESS. In a study by Li et al, BSO did not appear to affect time to recurrence or OS in patients with stage I ESS.[125] In a recent report of 384 women with low-grade ESS, lymph node metastasis and ovarian preservation were not significant prognostic factors for survival in this study. Lymph node metastasis was found in 7% of patients.[126] In two smaller series, only two of the nine patients with ESS who had undergone lymph node sampling were found to have lymph node metastases.[96,122] The choice of lymph node dissection for ESS should be made on an individual basis.

Adjuvant Therapy

Observation is generally recommended for stage I ESS. Patients with more advanced stages of ESS are typically offered additional therapy after surgical resection, although the data are limited given this rare tumor type. Because these tumors typically express estrogen and progesterone receptors, hormone therapy is considered first-line treatment. Limited retrospective data have reported response of metastatic and recurrent ESS to hormonal agents such as medroxyprogesterone acetate or letrozole.[118,122,124,128,129] A small retrospective study found longer recurrence-free survival and less toxicity among patients treated with aromatase inhibition compared with progestin therapy.[130] Tamoxifen is contraindicated in the treatment of ESS because of its stimulatory effect on the endometrial stromal cells.[128]

Because of its rarity and because low-grade ESS usually responds well to hormonal therapy, ESS has not been well studied in chemotherapeutic trials. A cisplatin-based chemotherapy regimen was tested in a study of uterine sarcoma in which about 10% of the cases were ESS.[131] Despite a relatively high RR of 54%, the regimen was too toxic to be clinically useful. Radiotherapy may help to improve local control, but its role as adjuvant therapy in ESS is unclear.[132]

Undifferentiated Endometrial Sarcoma

Histology

In undifferentiated endometrial sarcomas, previously considered high-grade ESS, the tumor cells tend to be larger, with more vesicular nuclei, coarse clumps of chromatin, and more prominent nucleoli.[133] Mitotic counts are usually low in low-grade ESS, and this is the principal criterion for distinguishing between the low- and high-grade forms.[133] However, numerous mitotic figures can be present in otherwise typical low-grade tumors, and high-grade tumors can have only a few mitotic figures.[117,134] Flow cytometry with DNA ploidy seems to be associated more with the behavior of the tumor than with mitotic count.[135] In the 2002 classification of ESS by the World Health Organization, high-grade tumors were considered as pleomorphic or undifferentiated sarcoma rather than as a type of ESS because of their distinctive and aggressive clinical behavior. Undifferentiated sarcomas generally stain for Ki67, p16, and p53 and not for estrogen and progesterone receptors. These tumors also do not have any known chromosomal abnormalities.[84]

Prognosis and Clinical Course

In contrast to individuals with low-grade ESS, those with undifferentiated sarcomas have poor OS regardless of stage. The median PFS in one series was 7.3 months, and OS was only 11.8 months.[136] Patients are also likely to have disease that progresses quickly despite an initial response to treatment.[136]

Treatment

Surgery

Undifferentiated endometrial sarcomas are treated with up-front surgical management, including hysterectomy and oophorectomy with or without lymphadenectomy. Because of the aggressive nature of this disease, these patients require adjuvant therapy.

Adjuvant Therapy

Unlike ESS, undifferentiated endometrial sarcomas are not responsive to hormone therapy. Adjuvant chemotherapy is similar to that for leiomyosarcoma, as discussed previously.

Adenosarcoma

Histology

Adenosarcomas have two tissue components: the mesenchymal tissue is malignant, and the epithelial part is benign. The epithelial component commonly resembles a proliferative or inactive endometrial gland, often appearing as cleftlike spaces dispersed throughout the proliferative stroma in a phyllode pattern. Slight atypia may be present.[86] The mesenchymal stromal component is usually homologous tissue, such as stromal sarcoma, fibrosarcoma, or leiomyosarcoma.[86,137] The pattern of stromal cell hypercellularity surrounding the glands is characteristic, and the stromal cells show variable atypia and mitosis.[85] Adenosarcomas with extensive stromal sarcoma proliferation are called *adenosarcoma with sarcoma overgrowth* if the sarcomatous component constitutes more than 25% of the tumor.[85,86] This subtype should be recognized because its prognosis is worse than that of a typical adenosarcoma and more similar to that of carcinosarcoma.[138]

Prognosis and Clinical Course

Adenosarcoma is considered a low-grade malignant tumor with an excellent prognosis.[85–87] Most cases are confined to the uterus at the time of diagnosis and require no adjuvant therapy. Distant metastases have been reported in 5% of cases, and the recurrence rate is approximately 23%, with about one-third of recurrences occurring more than 5 years after initial treatment.[85,86,139] Extrauterine spread at diagnosis, deep infiltrating tumors, sarcomatous overgrowth, LVSI, and tumor cell necrosis have all been associated with increased risk of recurrence but are rare.[85,101,121,140]

Treatment

Surgery

Management of adenosarcomas consists of hysterectomy, and as discussed previously, additional therapy is generally not required given the excellent prognosis.

Adjuvant Therapy

Only a few reports have described cases in which adenosarcoma was successfully treated with chemotherapeutic drugs such as liposomal doxorubicin.[87] Krivak and colleagues reported adjuvant chemotherapeutic treatment of nine patients with residual or recurrent adenosarcoma with sarcomatous overgrowth. The drugs used were cisplatin and ifosfamide; doxorubicin; and cisplatin and doxorubicin. The progression-free interval for four patients ranged from 7 to 22 months; all patients had died of recurrent or progressive disease by 39 months.[141] A study from MDACC including 100 patients with uterine adenosarcoma found no optimal treatment strategy for this disease; however, adjuvant therapy was associated with increased PFS.

MD ANDERSON PRACTICE TIPS

- Women with Lynch syndrome should undergo yearly screening with endometrial biopsy beginning at age 35 years. Prophylactic hysterectomy and salpingo-oophorectomy have been shown to be effective in decreasing the risk of endometrial and ovarian cancers and should be offered to women with Lynch syndrome after childbearing is complete.
- The surgical staging procedure for endometrial cancer includes total hysterectomy, bilateral salpingo-oophorectomy, and assessment of the lymph nodes. Sentinel lymph node mapping is standardly used at MDACC as an alternative to full lymphadenectomy in clinical stage I endometrial cancer. Several studies indicate that this practice has a low false-negative rate when compared with full pelvic and para-aortic lymphadenectomy, in both low-risk and high-risk tumors.
- At MDACC, minimally invasive approaches to surgical staging, both laparoscopic and robotic, are the standard of care for the majority of women with endometrial cancer.
- We approach the use of estrogen replacement therapy after treatment for endometrial cancer on an individual basis. Overall risk of disease recurrence in low-risk patients is low, even in the setting of exogenous estrogen replacement. Therefore, estrogen replacement therapy may be considered for this population on a case-by-case basis. If adjuvant therapy is given after surgery, we recommend a 6- to 12-month waiting period before initiation of hormone replacement therapy.
- At MDACC, we evaluate all patients who have experienced an isolated central pelvic recurrence after radiotherapy for radical pelvic surgery or pelvic exenteration; these procedures remain the only potentially curative options that offer the possibility of long-term survival. However, given the high incidence of major postoperative complications, such as urinary/intestinal tract fistulas, pelvic abscesses, septicemia, pulmonary emboli, and cerebrovascular accidents, we consider only selected patients with isolated central recurrences for this treatment.
- When selecting second-line therapy for metastatic/recurrent endometrial cancer, MSS testing can inform treatment decisions. Pembrolizumab has a RR of 53% for women with microsatellite instable tumors. The combination of pembrolizumab with lenvatinib has a RR of 38% among women with MSS tumors.

41 Tumors of the Uterine Cervix

Gloria Salvo
Mila P. Salcedo
Sol Basabe
Pedro T. Ramirez

KEY CONCEPTS

- Cancer of the cervix is the third most common gynecologic malignancy in the United States. The American Cancer Society estimated that there would be a total of 13,800 new cases of invasive cervical cancer and 4290 deaths in 2020.
- The nonavalent vaccine (Gardasil-9), which targets HPV-6, -11, -16, -18, -31, -33, -45, -52, and -58, is recommended to both boys and girls between the ages of 11 and 12 years old. A two-dose schedule with a 6- 12-month interval between doses is recommended if given before age 15 years. For people older than 15 years old or immunocompromised, three doses are required (0, 1–2, and 6 months).
- The 2018 revised International Federation of Gynecology and Obstetrics (FIGO) staging system main changes from the previous 2009 are the allowance of images and pathology, when available to allocate the stage. For stage IA only, depth of invasion (≤3 mm and >3 mm and ≤5 mm) is now considered to allocate a tumor as IA1 or IA2, respectively, because horizontal extent is no longer contemplated. Stage IB tumors are now divided according to their greatest dimension into IB1 (≤2 cm), IB2 (>2 cm and ≤4 cm), and IB3 (>4 cm). Nodal compromise is now considered part of the staging system. Positive pelvic nodes are now allocating as IIIC1 and positive paraaortic nodes are considered stage IIIC2.
- Radical hysterectomy with pelvic lymphadenectomy is the standard treatment for early-stage cervical cancer (FIGO 2018 IA2-IB2). After the results of a prospective randomized trial showing that minimally invasive surgery was associated with higher rates of locoregional recurrences (hazard ratio [HR], 4.26; 95% confidence interval [CI], 1.44-12.6; $P = .009$) and higher risk of death (HR: 6.00; 95% CI,1.77–20.3; $P = .004$], minimally invasive surgery is no longer recommended.
- First-line therapy recommended for recurrent of metastatic disease is cisplatin, paclitaxel, and bevacizumab. The Gynecologic Oncology Group 240 randomized trial showed that the addition of bevacizumab resulted in a significant improvement in overall survival compared with chemotherapy alone (median, 16.8 vs 13.3 months, respectively; HR, 0.77; 98% CI, 0.62–0.95).
- Pembrolizumab is the preferred regimen for second-line therapy in patients with recurrent or metastatic disease who are tumor programmed death-ligand 1 with an overall response rate as showed by the KEYNOTE-028 trial of 17% and duration of response was 5.4 months.

Cervical cancer is the third most common gynecologic malignancy in the United States. In 2020, the American Cancer Society estimated that there would be a total of 13,800 new cases of invasive cervical cancer and 4290 related deaths.[1] Persistent human papillomavirus (HPV) infection is the most important factor in the development of cervical cancer.[2] The incidence of this disease has decreased steadily over the past several decades because of screening tests and vaccination. Squamous cell carcinoma (SCC) and adenocarcinoma are the most common histologic subtypes.

The median age of diagnosis of cervical cancer is 50 years of age, and it is more frequently diagnosed among women age 35 to 44 years old. Cervical cancer is staged using the International Federation of Gynecology and Obstetrics (FIGO) staging system. Principal routes of spread include direct extension (uterine corpus, vagina, parametrium, bladder, or rectum), lymphatic, or hematogenous dissemination. Lymphatic metastasis is to the pelvic (obturator, external iliac, internal iliac, common iliac) or paraaortic lymph nodes (or both), and the most common sites of hematogenous spread are the lungs, liver,

and bones. In the United States, most cervical cancers are diagnosed in early stage (44%), followed by locally advanced (36%), and 15% at advanced disease[3] with 5-year survival rates of 92%, 56%, 17%, respectively.[3]

This chapter aims to describe pathogenesis of the disease, preinvasive lesions, diagnosis, and treatment in the upfront and recurrent settings.

ETIOLOGY

Risk factors associated with cervical cancer include HPV infection, immunosuppression, smoking, multiparity, increased number of sexual partners, and oral contraceptive use.[4]

Human Papillomavirus

HPV is the critical factor for the development of preinvasive and invasive cervical lesions. HPV is a small, nonenveloped, double-stranded DNA virus predominantly transmitted through sexual intercourse.[5,6]

More than 40 HPV genotypes infect the anogenital tract and other mucosal areas of the body.[7] The HPV types are further classified into low-risk or high-risk HPV depending on their oncogenic potential for cervical cancer and its precursors. Low-risk HPV genotypes include HPV-6 and -11 and usually cause benign anogenital warts.[8] Invasive lesions are much more commonly caused by high-risk HPV, including types 16, 18, 31, 45, 52, and 33.[9] Although the majority (~70%) of premalignant and invasive disease can be directly attributed to types 16 or 18, HPV DNA from any genotype is detectable in more than 99% of all cervical cancer specimens.[9,10]

In most cases, the transformed cells by the virus are managed by the individual's immune system, and the infection clears or preinvasive disease regresses. In some women, the transformed cells replicate, and if left untreated after several years, cervical cancer can develop. It is clear that women who have compromised immune systems (eg, genetic, iatrogenic, infectious, or any other cause) have a greater risk of developing a persistent HPV infection[11]; however, there is no way to predict which healthy women are unable to clear the virus spontaneously.

Other Risk Factors

Many studies have reported an increased risk of HPV infection and preinvasive and invasive cervical cancer in women who are immunocompromised, such as those with human immunodeficiency virus (HIV) infection.[12] It was found that rare high-risk HPV types are more common in cervical dysplasia of HIV-infected women, but most cases have multiple infections.[13]

Tobacco use is a well-established risk factor for cervical cancer. Cigarette smoking confers a 1.5- to 2.5-fold increase in cervix cancers. Overall, tobacco smoking is estimated to account for 21% of general cancer deaths worldwide.[14]

The number of sexual partners is an important risk factor for both preinvasive and invasive cervical cancer.[15] A collaborative study found a threefold increased relative risk of cervical cancer in women who have had six or more sexual partners, probably related to a higher risk of acquiring HPV infection.[16]

Many studies have produced controversial results on the effect of oral contraception on cervical cancer risk. The relative risk of cervical cancer is increased in current users of oral contraceptives, and it seems to decline after use ceases.[4,16]

HISTOPATHOLOGY

Squamous Cell Tumors and Precursors

Squamous Intraepithelial Lesions

Cervical SCCs are believed to develop from precursor or preinvasive lesions, which have been classified in a variety of ways but are generally based on how much of the epithelial layer contains atypical cells. The oldest system is the dysplasia–carcinoma in situ (CIS) system, with mild dysplasia, moderate dysplasia, and severe dysplasia or CIS. Another is the cervical intraepithelial neoplasia (CIN) classification, with mild dysplasia termed CIN1, moderate dysplasia termed CIN2, and CIN3 corresponding to both severe dysplasia and CIS. The Bethesda System for reporting cervical and vaginal cytologic abnormalities categorizes squamous abnormalities as follows: low-grade squamous intraepithelial lesion (LSIL), encompassing HPV infection and CIN1, and high-grade squamous intraepithelial lesion (HSIL), encompassing CIN2 and CIN3; and SCC.[17]

Invasive Cervical Cancer

Cervical cancer is classified mainly by its histologic origin, meaning from which type of cell is originated. The cervix has two different types of epithelium, the exo- and endocervix. Both epitheliums converge in what is called the transformation zone, the site where cervical cancer often develops. The principal types of cervical cancers are SCC (75%) and adenocarcinomas (25%). Other less frequent histology, such as neuroendocrine, adenoid cystic carcinoma, and carcinoid, account for 5% of all cervical cancers (Table 41–1). SCC develops from the cells of the exocervix and often begins in the transformation zone. On the other hand, adenocarcinomas develop from the glandular cells (mucus-producing cells) located in the endocervix. Less commonly, cervical cancers have features of both cell origins; these are called adenosquamous carcinomas.

TABLE 41–1 Histopathology

Classification	Subclassification
Squamous cell carcinoma	Large cell, keratinizing squamous cell carcinoma Large cell, nonkeratinizing squamous cell carcinoma Verrucous carcinoma Papillary squamous and transitional cell carcinoma Lymphoepithelioma-like carcinoma
Adenocarcinoma	Mucinous, endocervical variant Mucinous, intestinal type, signet ring variant Mucinous, adenoma malignum (minimal deviation variant) Mucinous, villoglandular adenocarcinoma (well differentiated) Endometrioid type Clear cell type Papillary serous type Mesonephric type
Adenosquamous carcinoma	
Adenoid cystic carcinoma	
Neuroendocrine	High-grade neuroendocrine (small and large cell) Low-grade neuroendocrine (carcinoid)
Undifferentiated carcinoma	
Mixed epithelial and mesenchymal tumors	

CERVICAL CANCER PREVENTION

Primary Prevention: Human Papillomavirus Vaccination

Three types of HPV preventive vaccines are currently commercially available worldwide. The bivalent vaccine (Cervarix) targets two types of high-risk HPV (HPV-16 and -18), which account for 70% of cervical cancer cases worldwide and is no longer available in the United States. The quadrivalent vaccine (Gardasil) targets HPV types 16 and 18 (high-risk HPV), as well as 6 and 11 (low-risk HPV), which usually cause genital warts. Currently in the United States, only the nonavalent vaccine (Gardasil-9) is available and targets HPV types 6, 11, 16, and 18 as the quadrivalent vaccine, as well as types 31, 33, 45, 52, and 58.[18–20] All three vaccines are most effective if given before first sexual intercourse and exposure to HPV. The vaccines have been shown in randomized clinical trials to have 93% to 98% efficacy in the prevention of cervical dysplasia (and presumably cervical cancer) in women not previously infected with HPV-16 and -18.[18–22]

The Centers for Disease Control and Prevention (CDC) recommends that the HPV vaccine be given to both boys and girls between the ages of 11 and 12 years of age, but it can be administered as early as 9 years of age.[23] A two-dose schedule with a 6- to 12-month interval between doses is recommended if given before age 15 years. For those who are 15 years or older or immunocompromised, three doses are required (0, 1–2, and 6 months).[23] Catch-up vaccination, given after the recommended age, should be offered to women and men aged 13 to 26 years who have not been previously vaccinated.[24] In 2018, the U.S. Food and Drug Administration approved the use of Gardasil-9 up to 45 years old for both men and women.[25] However, the Advisory Committee on Immunization Practices and CDC stated that vaccination between the ages of 27 and 45 years is not recommended for everyone and should be considered on a case-by-case basis.[4] The duration of immunity is not yet known, and it is not known whether a booster dose will be required. Routine cervical cancer screening is still recommended in vaccinated women.

Drolet et al[26] published a meta-analysis including data from more than 60 million individuals, demonstrating the impact of HPV vaccination to reduce HPV infections, anogenital warts, and CIN2 and higher lesions. In approximately 5 to 8 years after vaccination, the prevalence of HPV-16 and -18 decreases more than 80% in girls aged 13 to 19 years and approximately 66% among women aged 20 to 24 years. The reductions in anogenital warts were 67% among girls 15 to 19 years, 54% in young women (20–24 years), 48% in boys (15–19 years), and 32% in young adult men (20–24 years). After 5 to 9 years of vaccination, there was also a reduction of more than 50% in CIN2+ among girls aged 15 to 19 years and 31% among young women aged 20 to 24 years.[26]

Secondary Prevention

Cervical Cytology

Cervical cytology (Pap test) became available in the 1950s. It is known that cervical cytology has a low sensitivity; however, a widespread Pap testing has reduced the incidence of cervical cancer by 50% to 70%. This is partly because it takes many years for invasive cancer to develop after a persistent HPV infection and the development of dysplasia and because most women are tested repeatedly.[27]

Primary Human Papillomavirus Testing

There is evidence that HPV testing is effective for cervical cancer screening. HPV testing is more sensitive than cervical cytology.[28–30] Cervical cytology is still the most used screening test in developed countries; however, co-testing with HPV is now also recommended. HPV DNA testing has been recommended in countries or regions of the world in any level of resources available.[31] A large, randomized study in Canada including 19,009 women screened for cervical cancer with HPV testing versus liquid-based cytology concluded that HPV primary testing had significantly lower likelihood of CIN3+ at 48 months than liquid-based cytology.[32]

Guidelines for screening by the American Society of Colposcopy and Cervical Pathology (ASCCP) include[1]

- Screening for cervical cancer is recommended between the ages of 21 and 65 years.
- Cervical cancer screening should begin at age 21 years regardless of the age of onset of sexual activity.
- 21 to 29 years: cervical cytology every 3 years; no HPV testing
- 30 to 65 years: co-testing with cervical cytology and HPV every 5 years (preferred) or cervical cytology testing alone every 3 years
- Screening is NOT recommended for women older than 65 years of age who have had three consecutives negative cytology test results or two consecutives negative co-tests within 10 years before stopping screening (most recent test within past 5 years), provided they have no history of high-grade dysplasia (CIN2/3) or cancer (CIN2+) in the past 20 years. However, women presenting at age 65 years of age or older who have not had previous screening should undergo cervical cytology and HPV testing.
- Screening with cervical cytology or HPV testing is not recommended for women who have had a hysterectomy with removal of the cervix and who do not have a history of CIN2+.

The Bethesda System was developed in 1988 and last updated in 2001 and is now used widely.[17] The Bethesda System first states whether the sample is satisfactory or unsatisfactory, meaning that the sample is appropriate for diagnosis. The report next indicates whether the cellular material is normal. If other than normal, the abnormalities are further divided into squamous and glandular. The cytologist may also comment on whether there is evidence of infection (Table 41–2).

TABLE 41–2 The Bethesda System

Specimen adequacy	Satisfactory for evaluation Unsatisfactory for evaluation
General categorization (*optional*)	Negative for intraepithelial lesion or malignancy Epithelial cell abnormality Other
Interpretation or result	**Negative for intraepithelial lesion or malignancy** Organisms Other non-neoplastic findings (optional to report; list not comprehensive) Reactive cellular changes associated with (descriptive findings) Glandular cells status post hysterectomy Atrophy
	Epithelial cell abnormalities Squamous cell Atypical squamous cells (ASC) of undetermined significance (ASC-US) cannot exclude HSIL (ASC-H) Low-grade squamous intraepithelial lesion (LSIL) High-grade squamous intraepithelial lesion (HSIL) Squamous cell carcinoma Glandular cell Atypical glandular cells (AGCs; specific endocervical, endometrial, or not otherwise specified) AGCs, favor neoplastic (specific endocervical, or not otherwise specified) Endocervical adenocarcinoma in situ Adenocarcinoma **Other** (list not comprehensive) Endometrial cells in a woman 40 years of age or older

TREATMENT OF PREINVASIVE DISEASE

Management of Patients with Abnormal Cervical Screening Test Results

The current consensus guidelines from the ASCCP for the management of patients with abnormal cervical cancer screening test results (primary HPV screening, co-testing with HPV testing and cervical cytology, and cervical cytology alone) and treatment of cervical dysplasia in women 25 years or older are summarized next.[33,34]

In the recently published guidelines, the recommendations are based on risk of CIN3+ (CIN3, adenocarcinoma in situ [AIS], or cancer) determined by current tests results combined with patient's past history (Fig. 41–1). It has aligned the understanding of HPV natural history and cervical carcinogenesis based on the principle that persistent HPV infection is necessary for developing precancer or invasive cancer. The duration of the HPV infection and the HPV type are important for risk stratification. Thus, a negative HPV test result immediately preceding a low-grade abnormal co-test result reduces the estimated risk of CIN3+.[34]

If primary HPV screening is used and the results are positive for HPV, it is recommended to perform both a reflex HPV genotyping test, if not previously done, and a reflex cytology test. (Laboratories should perform a specific additional triage test in the setting of a positive screening test result.) If this is not feasible, referral for colposcopy is acceptable. If positive HPV-16 or -18 and negative cytology (negative for intraepithelial lesion or malignancy, NILM) is documented, a colposcopy is recommended.[34]

If minimally abnormal screening results (HPV-positive and -negative cytology, HPV-negative and LSIL with unknown previous screening history) are found, the recommendation is for surveillance with close follow up at 1 year.[34]

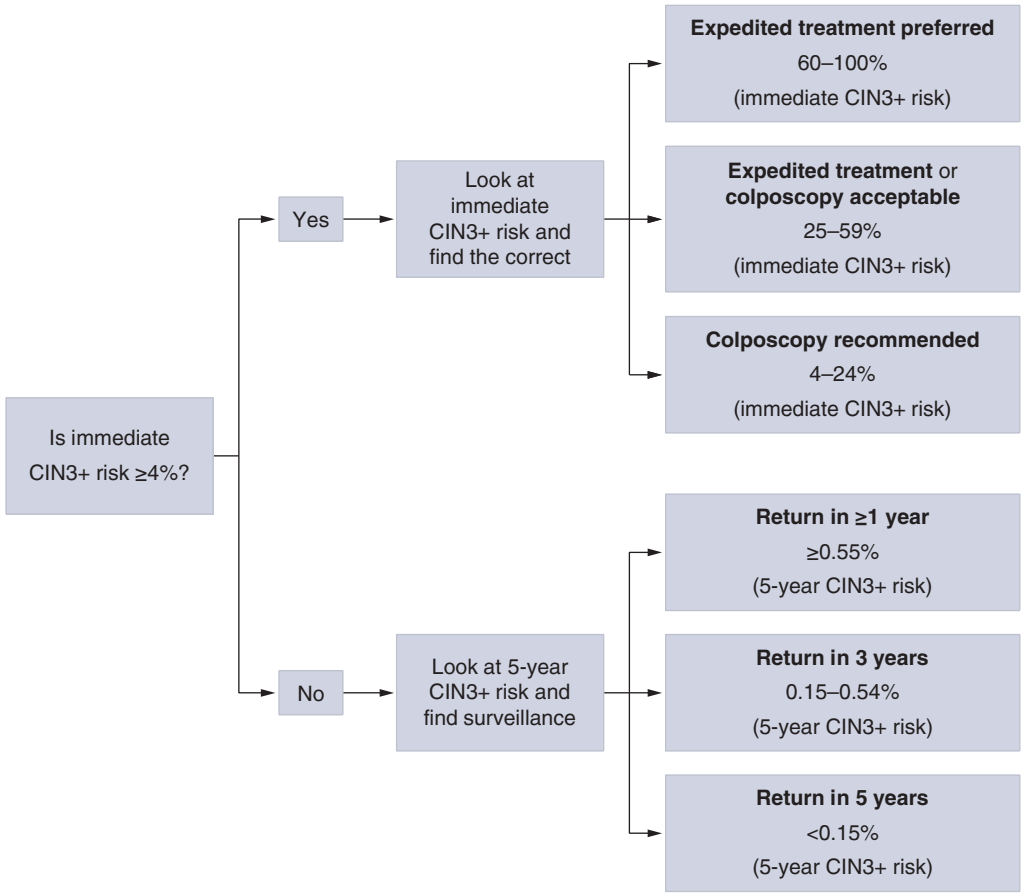

FIGURE 41–1 **Algorithm for management based on calculated risk, for given current results and history combination, the immediate cervical intraepithelial neoplasia (CIN) 3+ risk is examined. If this risk is 4% or greater, immediate management via colposcopy or treatment is indicated. If the immediate risk is less than 4%, the 5-year CIN3+ risk is examined to determine whether patients should return in 1, ,3 or 5 years. (Reproduced with permission from Perkins RB, Guido RS, Castle PE, et al: 2019 ASCCP Risk-Based Management Consensus Guidelines for Abnormal Cervical Cancer Screening Tests and Cancer Precursors, *J Low Genit Tract Dis.* 2020 Apr;24(2):102-131.)**

Atypical Squamous Cells

Treatment depends on the subcategory based on the HPV test and cervical cytology: atypical squamous cells of undetermined significance (ASC-US) or cannot exclude a higher grade lesion (ASC-H).

1. ASC-US: ASCs of undetermined significance are the most common cytologic abnormalities.[35] Women with HPV-positive ASC-US cytology in their initial screening should undergo colposcopy because their immediate risk of CIN3+ is approximately 4.5%. Women with HPV-negative ASC-US cytology screening in the setting of an unknown history can be reevaluated at 3 years (estimated 5-year CIN3+ risk, 0.40%).[33,34]
2. ASC-H: Approximately 5% to 10% of ASC cases are classified at ASC-H.[35] For women with ASC-H cytology, colposcopy is recommended regardless of HPV result.[34]

Low-Grade Squamous Intraepithelial Lesion

LSIL has a greater likelihood of resolving spontaneously; however, in some cases, it might progress to more severe dysplasia.[35] Schlecht and colleagues[36] analyzed 118 women with LSIL who were followed for approximately 53 months; 88.1% regressed to a lower grade (ASC-US or negative cytology), and half of these abnormalities regressed within 6 months.

Colposcopy is recommended after an HPV-positive LSIL screening results in the general population with unknown previous screening history. Follow-up in 1 year is recommended if HPV-negative and LSIL cytology is documented with unknown previous screening history. A 1-year follow-up period is also recommended in a patient with a new positive HPV test result and LSIL cytology after a documented negative HPV test or co-test within an appropriate screening interval or colposcopic examination less than CIN2 within the previous year. Surveillance is recommended rather than immediate colposcopy for low-grade abnormalities (HPV-positive ASC-US or LSIL) if a patient has at least one previous negative HPV-based test result.[34]

Regarding long-term follow-up after a low-grade cytology (HPV-positive and -negative for intraepithelial lesion or malignancy cytology, ASC-US, or LSIL) without evidence of cytologic or histologic HSIL, continued surveillance according to risk estimation using available data is recommended.

High-Grade Squamous Intraepithelial Lesion

A diagnosis of HSIL indicates CIN2/3 or more severe dysplasia.[35] Women with HSIL cytology undergoing expedited treatment (without biopsy confirmation) are diagnosed with CIN3+ in 49% to 75% of cases.[34] Expedited treatment is preferred, but colposcopy with biopsy is acceptable in nonpregnant patients 25 years or older when the risk of CIN3+ is 60% or higher. If HSIL cytology and HPV-16 positive are presented, the immediate CIN3+ risk is 60%, and cancer risk is 8.1%. thus, expedited treatment is preferred.[34]

Atypical Glandular Cells and Adenocarcinoma in Situ

Although uncommonly diagnosed, atypical glandular cells (AGCs) and AIS carries an underlying risk of CIN2+ of approximately 9% and of invasive cancer in approximately 2% to 3%. Cytologic AGCs is associated with a histologic diagnosis of AIS in 3% to 4%.[34,35,37] The recommendation is for colposcopy with endocervical sampling except in pregnancy. Endometrial sampling should also be performed in women who are older than 35 years or at risk for endometrial cancer (abnormal uterine bleeding, obesity, conditions suggesting chronic anovulation). For women presenting atypical endometrial cells specified, initial evaluation with endometrial and endocervical sampling is preferred, with colposcopy acceptable at initial evaluation.[34]

Treatment of Cervical Intraepithelial Neoplasia

The consensus recommendation is to qualify histologic HSIL using the CIN nomenclature, specifying CIN2 or CIN3, when it is possible. Treatment is preferred to observation if histologic HSIL cannot be specified when it is reported as histologic HSIL only or CIN2/3 (not specified). Excisional therapy consists of loop electrosurgical excision procedure (LEEP or large loop excision of the transformation zone), cold knife conization, and laser cone biopsy. Ablation treatment includes cryotherapy, laser ablation, and thermal ablation. The choice of treatment modality depends on the availability of equipment and experience and expertise of the clinician. Hysterectomy is unacceptable as primary therapy solely for the treatment of patients with histologic HSIL.[34]

Expedited treatment (treatment without preceding colposcopic biopsy) is preferred for nonpregnant patients who are 25 years or older with HSIL cytology and concurrent positive testing for HPV-16 and for those never or rarely screened patients with HPV-positive HSIL cytology regardless of HPV genotype. Shared decision making for expedited treatment should be used, especially for patients with concerns about the potential impact of treatment on pregnancy outcomes.[34]

Cervical Intraepithelial Neoplasia Grade 1

CIN1 is a histologic expression of HPV infection. Histologic LSIL (CIN1) and cytologic ASC-US/HPV-positive

and cytology showing LSIL are biologically the same and should be managed similarly.

When CIN1 or no lesion are found on histology (colposcopy with biopsy) after HPV-positive and cytology with ASC-US or LSIL, there is a 5-year risk of CIN3+ of approximately 2%. One-year surveillance is recommended after colposcopy with biopsies of histologic LSIL (CIN1) or less, preceded by a low-grade co-test result (HPV-positive and LSIL cytology, HPV-positive and ASC-US cytology, or repeated HPV-positive and negative for intraepithelial lesion or malignancy cytology).[34]

Observation is preferred to treatment for histologic CIN1. For women 25 years or older, if histologic LSIL (CIN1) persists for more than 2 years, observation is preferred but treatment is acceptable. If treatment is selected and the entire squamocolumnar junction and all lesions are fully visualized on colposcopy, either excision or ablation treatments are acceptable. Treatment of CIN1 in less than 2-year follow-up is an acceptable option based on patient preference, after shared decision making, but it is considered a special situation because the immediate estimated CIN3+ risk is less than 25%.[34]

The 1-year risk of CIN3+ of a woman with a diagnosis of histologic LSIL (CIN1) after ASC-H cytology is 1.4% and after HSIL cytology is 3.9%. When CIN1 is preceded by ASC-H, observation in 1 year with HPV-based testing is recommended if the colposcopic examination can visualize the entire squamocolumnar junction and the upper limit of lesions and the endocervical sampling, if collected, is negative. When CIN1 is preceded by HSIL, it is acceptable to review the cytologic, histologic, and colposcopic findings. If the review changes the diagnosis, the guidelines should be followed for management. If cytology shows HSIL and biopsy shows histology CIN1 or less, either a diagnostic excisional procedure or observation with HPV-based testing and colposcopy in 1 year is acceptable (only if colposcopy visualized the entire squamocolumnar junction and upper limit of lesions and endocervical sampling is less than CIN2).[34]

Cervical Intraepithelial Neoplasia Grades 2 and 3

Approximately 40% of CIN2 lesions and 30% of CIN3 lesions regress spontaneously.[28] Approximately 22% of CIN2 lesions progress to CIN3, and 5% progress to cancer. Furthermore, approximately 15% of CIN3 lesions progress to cancer.[35,37] Because CIN3 is considered an immediate cancer precursor, treatment is recommended in women presenting with HSIL (CIN3), and observation is unacceptable.[34] Treatment is recommended in women presenting with HSIL (CIN2) unless the patient's concerns about the effect of treatment on future pregnancy outweigh concerns about cancer; then either treatment or observation is acceptable. If observation is the management option, then it should include colposcopy and HPV-based testing every 6 months for up to 2 years. Observation is unacceptable if the entire squamocolumnar junction or the upper limit of lesions is not visualized or when the results of an endocervical sampling, if performed, is CIN2+ or higher.[34]

Regarding treatment for HSIL histology (CIN2 or CIN3), the excisional treatment is preferred to ablative. After treatment, HPV-based testing at 6 months is preferred. If HPV-based tests are positive, colposcopy and appropriate biopsies should be performed. Follow-up at 6 months with colposcopy and endocervical curettage is acceptable. After this, annual HPV or co-testing is preferred until three consecutive negative test results have been obtained. Long-term follow-up with HPV testing or co-testing for at least 25 years is recommended in patients treated for histologic or cytologic HSIL even if this extends screening past age 65 years.[34]

Of note, these guidelines do not apply to rare abnormalities or special populations such as women younger than 25 years and pregnant women, with additional risk factors or other complicating history. After immediate treatment, surveillance and the next steps in the management should follow ASCCP guidelines.

Adenocarcinoma in Situ

An initial diagnostic conization excisional procedure to rule out invasive adenocarcinoma is recommended if a histologic AIS is presented in a cervical biopsy. If the margins of the specimen are involved or endocervical sampling obtained above the conization bed is positive, re-excision to increase the likelihood of complete excision is preferred even if hysterectomy is planned. After the initial management, hysterectomy is preferred. Fertility-sparing management for appropriately selected patients is acceptable. Long-term follow-up is recommended for women who do not undergo hysterectomy.[34]

The new Society of Gynecologic Oncology (SGO) guidelines recommend that simple hysterectomy is preferred for patients with confirmed diagnosis of AIS with negative margins on the conization specimen. Either modified radical hysterectomy or simple hysterectomy is acceptable for patients with confirmed diagnosis of AIS with positive margins on the conization specimen. Surgical assessment of lymph nodes is acceptable at the time of hysterectomy but not required and should be guided by the surgeon's risk assessment, which may include factors such as margin status of the preceding excisional specimen or postexcisional endocervical sampling results, pathologist concern for malignancy, HPV results (HPV-16– or -18–positive vs other high-risk HPV type), and patient risk factors.[38]

INVASIVE CERVICAL CANCER

Clinical Presentation

Patients with early-stage disease are frequently asymptomatic; their lesions may be discovered incidentally after an abnormal Pap smear. In patients with gross lesions, the most common presenting symptom is abnormal vaginal bleeding or postcoital bleeding. Other symptoms such as malodorous vaginal caused by tumor necrosis with superimposed infection by anaerobic organisms can be present. In more advanced disease, leg swelling caused by compression of the venous or lymphatic system, lower back pain caused by nerve compression or bone involvement, and or bowel symptoms caused by cancer invasion may be present. If the tumor protrudes into the vagina, bladder, or rectum, vaginal passage of urine or stool can occur.

Diagnosis and Staging

Pelvic Examination

Pelvic examination including visualizing the cervix using a speculum may reveal a normal cervix or a cervical lesion. Any abnormal finding in the cervix should undergo a biopsy even with a normal Pap smear. Visible lesions may appear as an exophytic tumor, a superficial ulceration, or a lesion extending from the endocervix. A rectovaginal examination gives an estimate of tumor size and vaginal and parametrial compromise.

Biopsy

Histologic evaluation of a cervical biopsy to confirm invasive cervical carcinoma is mandatory. If there is a visible lesion, the biopsy should be from the most suspicious zone, avoiding necrotic areas that are often nondiagnostic. In women with no visible lesion but who are symptomatic or with abnormal Pap smear, a colposcopy and directed biopsy is indicated. Cervical conization and LEEP are diagnostic tools in patients with suspected malignancy not found on a biopsy or inadequate colposcopy, patients with high-grade cervical neoplasia, patients with moderate to severe dysplasia in an endometrial curettage, and in microinvasive disease for treatment decision making.

Staging

Cervical carcinomas are staged using the FIGO staging system. Tumor stage is allocated at the time of diagnosis and is not altered, even upon recurrence. The 2018 revised FIGO staging system allows images and pathology, when available, to allocate the stage.[39–41] In the previous staging system, cervical cancer was only staged clinically. Other changes mostly embrace early-stage disease. Horizontal extent is no longer considered for stage IA1 and IA2, and only depth of invasion is now considered. Stage IB is now divided into IB1 (tumors ≤2 cm), IB2 (tumors >2 to ≤4 cm), and IB3 (tumors >4 cm) rather than IB1 and IB2 as was previously based on tumor size 4 or smaller and larger than 4 cm. Nodal compromise, although known to be a mayor prognostic factor, did not change the stage in the previous system. In the FIGO 2018 classification, positive pelvic nodes allocate tumors into stage IIIC1 and positive paraaortic nodes in stage IIIC2. Sentinel lymph nodes (SLNs) with macro- or micrometastasis are considered as IIIC tumors (Table 41–3).

Images

Image studies such as pelvic ultrasound (vaginal or transrectal), computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET)–CT play an important role in the pretreatment evaluation of patients with cervical cancer because they have shown to be more accurate than pelvic examination in determining tumor size, location of the tumor within the cervix, lymph node compromise, and vaginal and parametrial invasion.[42,43]

MRI is significantly more accurate in measuring tumor size and delineating cervical tumor boundaries and local tumor extension compared with CT scan because of its distinctive tissue contrast and multiplanar capability.[44,45] It is also indicated in the pretreatment evaluation of young women with small-volume disease who wish to preserve fertility.

Several studies have found that the accuracy of pelvic ultrasound, when performed by expert radiologists, is comparable to that of MRI with the advantages of being low cost and widely available.[43] CT is able to identify extrauterine spread of disease, including enlarged pelvic and paraaortic lymph nodes, extension to the pelvic sidewalls and hydronephrosis, bladder rectum compromise, and the presence of distant metastases. PET-CT is useful in the detection of lymph node metastases, with sensitivities of 75% to 100% and specificities of 87% to 100%, demonstrating abnormal tracer uptake even in normal-size nodes.[46] PET-CT (preferred) or chest, abdomen, and pelvic CT scan should be performed in patients with tumors stage IB1 or greater and when an invasive tumor is an incidental finding on a simple hysterectomy specimen.

Tumor Markers

Squamous cell carcinoma antigen (SCC-Ag) is the most commonly used serum marker in patients with cervical cancer. Recent studies have shown that the abnormal cut-off value used for serum SCC-Ag is 1.5 ng/mL.[47,48] However, different cut-off values are used for

TABLE 41–3 Revised 2018 International Federation of Gynecology and Obstetrics Staging System for Cervical Cancer

Stage	Subclassification
Stage I: the carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)	**IA:** invasive carcinoma that can be diagnosed only by microscopy with maximum depth of invasion ≤5 mm[a] **IA1:** measured stromal invasion ≤3 mm in depth **IA2:** measured stromal invasion >3 mm and ≤5 mm in depth **IB:** invasive carcinoma with measured deepest invasion >5 mm (greater than stage IA); lesion limited to the cervix uteri with sized measured by maximum tumor diameter[b] **IB1:** invasive carcinoma >5 mm depth of stromal invasion and ≤2 cm in greatest dimension **IB2:** invasive carcinoma >2 cm and ≤4 cm in greatest dimension **IB3:** invasive carcinoma >4 cm in greatest dimension
Stage II: the cervical carcinoma invades beyond the uterus but has not extended onto the lower third of the vagina or to the pelvic wall	**IIA:** involvement limited to the upper two thirds of the vagina without parametrial invasion **IIA1:** invasive carcinoma ≤4 cm in greatest dimension **IIA2:** invasive carcinoma >4 cm in greatest dimension **IIB:** with parametrial invasion but not up to the pelvic wall
Stage III: the carcinoma invades the lower third of the vagina and/or extends to the pelvic wall and/or causes hydronephrosis or a nonfunctioning kidney and/or involves pelvic and/or paraaortic lymph nodes	**IIIA:** carcinoma involves lower third of the vagina, with no extension to the pelvic wall **IIIB:** extension to the pelvic wall and/or hydronephrosis or a nonfunctioning kidney (unless known to be from another cause) **IIIC:** involvement of pelvic and/or paraaortic lymph nodes (including micrometastases),[c] irrespective of tumor size and extent (with r and p notations)[d] **IIIC1:** pelvic lymph node metastasis only **IIIC2:** paraaortic lymph node metastasis
Stage IV: the carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum; a bullous edema, as such, does not permit a case to be allotted to stage IV	**IVA:** spread of the growth to adjacent organs **IVB:** spread to distant organs

[a]Imaging and pathology can be used, when available, to supplement clinical findings with respect to tumor size and extent in all stages. Pathological findings supersede imaging and clinical findings.
[b]The involvement of vascular or lymphatic spaces should not change the staging. The lateral extent of the lesion is no longer considered.
[c]Isolated tumor cells do not change the stage but their presence should be recorded.
[d]Adding notation of r (imaging) or p (pathology) to indicate the finding that are used to allocate the case to stage IIIC. For example, if imaging indicates pelvic lymph node metastasis, the stage allocation would be stage IIIC1r; if confirmed by pathological findings, it would be stage IIIC1p. The type of imaging modality or pathology technique used should always be documented. When in doubt, the lower staging should be assigned.
Adapted with permission from Corrigendum to "Revised FIGO staging for carcinoma of the cervix uteri" [Int J Gynecol Obstet 145(2019) 129-135], *Int J Gynaecol Obstet* 2019 Nov;147(2):279-280.

serum SCC-Ag to evaluate the clinical significance, and these vary among studies. Hong et al[49] noted that persistently elevated serum SCC-Ag level (>10 ng/mL in a 2-year follow-up with at least one serum SCC-Ag measurement between the first 1–3 months and serial SCC-Ag evaluations when SCC-Ag >2 ng/mL) after radiotherapy is a strong predictor of treatment failure. Furthermore, another study that included patients with SCC of the uterine cervix who had achieved complete remission after primary treatment showed that patients with pretreatment SCC-Ag greater than 1.86 ng/mL or posttreatment SCC-Ag >greater than 0.9 ng/mL should be considered at high risk for cancer recurrence.[48] Davelaar et al[50] reported that in patients with early-stage SCC of the cervix poor overall survival (OS) and poor disease-free survival (DFS) were associated with an SCC-Ag level higher than 1.1 ng/mL. Similarly, other studies reported that in patients with stage IB to IIIB cervical SCC who underwent neoadjuvant chemotherapy followed by radical surgery, SCC-Ag level greater than 3 ng/mL could be considered an independent poor prognostic factor for progression-free survival (PFS) and OS.[51,52]

Although the ranges of sensitivity and specificity of this marker for recurrence were 56% to 86% and 83% to 100%, respectively; the majority of studies showed that the sensitivity of this tumor marker is low.[51,53,54] The investigators suggested that future research may need to focus on larger sample studies and the combination of SCC-Ag and other tumor markers, such as

cytokeratin fraction 21-1 (CYFRA 21-1), carbohydrate antigen 19-9 (CA 19-9), and carcinoembryonic antigen (CEA), to assess its limitations and improve its accuracy for future screening purposes.

Cancer antigen 125 (CA-125) is a gynecologic tumor marker most frequently used in ovarian and advanced endometrial cancer. In cervical cancer, Ngan et al[55] found that higher stage disease was associated with increased levels of CA-125 (>35 U/mL). Abnormal levels of CA-125 were detected in 15% of patients with stage I cervical adenocarcinoma, 25% of patients with stage II cervical adenocarcinoma, 33% of patients with stage III to IV cervical adenocarcinoma, and 75% of patients with recurrent adenocarcinoma of the cervix. Because this tumor marker has shown a sensitivity of 20% to 75% for cervical adenocarcinoma and because of its low negative predictive value, it is not considered a diagnostic tool to help assess patients with cervical cancer.[51,56]

CA 19-9 is associated primarily with hepatocellular carcinoma and pancreatic adenocarcinoma. It reflects inflammatory processes among epithelial cells and indicates poor prognosis when elevated in serum. Borras et al[57] reported that the CA 19-9 level was significantly higher in patients with cervical adenocarcinoma than in those with cervical SCC. Although studies have shown that CA19-9 could be a useful tumor marker in the early detection of tumor relapse in cervical cancer patients undergoing radiation therapy, the overall sensitivity of this tumor marker was found to be only 41.7%.[58] Investigators concluded that it is not commonly used in patients with cervical adenocarcinoma.

CYFRA 21-1 is an enzyme-immunoassay that measures serum fragments of cytokeratin 19. Studies have shown that elevated levels of CYFRA 21-1 have been found in 63% of patients with advanced SCC of the cervix.[59,60] CYFRA 21-1 elevation was found to have a correlation with tumor stage, tumor size, depth of stromal invasion, lymphovascular invasion, parametrial involvement, and lymph node status. Because the sensitivity of CYFRA 21-1 was lower than that of SCC-Ag, it was reported that in combination, it may be more useful in predicting disease recurrence. However, the clinical relevance of CYFRA 21-1 is still debated as with SCC-Ag.

CEA is a set of related glycoproteins involved in cell adhesion that is normally produced by gastrointestinal (GI) tissue during fetal development; however, production generally stops after birth. However, the serum levels are elevated in some cancers such as colorectal and gastric carcinoma, as well as some non-neoplastic conditions such as ulcerative colitis and pancreatitis. Borras et al[57] found that the overall sensitivity of this tumor antigen for detecting carcinoma of the uterine cervix was 33%. In this study, CEA showed a higher sensitivity for cervical adenocarcinoma (38.5%) compared with 32% for cervical SCC. Investigators determined that CEA levels decreased in 20% to 33% of patients with advanced cervical cancer that responded to therapy and was elevated in 36% of patients with cervical cancer who developed recurrent disease and was also elevated in 75% of all patients, including those with adenocarcinoma and adenosquamous and squamous carcinoma with metastatic disease. No prognostic value was found for its correlation with OS, and it was suggested that this tumor marker could reach a higher percentage of detection of cervical adenocarcinoma in combination with CA-125 and CA19-9. Conversely, a recent study showed that abnormal levels of CEA suggested a high probability (86.1%) of having parametrial and nodal invasion, which play a significant role in the stage of the disease and further treatment decision.[61]

Tumor Markers Under Investigation

Mathur et al[62] conducted a study including 15 different groups of patients with preinvasive and invasive cervical cancer at different stages of the disease and compared them with a control group with persistently normal Pap smears. The aim of the study was to verify the diagnostic importance of measuring serum levels of *insulinlike growth factor II (IGF-II)* and other tumor markers (Insulin Like Growth Factor Binding Protein 3 (IGFBP3), vascular endothelial growth factor [VEGF]-B and -C) for the early detection of cervical cancer. This study showed that serum measurements of IGF-II are useful in the assessment of patients with noninvasive disease, such as Atypical squamous cells of undetermined significance (ASCUS) with CIN or CIN1 (100% sensitivity and specificity). In women with ASCUS and CIN on biopsy, pretherapy CIN and persistent CIN (all grades) had IGF-II ranging from 1036 to 1128 ng/mL, which was significantly elevated in contrast to control participants. Of note, levels greater than 1300 ng/mL (824 ng/mL is considered the clinically significant cut-off value) seemed to be associated with advanced cervical cancer because this concentration was seen in the persistent and late cervical cancer groups. The investigators also demonstrated that measuring IGF-II levels could be useful for monitoring efficacy of therapy in patients with cervical cancer. (Surgical therapy was the standard of care for all patients with CIN, but adjuvant chemoradiation was administered to women with recurrent or persistent cervical cancer.) Investigators concluded that measuring serum IGF-II levels could be considered a useful screening tool for the detection of an early noninvasive lesions and a diagnostic tool for ASCUS and CIN.

VEGF-C is a proangiogenic cytokine that plays a specific role in the process of neoangiogenesis, which is involved in the progression of the disease and metastasis. Mathur et al[62] found that the serum and tissue levels of this particular VEGF were significantly higher

in patients with advanced cervical cancer. Franc et al[63] showed that VEGF-C is expressed in SCC of the uterine cervix, especially in clinical stage IB to IIIB disease, and that this expression is primarily involved in lymphangiogenesis. VEGF-C expression increases as the clinical stage increases. Similarly, another study showed that the expression of VEGF-C, along with other cytokines, may be associated with lymph node metastasis and may have synergistic effects on the malignant progression in patients with cervical cancer.[64] This tumor marker, as many others, fails in cervical cancer screening when considered individually and shows the greatest utility as a diagnostic tool when combined with other tumor markers, such as SCC-Ag.[54]

YKL-40 (amino acids tyrosine, lysine, and leucine), also known as CHI3L1 or human cartilage glycoprotein-39, is a group of proteins that act as growth factors for several cell types. YKL-40 has been suggested to play a pathophysiological role in tissue remodeling and inflammation, but its true function remains to be determined. Several studies have revealed that elevated serum levels of YKL-40 are present in numerous solid tumors and that it is a potential biomarker in the detection and management of adenocarcinoma of several organs, including the colon, ovary, lung, and breast.[65–68] Mitsuhashi et al[69] showed that increased serum preoperative levels of YKL-40 correlated with the persistence of disease or relapse, independent from the clinical stage and age of patients with cervical adenocarcinoma. It was demonstrated that serum YKL-40 level was elevated in early-stage SCC and adenocarcinoma of the cervix. The sensitivity of YKL-40 for adenocarcinoma was shown to be 78% for all disease and 68% for stage I tumors, suggesting that accuracy was insufficient for screening purposes. A more recent study showed that there is a correlation between CHI3L1 expression and vascular mimicry formation (an alternative microvascular system that develops tumor vascular networks that correlate with tumor growth, metastasis, and short survival time of patients with a number of cancers) in cervical cancer.[70] This suggested that increased CHI3L1 expression mediates not only angiogenesis but also vascular mimicry formation, thereby facilitating cancer aggressiveness and metastasis. This study proposed a feasible therapeutic strategy for targeting CHI3L1 expression in cervical cancer with both classic angiogenesis and vascular mimicry formation, other than considering it a tumor marker for screening.

Thymidine kinase (TK) is a pyrimidine pathway enzyme involved in nucleic acid synthesis and is considered to be a marker of proliferation. It has been studied in hematologic malignancies and colorectal and breast cancers, among others.[71–74] Recently, it was found that the salvage and de novo DNA synthesis pathways may be involved in cell proliferation of cervical carcinoma, mechanisms in which TK plays an essential role.[75] This study showed that serum TK level was significantly higher in patients with invasive cervical carcinoma than in normal women and patients with CIS. In patients who underwent pelvic lymph node dissection, high serum TK levels could not predict pelvic lymph node metastasis. Additionally, high serum TK levels were found to be an independent prognostic factor with no correlation to any other clinicopathologic factors such as patient age, clinical stage, or histologic type. TK may play a role in influencing the malignant behavior of invasive cervical carcinoma, and the investigators concluded that high serum TK levels are significantly associated with poorer survival in patients with advanced cervical carcinoma.

Macrophage colony-stimulating factor (M-CSF) constitutes a group of cytokines called hematopoietic growth factors that stimulate the proliferation and differentiation of monocytes to macrophages, playing a role in the inflammatory response. Increased expression of M-CSF and its receptor is correlated with poor prognoses in breast, ovarian, and prostate cancers. Recent studies have found an autologous production in various human cell lines in vitro and by some tumors in vivo, such as uterine cervix cancer.[76] Sidorkiewicz et al[77] demonstrated that M-CSF plasma levels were significantly higher than SCC-Ag and CA-125 in patients with cervical cancer and that this could be clinically useful in the initial assessment of cervical cancer. However, they concluded that the greatest diagnostic value is demonstrated when combined with other tumor markers, such as VEGF, CA-125, and SCC-Ag. Zajkowska et al[78] showed that high levels of M-CSF were found in stages II to IV of patients with cervical cancer with a sensitivity of 72% to 77%. Nevertheless, their conclusion was that combining M-CSF and SCC-Ag measurements might improve early detection of cervical cancer compared with the use of either marker alone.

Epigenetics are described as genomic structural modifications that affect gene expression but do not alter the underlying DNA sequence. Over the years, it has been shown that epigenetic changes play an important role in tumorigenesis. Epigenetic mechanisms for the regulation of gene expression include DNA methylation, histone modifications, and noncoding RNAs. Recently, it has become apparent that the non–protein-coding portion of the genome may play a major biological role in health and disease, particularly in cancer. The two broad classes of these noncoding RNAs (ncRNAs) include microRNAs (miRNAs) and long noncoding RNAs (lncRNAs). miRNAs are endogenously expressed small RNA sequences that act as posttranscriptional regulators of gene expression, and their role in cancer has been extensively studied. Several miRNAs have been found to be related to cervical cancer (miR-361-5p,

miR-29a, miR-99, miR-196a, miR-126, miR-125) and its carcinogenetic role (overexpression, downregulation, upregulation).[79] Laengsri et al[80] concluded that the detection of miRNAs in circulating blood is a means for reducing the number of invasive specimen collections. The differences in biological properties of cell lines and primary tissue from cervical biopsy affect miRNA expression levels. Also, host genetic variation, aging, and duration and type of viral infection also impact cervical cancer susceptibility. To increase accuracy, profiles of miRNAs in serum would need to be verified in large sample sizes. Finally, the construction of panels of candidate miRNAs from blood specimens—for use as screening, diagnostic, or prognostic markers and for prediction of risk of cervical cancer by single nucleotide polymorphism (SNP) in miRNAs—might be useful for future clinical application. Similarly, another study concluded that in the context of invasive cervical cancer screening, an important issue to be investigated is whether miRNA signatures could be associated with current and future risk of high-grade CIN, most likely in combination with other different markers, to improve risk stratification. The investigation of miRNA levels in cervical exfoliated cells certainly opens new possibilities for studying molecular markers in the context of screening programs.[81]

TREATMENT OF INVASIVE CERVICAL CANCER

Early-Stage Disease: FIGO 2018 Stages IA1, IA2, IB1, IB2, and IIA1

Overall, for early-stage cervical cancer, radical surgery and radiation therapy are both acceptable treatment options (Fig. 41–2).[82] In young patients, radical hysterectomy with ovarian preservation to avoid premature menopause is preferred because radiation is associated with long-term sexual and ovarian dysfunction. Because ovarian metastases in early stage are infrequent (0.8% for squamous and 1.5% for adenocarcinomas),[83] the ovaries are typically preserved in premenopausal women. There are two hysterectomy classifications used among gynecologic oncologists, the Piver-Rutledge-Smith classification[84] and the Querleu-Morrow-Cibula classification[85] (Table 41–4).

For patients with stage IA1 without lymph vascular space invasion (LVSI), the recommendation is a nonfragmented cone biopsy with 3-mm negative margins (negative for invasive disease and HSIL without any further treatment). If margins are positive, an extrafascial hysterectomy with pelvic lymphadenectomy with or without SLN mapping is recommended. As a fertility-sparing option, a reconization or trachelectomy can be done.[82]

In patients with stage IA1 with LVSI and IA2, the indication is a modified radical hysterectomy with pelvic lymphadenectomy with or without SLN mapping or, in nonsurgical candidates, external-beam radiation therapy (EBRT) and brachytherapy.

For patients wishing to preserve fertility a cone biopsy with negative margins with pelvic lymphadenectomy (if margins are positive, a reconization or trachelectomy should be performed) or a radical trachelectomy with pelvic lymphadenectomy, SLN mapping, or both.

For stages IB1, IB2, and IIA1, the indication is a radical hysterectomy with pelvic lymph node dissection with or without SLN mapping with or without paraaortic lymphadenectomy or pelvic radiation and brachytherapy with concurrent platinum-containing chemotherapy (cisplatin). Many centers around the world perform only SLN mapping and not a full pelvic lymphadenectomy as the nodal assessment in patients with early-stage cervical cancer. Currently, some have recommended class II hysterectomy rather than conventional class III hysterectomy in stages IB and IIA disease only for tumors smaller than 2 cm because it has fewer complications with no difference in the 5-year survival rate.[86]

With regards to the approach, radical hysterectomy was routinely performed through a minimally invasive approach (laparoscopy or robotics). However, in 2018, a multicenter, prospective, randomized trial (Laparoscopic Approach to Cervical Cancer (LACC) trial) compared oncologic outcomes in patients with early-stage cervical cancer (FIGO 2009 stage IA1 with LVSI-IB1) who underwent radical hysterectomy by an open versus a minimally invasive approach. The investigators found that DFS rate at 4.5 years was 86% with minimally invasive radical hysterectomy and 96.5% with open surgery. The study also showed that minimally invasive surgery was associated with higher rates of locoregional recurrences (hazard ratio [HR], 4.26; 95% confidence interval [CI], 1.44–12.6; P = .009) and higher risk of death (HR, 6.00; 95% CI, 1.77–20.3; P = .004).[87] A propensity score study of women with FIGO 2009 stage IA2 or IB1 cervical cancer who underwent radical hysterectomy (minimally invasive, 1225 and open, 1236) showed similar results.[88] With a median follow-up period of 45 months, the minimally invasive approach was associated with a higher 4-year mortality rate (9.1 vs 5.3%). Several retrospective studies were subsequently published showing similar results.[89,90] The most recent National Comprehensive Cancer Network (NCCN) 2020 guideline do not recommend the minimally invasive approach and support the use of open radical hysterectomy.[82] Secondary analysis from the LACC trial showed no difference in overall perioperative complications[91] with similar quality of life outcomes between groups (minimally invasive vs open radical hysterectomy).[92]

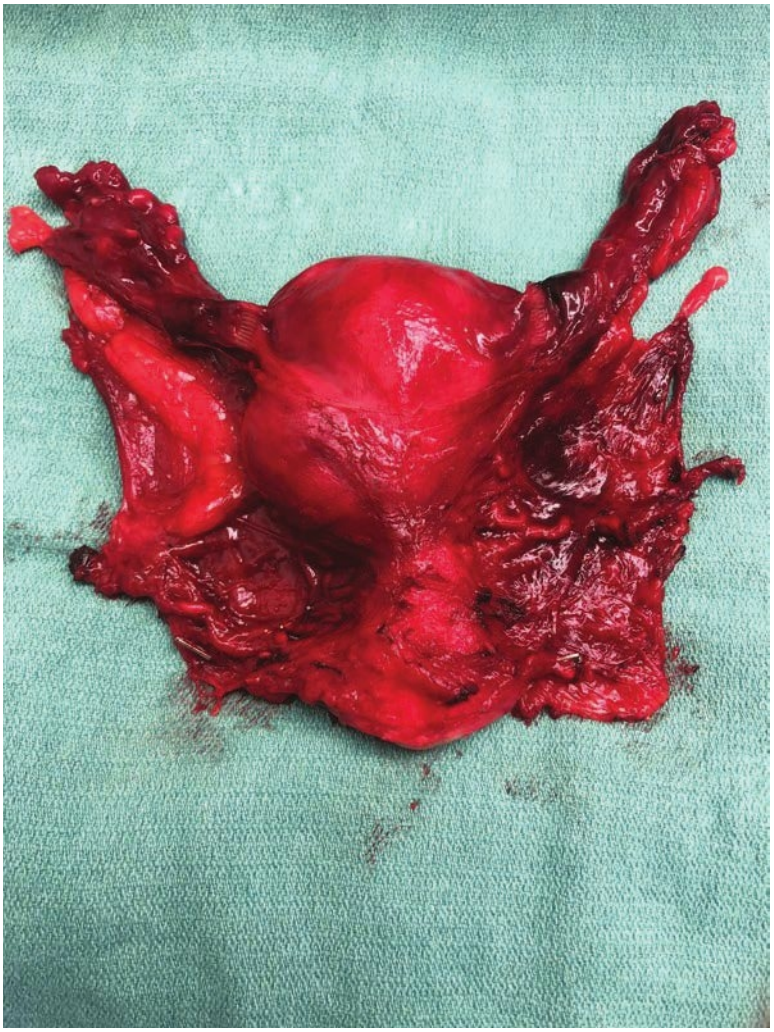

FIGURE 41–2 Radical hysterectomy specimen demonstrating the uterus and cervix, bilateral parametrial tissue, and upper vagina.

Cut-Through Hysterectomy

Invasive cervical cancer may be coincidentally diagnosed in the specimen of a simple hysterectomy, an event reported in approximately 15% of patients.[93] The NCCN guidelines recommend that after careful review of the pathological specimen, patients with stage IA1 disease without LVSI need no further treatment. For higher stages (IA1 with LVSI, IA2, IB1), positive margins, or gross residual disease after imaging studies, pelvic radiation with brachytherapy (with or without concurrent chemotherapy) is recommended. Optional radical parametrectomy with or without adjuvant treatment is recommended by the guideline.[82] A radical parametrectomy consists in removal of the upper vagina, parametrium, and regional lymph nodes. However, a recent study by Pareja et al[94] of 30 patients who underwent radical parametrectomy showed that in patients with low-risk factors (squamous, adenocarcinoma, or adenosquamous; lesions <2 cm in size and invading <10 mm), no radical parametrectomy specimen had residual tumor. None of the patients received adjuvant therapy. After a median follow-up of period 99 months (range, 6–160 months), only one patient recurred. The authors concluded that radical parametrectomy may be avoided in patients with low-risk early-stage cervical cancer detected after a simple hysterectomy because the rates of residual disease (parametrial or vaginal) and the need for adjuvant treatments or recurrences are very low.[94]

Adjuvant Treatment

When there is a combination of risk factors such as large tumor size (>4 cm), deep stromal invasion (>one third stromal invasion), or LVSI, EBRT with concurrent chemotherapy is recommended. The Sedlis criteria are used to guide adjuvant treatment decisions, include (1) greater than one third stromal invasion, (2) LVSI, and

TABLE 41–4 Hysterectomy Classifications

Piver-Rutledge-Smith Classification	
Class	**Description**
Class I: simple hysterectomy	Removal of the uterus along with the cervix
Class II: modified radical hysterectomy	Removal of the uterus with part of the paracervical and parametrial tissue in the lateral aspect of the cervix after dissecting the ureters away. Half of the cardinal ligament (lateral aspect), the uterosacral ligament (posterior aspect), and one third of the upper vagina are all removed.
Class III: radical hysterectomy	Removal of the uterus similar to that of class II, but the tissue structure is removed to a greater extent, generally close to the pelvic sidewall laterally and sacrum posteriorly; the upper half of the vagina is also removed.
Class IV: extended radical hysterectomy	Complete removal of the cervix, uterus, parametrial tissue, cardinal, and uterosacral ligaments. In addition, the ureter is completely dissected from the vesicouterine ligament, and the superior vesical artery is transected.
Class V: partial exenteration	Partial excision of the involved organs. In addition to the above procedures, this encompasses the removal of the distal ureter and urinary bladder.
Querleu-Morrow-Cibula Classification	
Type	**Description**
Type A: extrafascial hysterectomy	The paracervix is transected medial to the ureter but lateral to the cervix. The uterosacral and vesicouterine ligaments are not transected at a distance from the uterus. Vaginal resection is generally at a minimum, routinely <10 mm, without removal of the vaginal part of the paracervix (paracolpos).
Type B: modified radical hysterectomy	Partial resection of the uterosacral and vesicouterine ligaments is a standard part of this category. The ureter is unroofed and rolled laterally, permitting transection of the paracervix at the level of the ureteral tunnel. The caudal (posterior, deep) neural component of the paracervix caudal to the deep uterine vein is not resected. At least 10 mm of the vagina from the cervix or tumor is resected.
Type C: radical hysterectomy	**Type C1**, which corresponds to the nerve-sparing modification, requires separation of two parts of the dorsal parametria; the medial part, which entails rectouterine and rectovaginal ligaments; and the lateral laminar structure, also called mesoureter, which contains the hypogastric plexus. Furthermore, type C1 requires only a partial dissection of the ureter from the ventral parametria, which is usually asymmetric toward more extensive resection of the medial leaf of the cranial (above the ureter) part of the ventral parametria. **Type C2**, which aims for a complete parametrial resection. The ureter is completely dissected from the ventral parametria up to the urinary bladder wall. Defining the resection limits on the longitudinal (deep parametrial or vertical) plane is crucial for distinguishing between types C1 and C2.
Type D: laterally extended hysterectomy	This type differs from type C2 only in the lateral extent of the lateral parametria resection. Ureteral dissection and resection of both dorsal and ventral parametria is identical to the type C2. Laterally, however, it requires ligation and removal of the internal iliac artery and vein, together with their branches, including the gluteal, internal pudendal, and obturator vessels.

Data from Piver MS, Rutledge F, Smith JP. Five classes of extended hysterectomy for women with cervical cancer. *Obstet Gynecol*. 1974;44(2):265-272 and Cibula D, Abu-Rustum NR, Benedetti-Panici P, et al. New classification system of radical hysterectomy: emphasis on a three-dimensional anatomic template for parametrial resection. *Gynecol Oncol*. 2011;122(2):264-268.

(3) tumor size larger than 4 cm.[95] The risks of recurrence and death in the presence of these factors are up to 30% after surgery alone.[95,96] Other risk factors such as positive margins or pathologically confirmed positive pelvic lymph nodes or microscopic involvement of the parametrium (sometimes referred to as Peters' criteria)[97,98] are considered high-risk factors. For patients with these criteria, the recurrence risk is approximately 40% with a risk of death up to 50% after surgery alone.[98,99] If high-risk features are found, metastatic disease should be excluded (CT or PET-CT), and radiation therapy with concurrent chemotherapy

and brachytherapy are recommended. The benefit of adjuvant radiation therapy was shown in a 2012 meta-analysis that compared adjuvant radiotherapy with no further treatment after hysterectomy in 397 women with early-stage cervical cancer. Adjuvant therapy resulted in a reduction in the risk of disease progression (relative risk [RR], 0.58; 95% CI, 0.37–0.91) with no difference in the risk of death at 5 years (RR, 0.84; 95% CI, 0.3–2.36).[100]

Data suggest that chemoradiation may improve the risk of recurrence. A retrospective analysis of 129 patients with intermediate-risk disease treated over a 13-year period compared outcomes after treatment with platinum-based chemoradiation (n = 89) or radiation alone (n = 40).[101] Compared with radiation alone, chemoradiation resulted in a lower recurrence rate (9 vs 23%; P = .049) and a trend toward improved PFS at 5 years (90 vs 78%; HR, 2.82; 95% CI, 0.99–8.02). However, the authors reported there was no difference in OS between groups. There is an ongoing prospective study, Gynecologic Oncology Group (GOG) 263, to evaluate the benefits and risks of radiotherapy versus chemoradiation as adjuvant treatment in women with stage I or II cervical cancer.

Fertility-Sparing Surgery in Early-Stage Cervical Cancer

Thirty-seven percent of cervical cancers are diagnosed in women younger than the age of 45 years, with disease confined to the cervix in 46% of cases[3]; therefore, fertility-sparing surgery has emerged as an alternative without compromising oncologic outcomes. Fertility-sparing surgeries include conization, simple trachelectomy, and radical trachelectomy. Whereas a conization is a resection of the cervix in a cone-shape manner, a simple trachelectomy involves a more extensive removal of most of the cervix in a cylinder shape. Both procedures are performed vaginally. The difference between a radical and a simple trachelectomy is that a radical trachelectomy involves the removal of the parametrium, in addition to the cervix. It is reassuring that a recent Surveillance, Epidemiology, and End Results (SEER) data analysis (n = 2571) showed that uterine-preserving surgery such as cone or trachelectomy is not associated with a higher risk of death compared with non–uterine-preserving surgery (hysterectomy).[102]

Tumor size, FIGO stage, additional risk factors, and location of the lesion within the cervix and its proximity to other structures as the vaginal fornix are key in choosing the appropriate surgical technique. The goal is to remove a large portion of the cervix to remove the entire lesion, with adequate margins, and to allow adequate pathologic evaluation. Most experts agree that at least 5 mm of free margins from the level of the tumor to the endocervical cut margin is required to reduce the risk of local recurrence. If 5 mm of free margin is not obtained, an additional "slice" of cervix should ideally be removed; otherwise, a definitive hysterectomy should be performed.

Candidates for fertility-sparing treatment are women wishing to preserve future fertility; 40 years of age or younger; with tumors smaller than 2 cm; with FIGO 2018 stage IA1 to IB1; and with squamous, adenosquamous, or adenocarcinomas; and with negative nodes. The rationale behind this recommendation is that risk factors such as positive lymph nodes, deep infiltration, and lymphovascular space invasion are more likely to occur with increased tumor size and with other histology (eg, neuroendocrine carcinomas). As tumor size increases, so does the need of adjuvant therapy as shown by Park et al[103] (13.6% vs 34.0%; P <.001) when comparing tumors smaller than 2 and 2 to 4 cm. The need for adjuvant therapy precludes the possibility of maintaining fertility. Because patients who meet the criteria for fertility preservation treatment have a highly curable disease, it is of paramount importance that conservative procedures are accompanied by meticulous review of the preoperative pelvic MRI with an experienced radiologist, rigorous preoperative counseling, and a pathologic evaluation of the cone or simple trachelectomy specimen by an experienced gynecologic pathologist.

For women with FIGO 2018 stage IA1 cervical cancer without LVSI and who have no evidence of intermediate- or high-risk features, conization alone is a standard treatment option regardless of fertility interests with no need for nodal assessment.[104] A study analyzing data from a national cancer database (n = 1409) of women ages 40 years and younger with stage IA1 cervical cancer found no significant difference in 5-year survival rate between those who underwent conization versus hysterectomy (98 vs 99%); data regarding LVSI was not available.[105]

For patients with 2018 FIGO stage IA1 with LVSI, IA2, or IB1, fertility-sparing surgery requires some form of lymph node assessment in addition to the cervical procedure. Radical trachelectomy is the treatment of choice. To date, simple trachelectomy as an alternative to radical trachelectomy has been studied only in retrospective studies and is not the suggested surgery.

The best available data comparing conization with radical trachelectomy is a meta-analysis of 60 studies including 2854 patients, most with stage IA1 to IB1 disease (some studies included patients with stage IB2 or IIA). The results were pooled for each procedure, conization and radical trachelectomy, but tests of significance were not performed comparing the two procedures. For conization and radical trachelectomy, recurrence rates were as follows: stage IA (0.4 and 0.7%) and stage IB (IB1;0.6 vs 2.3%), with mortality rates of 0% and 0.7%; respectively. The pregnancy

and preterm delivery rates for conization were 36% and 7%, respectively, and for radical trachelectomy were 21% and 27%.[106]

Recurrence rate of patients undergoing different fertility-sparing options were evaluated by Pareja et al.[107] The recurrence rate for abdominal radical trachelectomy (all sizes), vaginal radical trachelectomy (all sizes), neoadjuvant chemotherapy, and abdominal radical trachelectomy (tumors <2 cm) ranged from 3.8% to 7.6%. The authors found that the recurrence rate after vaginal and laparoscopic radical trachelectomy in patients with tumors larger than 2 cm was 17% and 21%, respectively, and hence concluded that the procedure is not recommended for patients with tumors 2 to 4 cm in size.[107] A large systematic review by Bentivegna et al[108] evaluated oncologic outcomes in six different fertility-sparing techniques. The study included 1364 patients who underwent vaginal trachelectomies, 230 who underwent simple trachelectomy or conizations, 99 who underwent neoadjuvant chemotherapy followed by conservative surgery, and 987 who underwent abdominal radical trachelectomies (660 laparotomic, 238 laparoscopic, and 89 robotic). Recurrent disease was found in 58, 4, 6, 48 patients, respectively, with 24, 0, 2, and 12 patients dying from the disease in each treatment group, respectively.[108]

Fertility-Sparing Options for Tumors 2 to 4 cm in Size

Currently, standard treatment for patients with 2- to 4-cm cervical cancers is radical hysterectomy. There is not a well-defined strategy for patients with lesions larger than 2 cm who wish to preserve fertility. The rate of positive nodes varies from 10% to 45%, which is an indication for adjuvant treatment that precludes fertility preservation. Neoadjuvant chemotherapy to reduce tumor size followed by a fertility-sparing procedure may be an option. Five studies of neoadjuvant chemotherapy followed by fertility-sparing surgery showed a 71% response rate and better obstetric outcome than upfront trachelectomy.[109] A very recent meta-analysis of 86 patients who underwent neoadjuvant chemotherapy followed by fertility-sparing surgery confirmed that more radical surgery results in less favorable pregnancy outcome compared with less radical surgery.[110] The potential use of this approach is being evaluated in a multicenter, prospective, single-arm, phase II trial Neo-Adjuvant Chemotherapy and Conservative Surgery in Cervical Cancer to Preserve Fertility (CONTESSA) addressing the safety of neoadjuvant chemotherapy followed by fertility-sparing surgery in young women (40 years and younger) with FIGO 2018 stage IB2 cervical cancer with tumors measuring 2 to 4 cm. The primary endpoint is to assess the rate of successful fertility-sparing surgery and no adjuvant therapy. Eligible patients should undergo three cycles of platinum-based chemotherapy in combination with paclitaxel. After three cycles of neoadjuvant chemotherapy, a clinical examination and pelvic MRI should be performed to assess tumor response. Patients with complete or partial response (lesions <2 cm) should then proceed to fertility-sparing surgery (simple trachelectomy or large cone).[111]

Obstetric Outcomes After Fertility-Sparing Surgery

Bentivegna et al,[112] published a systematic review including 2777 patients who underwent five different fertility-sparing surgical procedures and 944 subsequent pregnancies. The overall fertility, live birth, and prematurity rates after these procedures were 55%, 70%, and 38%, respectively. The pregnancy rate was higher in patients after vaginal (63%) or minimally invasive radical trachelectomy (59%) compared with a laparotomic radical trachelectomy (49%). The choice among fertility-saving procedures depends first and foremost on the oncologic characteristics of the tumor.

Open versus Minimally Invasive Approach in Fertility-Sparing Surgery

Radical trachelectomy has been shown to be safe and feasible by open and minimally invasive approaches.[113–115] In the United States, there has been a significant increase in the use of minimally invasive radical trachelectomy from 29% in 2010 to 75% in 2015 (P <.001).[116] Oncologic outcomes among approaches has only been evaluated in small retrospectives studies. A review by Bentivegna et al[108] showed a 5% recurrence rate for the open and 6% for the laparoscopic approach. More recently, a retrospective national database study including 246 patients undergoing open or minimally invasive radical trachelectomy showed a 4-year OS rate of 92% (95% CI, 83.5%–96.5%) for the open and 96% (95% CI, 88.7%–98.4%) for the minimally invasive approach.[116] An ongoing (International radical trachelectomy assessment: **IRTA study**), international, retrospective registry is comparing DFS between patients who underwent open versus minimally invasive radical trachelectomy.[117] Preliminary results have been presented and showed that among 698 patients (open, 388; minimally invasive, 310), there was no difference in intraoperative complications (P = .23) or postoperative complications (23% in the open and 25% in the minimally invasive group; P = .56). There was higher rate of readmission (2% vs 11%; P <.001) and reoperation (2% vs 5%; P = .01) in the minimally invasive group. With a median follow-up time of 50.9 months (range, <1–179 months), overall, there was no difference in DFS between approaches with a 5.4% recurrence rate in the open versus 6.4% in the minimally

invasive group (P = .37). The 4.5-year DFS (open vs minimally invasive) was 93.6% (95% CI, 92.2%–95.0%) versus 91.1% (95% CI, 89.1%–93.2%), respectively. OS was similar between groups (P = .91). Recurrence rate based on tumor size showed that patients who underwent minimally invasive surgery and had tumors 1 to 2 cm in size before surgery were more likely to have a recurrence compared with those who underwent open surgery (12.1% vs 8.3%; P = .010). The authors concluded that minimally invasive radical trachelectomy was found to have worse oncologic outcomes in tumors 1 to 2 cm in size. However, no difference was noted in patients with smaller tumors.

More Conservative Options

The possibility of less radical surgery including simple hysterectomy, simple trachelectomy, or cervical conization with or without SLN biopsy and/or pelvic lymph node dissection may be an option not only for patients desiring future fertility but also for all patients with low-risk early-stage cervical cancer. Low-risk tumors include squamous carcinoma, adenocarcinoma, or adenosquamous carcinoma; lesions smaller than 2 cm; stromal invasion less than 10 mm; and no LVSI.

Only retrospective studies have reported on the oncologic safety of more conservative surgery in this group of patients.[118] Three ongoing prospective trials are evaluating the role of conservative management of patients with low-risk cervical cancer. The first is the ConCerv trial, which evaluates the safety and feasibility of performing conservative surgery in women with early-stage cervical cancer. This is a prospective single-arm study evaluating 100 patients. Surgical options include conization with pelvic lymph node assessment only, simple hysterectomy and pelvic node assessment, or patients who had undergone an "inadvertent" simple hysterectomy with a postoperative diagnosis of cancer.

Two ongoing studies are addressing conservative management of patients with low-risk cervical cancer. The Radical Versus Simple Hysterectomy and Pelvic Node Dissection With Low-risk Early Stage Cervical Cancer (SHAPE) trial is a randomized phase III trial comparing radical hysterectomy with pelvic lymphadenectomy versus simple hysterectomy with pelvic lymphadenectomy in patients with low-risk early-stage (IA2-IB1) cervical cancer (adenocarcinoma, squamous, or adenosquamous carcinomas; ≤2 cm tumors; with ≤10 mm stromal invasion; with or without LVSI). The primary endpoint of the study is pelvic relapse-free survival. The study aimed to enroll 700 patients and is to be completed by 2023. GOG 278 is a multicenter prospective cohort study that is evaluating the physical function and quality of life before and after surgery in patients with stage I cervical cancer treated with non-radical surgery. It includes stage IA1 (LVSI present) and IA2-IB1 (≤2 cm) with no radiologic metastatic disease.

Sentinel Lymph Node Mapping

Lymphatic mapping is based on the principle that if the SLN that is the first lymph node draining from the tumor is negative, more extensive lymphadenectomy may be avoided (Fig. 41–3).

The SLN mapping technique consists of a tracer, a dye or radiocolloid technetium 99m (Tc99), injected

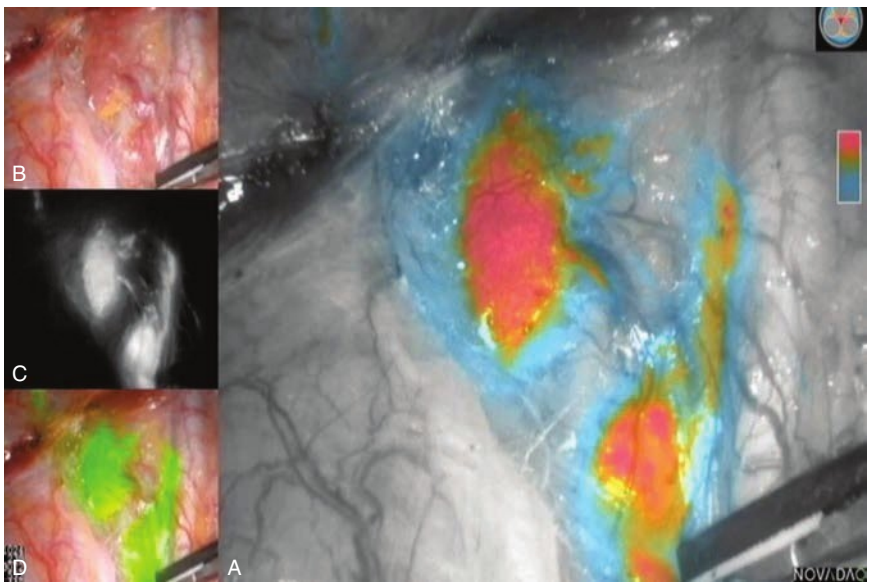

FIGURE 41–3 **Image of sentinel lymph node (SLN) mapping performed through a minimally invasive surgery. A. SLN with use of color-segmented fluorescence. The *left panel* demonstrates image with regular white light (B), "night vision" (C), and green fluorescent imaging (D).**

into the cervix. A mapping algorithm[82] should be followed, removing all SLNs. If there is a grossly suspicious node even without uptake of the tracer, it should be removed. Because the cervix is a central structure and can drain to either the left or right hemipelvis, if a SLN is detected in both hemipelves (bilateral detection), no further nodal removal is needed. If only one hemipelvis was mapped, a pelvic lymphadenectomy should be performed in the nonmapping hemipelvis.

Over the past 20 years, SLN mapping in patients with cervical cancer has been evaluated in both retrospective and prospective studies, which have collectively shown that in well-selected patients, the sensitivity is approximately 99%.[119] The (SENTICOL [Ganglion Sentinelle dans le Cancer du Col]) I trial was prospective study, aimed to determine if bilateral negative SLNs accurately predicted absence of lymph node metastasis in early cervical cancer patients. A total of 139 patients were included. Unilateral and bilateral detection rates were 97.8% and 77%, respectively. No false-negative results were observed in patients whom SLNs were identified bilaterally, concluding that SLN biopsy was reliable when SLNs were detected bilaterally.[120]

SLN biopsy appears to perform better than imaging studies in detecting metastatic disease. A meta-analysis of 72 studies, including 5042 women with cervical cancer, evaluated several approaches to identify metastatic nodes. The sensitivity and specificity for the detection of lymph node metastases were 91% and 100% for SLN mapping, 75% and 98% for PET-CT, 56% and 93% for MRI, and 58% and 92% for CT.[121]

Low-Volume Disease

Positive SLNs are classified according to the size of the nodal metastases as macrometastases (>2 mm), micrometastases (0.2–2 mm), and isolated tumor cells (ITCs) (<0.2 mm). Ultrastaging, which mandates serial sectioning of each node at multiple levels, and immunohistochemical staining with pancytokeratin antibodies (AE1/AE3) is performed if metastases are not identified with hematoxylin and eosin (H&E) stains. Ultrastaging increases the probability of finding low-volume disease (micrometastases and ITCs). It has been shown to identify 15% to 22% positive nodes that would have been missed by only a pelvic lymphadenectomy and regular H&E. The impact of low-volume disease in oncologic outcomes is still under review. A study by Cibula et al[122] retrospectively evaluated 645 patients with early-stage disease who underwent SLN and pelvic lymphadenectomy with ultrastaging. Macrometastasis, micrometastasis, and ITC were detected in 14.7%, 10.1%, and 4.5% patients, respectively. The presence of ITC was not associated with significant risk, both for recurrence free survival and OS. OS was significantly reduced in patients with macrometastasis and micrometastasis. The presence of micrometastasis was associated with significant reduction of OS, which was equivalent to patients with macrometastasis, with no prognostic significance for ITC. A subanalysis of patients included in the (SENTICOL [Ganglion Sentinelle dans le Cancer du Col]) 1 trial concluded that evidence of micrometastasis or ITCs in the SLN of untreated patients with early cervical cancer did not impact PFS.[123] Two ongoing prospective trials Sentinel Lymph Node Biopsy in Patients With Early Stages Cervical Cancer (SENTIX and SENTICOL III) will shed some light on the significance of low-volume disease. Data on the oncological outcome from both trials will not be available until 2020 and 2025, respectively.[120,124]

Frozen Section

The concept of frozen section evaluation of SLNs has been proposed as a means to determine whether to abandon or continue the intended procedure based on lymph node status of disease. Several studies have reported the sensitivity of SLN frozen section to be as low as 53%.[125–128] The SENTICOL study failed to detect lymph node involvement intraoperatively in 15 of 20 patients, including not only low-volume disease (12 cases) but also three cases of macrometastasis.[125] There remains significant controversy as to the value of this approach.

Locally Advanced Disease: FIGO 2018 Stages IB3, IIA2, IIB, IIIC1, IIIC2, and IVA

In locally advanced disease, the standard recommendation is EBRT with concurrent weekly platinum-based chemotherapy and brachytherapy.[98,129,130]

In stages IB3 and IIA2, CT scan or PET-CT should be performed to rule out nodal disease. In patients with radiologically positive nodes ($IIIC_r$), the treatment depends on the location of the compromised nodes. If only pelvic nodes are positive (IIIC1), chemoradiation and brachytherapy are indicated. If paraaortic nodes are positive ($IIIC2_p$ with positive or negative pelvic nodes), extended-field chemoradiation with brachytherapy is the treatment of choice. If distant metastatic disease is found, biopsy to confirm it and systemic chemotherapy are indicated.

Neoadjuvant Chemotherapy for Locally Advanced Cervical Cancer

Although chemoradiation therapy with cisplatin remains the standard treatment for patients with locally advanced disease, the overall recurrence rate is approximately 40%. Therefore, additional treatment strategies are being studied to improve oncologic outcomes. A phase III trial including 633 women with locally

advanced (FIGO 2009 stage IB2, IIA, or IIB) squamous cervical cancer were randomly assigned to either three cycles of neoadjuvant chemotherapy (paclitaxel and carboplatin once every 3 weeks) followed by radical hysterectomy or to standard chemoradiation. Compared with standard chemoradiation, those receiving neoadjuvant chemotherapy followed by surgery had worse 5-year DFS (69.3 vs 76.7%, respectively; HR, 1.38; 95% CI, 1.02–1.87) with similar 5-year OS between the two groups (75.4 vs 74.7%; respectively; HR, 1.025; 95% CI, 0.75–1.40). Delayed toxicities at 2 years or later after treatment completion were worse in the group treated with chemoradiation.[131] Similarly, the preliminary results of a phase III trial (European Organization for Research and Treatment of Cancer 55994), including 620 patients with stage IB2 to IIB cervical cancer, showed that patients randomly assigned to neoadjuvant chemotherapy followed by surgery experienced worsened 5-year PFS rates (57 vs 66%; difference, 9%; 95% CI, 2%–18%) and comparable 5-year OS rates (72 vs 76%; HR, 0.87; 95% CI, 0.65–0.15) as those receiving concomitant chemoradiation. Although short-term grade 3 or greater toxicities were higher with neoadjuvant therapy followed by surgery (41% and 23%, respectively), long-term toxicities were less frequent compared with chemoradiation (15% vs 21%).[132]

In summary, neoadjuvant chemotherapy before definitive hysterectomy does not offer an OS advantage relative to primary chemoradiation, and it has been associated with inferior DFS. Therefore, if chemoradiation is available, it should be recommended.

Radiation Therapy

Radiation therapy is used in cervical cancer as (1) definitive (upfront primary) treatment for patients with locally advanced disease or nonsurgical candidates and (2) adjuvant treatment after surgery in patients with high-risk factors (positive nodes, positive margins, deep stromal invasion, parametrial compromise, large tumor size, LVSI).

CT-based treatment planning is considered standard in EBRT. Brachytherapy is a critical component in patients that do not undergo surgery as part of primary treatment. It is also used as part of adjuvant therapy.

External-Beam Radiation Therapy

EBRT to the pelvis is delivered using multiple conformal fields or intensity-modulated volumetric techniques. Typically, the whole pelvis is treated with external-beam radiation to 45 Gy in 25 once-daily fractions of 1.8 Gy.

For patients with locally advanced disease, the primary tumor and regional lymphatics at risk are typically treated with EBRT to a dose of 40 to 50 Gy. The primary tumor is then boosted using brachytherapy with an additional 30 to 40 Gy for a total point A (represents a paracervical reference point and is used as a dosing parameter) dose of 80 Gy for small-volume tumors and 85 Gy or more for larger volume tumors. Grossly involved unresected nodes may be boosted with an additional 10 to 20 Gy.[82] For locally advanced disease, a total of 86 to 90 Gy with EBRT and brachytherapy is the usual recommended dose.

As adjuvant treatment (after primary surgery), EBRT is recommended at a dose of 45 to 50 Gy. Grossly involved unresected nodes may be treated with a boost of 10 to 20 Gy.[82]

Intensive-modulated radiation therapy (IMRT) can deliver the nodal boost simultaneous to the EBRT and better spare normal tissues, but randomized data evaluating the efficacy are pending. The Standard Versus Intensity-Modulated Pelvic Radiation Therapy in Treating Patients With Endometrial or Cervical Cancer (TIME-C) trial compared patients with endometrial and cervical cancer ($n = 278$) receiving four-field radiation to IMRT after radical hysterectomy, showing that IMRT was associated with significantly lower scores for GI and urinary toxicity than standard radiation therapy.[133] For patients undergoing radiation therapy, it is important to avoid treatment breaks because prolonged treatment is associated with worse oncologic outcomes.[134,135] Extending the overall treatment beyond 6 to 8 weeks results in a 0.5% to 1% decrease in pelvic control and decreases specific survival for each extra day of overall treatment. For brachytherapy, time to completion of brachytherapy longer than 56 days was associated with a higher rate of pelvic failure (HR, 2.8; 95% CI, 1.2–16; $P = .02$). The 3-year pelvic failure for longer than 56 days versus 56 days or less was 26% vs 9% ($P = .04$).[136]

It is important during treatment planning to minimize the potential impact on surrounding tissues such as sigmoid colon, rectum, bladder, small bowel, bone, and bone marrow because side effects may be magnified by concurrent chemotherapy. To avoid early menopause in young women with cervical cancer, ovarian transposition (moving the ovaries upper into the abdomen to avoid the area of EBRT) may be considered. However, a systematic review showed that the proportion of women with preserved ovarian function after ovarian transposition was 65% (95% CI, 56–74; 95% CI, 85–106).[137]

In the recurrent setting, stereotactic body radiotherapy allows for delivery of very high doses of focused external-beam radiation and may be applied to isolated metastatic sites.[138,139]

Concurrent Chemotherapy with Radiation Therapy (Chemoradiation)

Three landmark publications in the *New England Journal of Medicine* in 1999 changed practice regarding

radiation therapy for cervical cancer because all three studies demonstrated that the combination of EBRT with chemotherapy (chemoradiation) improved oncologic outcomes in patients with locally advanced cervical cancer.

Rose et al,[140] published a GOG randomized trial of EBRT in combination with concurrent chemotherapy (group1, cisplatin alone; group 2, cisplatin, fluorouracil, and hydroxyurea; and group 3, hydroxyurea alone) in 526 patients with locally advanced cervical cancer (stage IIB–IVA with negative lymph nodes). All patients received EBRT and were randomized to receive one of three chemotherapy regimens. The median follow-up period was 35 months. Both groups that received cisplatin regimen had a higher rate of PFS than the group that received hydroxyurea alone (P <.001). The relative risks of progression of disease or death were 0.57 (95% CI, 0.42–0.78) in group 1 and 0.55 (95% CI, 0.40–0.75) in group 2 compared with group 3. The OS rate was significantly higher in groups 1 and 2 than in group 3, with relative risks of death of 0.61 (95% CI, 0.44–0.85) and 0.58 (95% CI, 0.41–0.81), respectively. The study concluded that EBRT with concurrent chemotherapy regimens that contain cisplatin improved OS and PFS rates among women with locally advanced cervical cancer.

A second study by Morris et al,[141] compared pelvic and paraaortic EBRT alone (n = 193) versus pelvic EBRT and concurrent chemotherapy with fluorouracil and cisplatin (n = 193) in women with locally advanced cervical cancer confined to the pelvis (stages IIB–IVA or stage IB or IIA with a tumor diameter of ≥5 cm or involvement of pelvic lymph nodes). Patients were then to receive one or two applications of low-dose-rate intracavitary radiation, with a third cycle of chemotherapy planned for the second intracavitary procedure in the combined-therapy group. With a median follow-up time of 43 months, the estimated cumulative rates of survival at 5 years were 73% for patients treated with combined therapy (EBRT and chemotherapy) and 58% for those treated with EBRT alone (P = .004). Cumulative rates of DFS at 5 years were 67% and 40%, respectively (P <.001). The rates of both distant metastases (P <.001) and locoregional recurrences (P <.001) were significantly higher among patients treated with EBRT alone. The study concluded that the addition of chemotherapy to EBRT and brachytherapy significantly improved survival among women with locally advanced cervical cancer.

The third study by Keys et al,[142] a GOG trial, aimed to determine whether weekly cisplatin during EBRT improve PFS and OS among patients with bulky (≥4-cm) stage IB cervical cancer. Patients were randomly assigned to receive EBRT alone (n = 186) or in combination with weekly cisplatin for up to six doses (n = 183) followed in all patients by adjuvant hysterectomy. The relative risks of progression of disease and death were 0.51 (95% CI, 0.34–0.75) for combined EBRT and cisplatin and 0.54 (95% CI, 0.34–0.86) for EBRT alone. The rates of both PFS (P <.001) and OS (P = .008) were significantly higher in the combined-therapy group at 4 years. In the combined-therapy group, there were higher frequencies of transient grade 3/4 adverse hematologic (21% vs 2% in the EBRT group) and GI effects (14% vs 5%). The study concluded that adding weekly cisplatin to pelvic EBRT followed by hysterectomy significantly reduced the risk of disease recurrence and death in women with bulky stage IB cervical cancers.

Brachytherapy

Brachytherapy is the local application of radiation to the cervix and vagina, a critical component of locally advanced cervical cancer treatment allowing for a higher dose to the cervix, sparing the surrounding tissue. The role of brachytherapy was shown in a 2013 SEER database study including 7000 women with FIGO 2009 stage IB2 (>4 cm) to IVA cervical cancer. Using a matched cohort analysis of patients treated between 2000 and 2009, the use of brachytherapy resulted in significantly higher rates of cancer-specific survival (64 vs 52%) and OS (58 vs 46%) at 4 years.[143] Brachytherapy may be delivered with either a low-dose rate (LDR), pulse-dose rate, or high-dose rate (HDR) system. HDR and LDR brachytherapy appear to have similar efficacy and late complications.[144] LDR brachytherapy requires one or two insertions and HDR is given in three to six insertions. Multiple brachytherapy schemas have been used when combined with EBRT. One of the most common is HDR dose of 30 Gy in five fractions, which is equivalent to 40 Gy, to point A using LDR brachytherapy.

Treatment of Paraaortic Nodes

The recommendation for patients with common iliac or paraaortic nodal compromise is extended-field radiation therapy. This entails extending the superior pelvic field border to the level of the renal vessels.[82] This treatment is associated with a high risk of serious acute and late toxicity.[145] The use of IMRT, at least to the paraaortic nodal region, helps decrease morbidity. Extended-field radiation therapy to the paraaortic nodes (for occult or macroscopic compromised nodes) should provide a dose of 45 Gy.[82]

Advanced Stage: FIGO IVB

The preferred treatment is platinum-based chemotherapy with cisplatin or carboplatin. Many patients

with stage IVB disease may also have significant pelvic disease burden and EBRT in addition to systemic chemotherapy was proposed in a multi-institutional retrospective study.[146] A total of 95 patients with stage IVB who underwent EBRT and systemic chemotherapy ($n = 34$) or systemic chemotherapy alone ($n = 61$) from 2005 to 2015 were evaluated. The study showed that the OS was significantly longer in the EBRT with chemotherapy group (42 vs 18 months; $P < .01$). The authors concluded that EBRT in addition to chemotherapy gives a significant OS benefit and that further study is warranted to determine which subgroups may benefit the most from this treatment strategy.[146]

SURVEILLANCE

Surveillance recommendations as provided by the SGO[147] and the NCCN[82] are as follows. During the first 2 years after treatment, physical examination is recommended every 3 to 6 months. From years 3 to 5, this should be done every 6 to 12 months and annually after 5 years. Patients with high-risk disease (positive lymph nodes, parametrial compromise, or positive margins) can be evaluated more frequently, especially during the first 2 years, when most relapses occur. A recommended frequency is every 3 months for the first 2 years. The role of annual cervical or vaginal cytology is controversial because some studies have shown that Pap smear does not detect recurrences in asymptomatic patients with stage I or II disease.[147,148] If low-grade squamous dysplasia is diagnosed during surveillance, treatment is not recommended.

Imaging has a limited role in the follow-up of asymptomatic patients, and it should not be performed as part of routine surveillance in asymptomatic patients with stage I disease with no clinical suspicion of recurrence. In fertility-sparing surgical patients, pelvic MRI should be considered 6 months after surgery and yearly for 2 to 3 years. PET-CT should be considered if metastatic disease is suspected.[149]

For stage II or greater, PET-CT (preferred) or CT scan is recommended after 3 to 6 months of completing treatment. Cervical cancer survivors are at risk for secondary cancers (HPV-related malignancies, such as oropharyngeal cancer and anal cancer).[150]

RECURRENT CERVICAL CANCER

It is generally accepted that any lesions detected and documented as disease within 6 months after treatment should be considered persistent disease. The diagnosis of recurrence is usually made after 6 months.

Recurrent cervical cancer is frequently classified as locoregional or distant or metastatic recurrent disease. Most locoregional and distant recurrences (75%) are symptomatic, and 62% to 89% of cervical cancer recurrences are detected within 2 years of primary treatment. By year 5, 89% to 99% of recurrent disease has been detected.[151]

For women who underwent curative-intent therapy, the predominant site of disease recurrence is local (at the vaginal apex) or regional (pelvic sidewall). The risk of persistent or recurrent pelvic disease increases with more advanced stage. Some retrospective studies reported the distribution of anatomic sites of recurrence to be central (22%–56%) (vaginal apex or pelvis without sidewall involvement), pelvic sidewall (28%–37%), and distant metastases or multiple recurrence sites (15%–61%).[152–155] The estimated prevalence of organ site involvement by metastatic cervical cancer was pelvic or paraaortic nodes (75 and 62%, respectively), lung (33%–38%), liver (33%), peritoneum (5%–27%), adrenal gland (14%–16%), intestines (12%), or skin (10%).[153]

Locoregional recurrent usually presents with vaginal discharge, bleeding, dyspareunia, or pain. Patients with metastatic disease usually present with no symptoms, nonspecific complaints (fatigue, nausea, or weight loss), or symptoms related to the site of metastases. Patients with suspicion of recurrence should undergo a confirmatory biopsy. Images should be performed to determine site of recurrence. CT scan and PET-CT are the most frequently used. PET-CT for evaluation of local and distant disease has a sensitivity of 93% to 96% and specificity of 93% to 95%.[155]

Treatment of Locoregional Recurrent Disease

Options for therapy depend on the type of primary treatment received. For patients previously treated with EBRT with a local recurrence, surgical resection with curative intent (hysterectomy or pelvic exenteration) is recommended. Candidates for surgery include those with a central pelvic recurrence without sidewall fixation or associated hydronephrosis, with long disease-free interval (>12 months), and a recurrence size of less than 3 cm.[156] For patients who received primary EBRT, surgery including radical hysterectomy or pelvic exenteration is recommended with survival rates approaching 50%.[157,158] Exenteration is an ultraradical surgical procedure consisting of an en bloc resection of the female reproductive organs, lower urinary tract, and a portion of the rectosigmoid. Total exenteration refers to removal of the uterus, tubes, ovaries, parametrium,

bladder, rectum or rectal segment, vagina, urethra, and a portion of the levator muscles. In an anterior exenteration, the rectum is spared, but in a posterior exenteration, the bladder and urethra are preserved. A perineal phase, infralevator exenteration, resecting the anus, urethra, and portions of the vulva, may also be required. The choice of procedure is based on the location of the cancer. Reconstruction of the urinary tract (ileal conduit or continent diversion) or the GI tract (end colostomy, temporary ileostomy, double-barrel wet colostomy) may be required. A neovagina reconstruction can be offered in some cases to all types of pelvic exenteration. The potential for cure by exenterative surgery requires that the tumor be resected with negative margins. For patients successfully undergoing exenterative surgery (negative margins and no metastatic disease), the cure rate is approximately 50%.[159] Careful patient selection is required given the perioperative surgical morbidity. A recently published population-based retrospective study including 2647 patients from 2011 to 2015 who underwent pelvic exenteration for gynecologic cancers showed a perioperative complication rate of 68% with a mortality rate of 2%.[160]

For patients who have not received radiation therapy as primary treatment, have a relapse outside the radiated field, or are not surgical candidates, the recommendation is for radiation with or without chemotherapy (cisplatin or carboplatin) with or without brachytherapy.

For patients who have been previously treated with radiation and are not candidates for surgical resection, chemotherapy is recommended. Patients who experience recurrence after second-line therapy, either surgery or radiation, have a poor prognosis.[161] They can be treated with chemotherapy or best supportive care or can be enrolled in a clinical trial.

Treatment for Distant or Metastatic Recurrent Disease

First-Line Therapy

First-line therapy recommended for recurrent of metastatic disease is cisplatin, paclitaxel, and bevacizumab. The addition of bevacizumab to combined chemotherapy was evaluated in a randomized phase III trial (GOG 240). A total of 452 women with metastatic, persistent, or recurrent cervical carcinoma were randomly assigned to chemotherapy (cisplatin–paclitaxel or topotecan–paclitaxel) with or without bevacizumab. The addition of bevacizumab resulted in a significant improvement in OS compared with chemotherapy alone (median, 16.8 vs 13.3 months, respectively; HR, 0.77; 98% CI, 0.62–0.95). OS in women who did not receive prior radiation was higher in both groups (24.5 vs 16.8 months). Postprogression survival was not significantly different across groups (8.4 vs 7.1 months; HR, 0.83; 95% CI, 0.66–1.05). Significant improvement in PFS (median, 8.2 vs 6.0 months; HR, 0.68; 95% CI, 0.54–0.82) and significant improvement in overall response rate (49 vs 36%) were also seen.[162,163]

A 2017 systematic review and metanalysis including data from 19 trials of chemotherapy for patients with recurrent, persistent, or metastatic cervical cancer found a trend toward improved OS for the addition of bevacizumab to cisplatin–paclitaxel and topotecan–paclitaxel versus all other nonbevacizumab regimens.[164]

Because of toxicity related to cisplatin, carboplatin is a reasonable substitute particularly for patients with medical comorbidities and those previously treated with cisplatin-based chemoradiation. This is based on the results of the Japanese Clinical Oncology Group 0505 trial (JCOG 0505)[165] in which 253 women with stage IVB, persistent or recurrent cervical cancer were randomly assigned to receive cisplatin–paclitaxel or carboplatin–paclitaxel. Prior cisplatin therapy (primarily with chemoradiation) was noted in 43% and 50% of each group, respectively. The carboplatin–paclitaxel regimen was noninferior to cisplatin–paclitaxel in terms of median OS (18.3 months vs 17.5 months; $P = .032$) with a similar overall response rate (63 vs 60%). The carboplatin arm had significantly less serious (grade 4) neutropenic events (45 vs 75%; $P < .0001$) and less serious (grade 3/4) incidences of renal insufficiency (0 vs 2.4%). A systematic review including 1181 patients supports carboplatin as a reasonable alternative to cisplatin.[166]

Second-Line Therapy

Pembrolizumab is the preferred regimen for second-line therapy in patients with recurrent or metastatic disease who are positive for tumor programmed death-ligand 1 (PDL-1) or microsatellite instability high or deficient mismatch repair. In the phase Ib KEYNOTE-028 trial, among 24 women with PD-L1 metastatic or recurrent treatment-refractory cervical cancer, the overall response rate was 17%, and duration of response was 5.4 months.[167] Toxicities of pembrolizumab and other checkpoint inhibitors include rash, colitis, and pneumonitis. Other recommended agents as second-line therapy are bevacizumab, albumin-bound paclitaxel, docetaxel, fluorouracil, gemcitabine, ifosfamide , irinotecan, mitomycin, pemetrexed, topotecan, vinorelbine, and in certain circumstances, larotrectinib or entrectinib for *NTRK* gene fusion-positive tumors.[82]

MD ANDERSON PRACTICE TIPS

- The HPV DNA testing is effective for cervical cancer screening and has been recommended in countries or regions of the world in any level of resources available.
- Patients with stage IA2-IB1 cervical cancer seeking fertility preservation should be offered a radical trachelectomy.
- When performing a radical hysterectomy for stage IA2-IB2 FIGO 2018 cervical cancer, the open approach is the new standard of care.
- In patients with metastatic or recurrent cervical cancer, the combination of carboplatin, paclitaxel, and bevacizumab is the preferred treatment regimen.
- In patients with recurrent cervical cancer, molecular testing and PDL-1 status are routinely recommended.

42 Gestational Trophoblastic Disease

Han T. Cun
Aaron Shafer

KEY CONCEPTS

- Gestational trophoblastic disease (GTD) is a spectrum of rare tumors that arise from abnormal placental trophoblastic tissue, including benign disease such as complete and partial hydatidiform moles, as well as malignant tumors such as invasive mole, choriocarcinoma, placental site trophoblastic tumor, and epithelioid trophoblastic tumor.
- Risk factors for GTD include geography, socioeconomic status, dietary factors, maternal age, and previous GTD history.
- GTD is historically diagnosed based on pathology, but due to earlier detection because of routine early ultrasonography, diagnosis of a molar pregnancy based on histology alone may be difficult, and cytogenetic techniques can assist in diagnosis.
- The diagnosis of malignant disease, or gestational trophoblastic neoplasia, is based on increase or plateau of human chorionic gonadotropin (hCG) levels, tissue diagnosis of choriocarcinoma, or evidence of metastatic disease.
- After the diagnosis of malignant disease, it is imperative that patients be staged and scored using International Federation of Gynecology and Obstetrics 2000 staging incorporating the modified World Health Organization scoring system to determine whether single- or multiagent therapy is appropriate.
- Throughout the course of treatment, patients should be monitored with every 1- to 2-week serum hCG levels to determine response.

Gestational trophoblastic disease (GTD) is a spectrum of rare tumors arising from abnormal placental trophoblastic tissue. It ranges from benign disease, including complete and partial hydatidiform moles, to malignant tumors such as invasive mole, choriocarcinoma, placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT). The malignant disease is otherwise known at gestational trophoblastic neoplasia (GTN) or gestational trophoblastic tumor.

Our knowledge of hydatidiform moles dates back to 400 B.C., when Hippocrates was the first to describe them as "dropsy of the uterus."[1] By the mid-20th century, similar to other malignancies, survival rates were dismal. During this time, the mortality rate for invasive moles neared 15% because of hemorrhage, sepsis, embolic disease, or complications from surgery.[2] Additionally, choriocarcinoma had a mortality rate close to 100% when metastases were present and approached 60% even when hysterectomy was performed for nonmetastatic disease. Even benign hydatidiform moles had poor prognoses because of life-threatening hemorrhage and other medical complications. However, because of the identification of a specific and accurate biomarker used for follow-up as well as the development of an effective chemotherapy treatment, current management of patients with GTD yields cure rates approaching 100%.

EPIDEMIOLOGY

GTD is rare accounting for fewer than 1% of all gynecologic tumors. However, the exact rate of prevalence is difficult to determine because of the rarity of the disease, inconsistent use of definitions, and a lack of centralized databases.[3] Despite this, various studies have identified a number of risk factors associated with GTD. These include but are not limited to geography, socioeconomic status, dietary factors, maternal age, and previous GTD history.

GTD is variable throughout different regions of the world. In the United States, GTD occurs in roughly

1 in 1000 pregnancies, with the majority being benign hydatidiform moles, whereas the incidence of choriocarcinoma ranges from 2 to 7 in 100,000 pregnancies.[4] In a broader sense, the rate of GTD in North America, South America, and Europe is approximately 1 in 500 to 1000 pregnancies, but in East Asia, incidence reaches 1 in 120 pregnancies.[3,5] For malignant disease, the reported incidence of choriocarcinoma ranges from as low as 1 in 40,000 pregnancies in North America and Europe to 9.2 in 40,000 pregnancies in Southeast Asia.[2] These regional differences may reflect genetics and ethnicity as potential risk factors for GTD, but other causative factors such as socioeconomic status and diet may also play a role. For instance, in East Asia, the Middle East, the United States, and Brazil, women of lower socioeconomic status have up to a 10-fold higher rate of molar pregnancy compared with women of higher socioeconomic status.[6,7] Additionally, diets with low consumption of carotene and animal fat are associated with increased risk of complete hydatidiform moles[8,9] but not partial moles.[10]

Risk for GTD increases at the extremes of reproductive age as well. Specifically, the risk increases after the age of 35 years with a 5- to 10-fold increased risk after age 45 years.[11] However, women younger than 15 years of age also have a 2-fold risk of developing a molar pregnancy. Additionally, a history of previous molar pregnancy also increases the risk of subsequent GTD up to 10 times compared with the occurrence of sporadic moles.[12] Although various risk factors associated with the development of GTD have been identified, there are currently no prevention or risk reduction strategies available to decrease the development of GTD.

The majority, 80%, of GTDs are benign hydatidiform moles, 15% are invasive moles, and 5% are choriocarcinoma.[13] PSTT, a rare form of GTD, only accounts for 0.2 to 2% of GTDs and has the highest rate of morality because of its relative chemoresistence.[13] Choriocarcinoma is associated with an antecedent complete hydatidiform mole in 50% of cases, a history of abortion in 25%, term delivery in 20%, and an ectopic pregnancy in 5%. Choriocarcinoma after a partial mole is rare.[3,6]

PATHOGENESIS

All GTDs arise from placental tissue from a pregnancy with abnormal fertilization. In normal fertilization, the union of a sperm with an ovum initiates rapid cellular division and the development of a diploid embryo. Embryonic differentiation leads to the development of trophoblasts, specialized epithelial cells that support the development of the placenta and the villi. Normal trophoblasts are comprised of cytotrophoblasts, syncytiotrophoblasts, and intermediate trophoblasts. In GTD, abnormal fertilization results in a complex interplay of genetic and chromosomal abnormalities, leading to trophoblastic hyperplasia and cell cycle dysregulation.

Genetics

GTD is a unique lesion arising from fetal rather than maternal tissue. This occurs after the abnormal union of sperm and ovum, resulting in an imbalance or excess of paternal genetic material compared with maternal material.

In a complete mole, the maternal genetic material is lost during meiosis, and the empty ovum is fertilized by one sperm that duplicates its chromosomes or two separate sperm (dispermy). For instance, 80% to 92% of complete moles have a 46,XX karyotype after fertilization of an empty ovum by a haploid sperm (23X) that then undergoes duplication to create a diploid set of identical chromosomes (46,XX).[14] Additionally, complete moles may also develop after postzygotic diploidization of a triploid conception. Approximately 4% to 20% of complete moles result from dispermy, in which two sperm, fertilize an empty ovum, resulting in a 46,XX or 46,XY karyotype containing all paternal nuclear chromosomes.[6,15] Most are 46,XY, but approximately 5% of all complete moles result from dispermy with heterozygous 46,XX karyotype. Of note, a 46,YY mole has not been reported, suggesting that the X chromosome is required for survival.

Ultimately, these aberrations in fertilization result in nuclear chromosomes with sole paternal origin. The only maternal contribution is maternal mitochondrial DNA.[6,16] This is further supported by the finding that when paternal heterozygotes for the human leukocyte antigen (HLA) locus give rise to a hydatidiform mole, the HLA expression of the molar tissue is homozygous.[17]

In contrast to a complete mole, a partial mole results from the abnormal union of two sperm with one ovum with intact chromosomes, resulting in a triploid karyotype. Occasionally, a normal ovum can be fertilized by an abnormal diploid sperm.[6] Thus, the classic partial mole has a triploid karyotype (69 chromosomes), and both paternal and maternal chromosomes are present. The most common sex chromosome arrangement is XXY, but XXX and XYY also exist.[6] Of note, in triploid pregnancies, a partial mole results when the extra haploid chromosomes are of paternal origin, and a fetus develops when the extra haploid chromosomes are of maternal origin. Caution is used in the event that a partial mole is reported as diploid because the diagnosis is usually a misidentified complete mole, hydropic abortion, or twin pregnancy.

Malignant GTN may have contributions from both paternal and maternal genetic material. Choriocarcinoma

may be either paternal or biparental; however, the latter is more often associated with an intraplacental choriocarcinoma.[18]

Imprinting, Growth Factors, and Oncogenes

Imprinting is known to play a role in the development of GTD. Because paternal genetics impact placental growth but maternal genetics regulate fetal growth, the excess of paternal chromosomes leads to excessive placental or trophoblastic proliferation. The genomic imbalance contributes to changes in various growth factor gene expression and paternal antigen expression, leading to growth dysregulation and immunologic changes. Additionally, the malignant potential of moles may vary depending on its heterozygous or homozygous nature. For instance, one study found there was a Y chromosome detected in only 9% of hydatidiform moles but 50% of invasive moles and 74% of choriocarcinomas.[19]

Genetic mutations and instability have also been implicated in the development of GTD. For instance, one study evaluating samples from hydatidiform moles and choriocarcinoma found somatic point mutations and mitochondrial DNA instability.[20] These genetic aberrations lead to the potential changes in oncogenes, tumor suppressive genes, and various molecular pathways that affect malignant transformation.

Various oncogene products have been found to be elevated in GTD (Table 42–1). For instance, cell lines from choriocarcinoma have abundant expression of epidermal growth factor receptor (EGFR). This is driven by the paracrine effect of certain macrophage-derived cytokines such as interleukin-1 (IL-1-α, IL-1-β) and tumor necrosis factor, which can suppress cell growth and increase the expression of EGFR.[21] Additional studies have demonstrated the amplification and overexpression of oncogene products such as c-erbB-2, c-myc, c-fms, and mdm-2, which have been shown to be associated with higher proliferation index, more aggressive behavior, and malignant transformation of GTD.[22-24] Human placental growth hormone has also been detected in GTD and has been proposed as a possible biomarker.[25]

The downregulation of tumor suppressor genes may also play a role in disease development (see Table 42–1). For instance, GTD has been shown to downregulate p53, p21, and Rb,[26] and it has been shown that p53-dependent apoptosis likely mitigates trophoblastic proliferation.[27] Furthermore, other studies have also suggested that telomerase activity may also support the development of GTD and GTN.[22] Other molecules such as cell–cell adhesion molecules as well as matrix metalloproteinases and their tissue inhibitors also regulate invasion and thus may play a role in pathogenesis.[22]

Like many other diseases, the malignant transformation of GTD is likely a multistep process that involves many genetic changes that support tumor proliferation and invasion.

Familial Recurrent Hydatidiform Mole Syndrome

Familial recurrent hydatidiform mole syndrome is a rare disorder that leads to recurrent molar pregnancies. It is an autosomal recessive disorder with mutations in NLRP7 (70% of cases) or KHDC3L (5% of cases) that result in diploid complete moles of biparental origin compared with exclusively paternal origin.[28,29] Women with this disorder have a high rate of complete hydatidiform mole (74%), but partial moles (4%) are also possible. For these women, only 5% of pregnancies are normal; the rest are spontaneous abortions (17%).[30] Normal live birth may be difficult to achieve for these women and may require use of oocyte donation and reproductive endocrinology referral.

PATHOLOGY AND CYTOGENETIC TECHNIQUES

Historically, GTD was diagnosed based on pathology alone. Each histologic subtype has its own specific pathologic criteria and characteristics. However, because of the use of routine ultrasonography in early pregnancy, tissue is often obtained in an earlier gestation, and the diagnosis of molar pregnancy based on histology alone is difficult. Thus, diagnostic criteria has shifted to include cytogenetic techniques along with pathology to diagnosis GTD. Overall, recognizing moles and distinguishing complete from partial moles is important because of differing risk of persistent trophoblastic disease and malignancy, which is considerably higher after a complete mole (15%–20%) than a partial mole (<5%).

Complete Mole

Hydatidiform moles are confined to the uterus. Complete hydatidiform moles are characterized by total hydatidiform enlargement of the villi surrounded by hyperplastic and atypical trophoblasts. Fetal parts, fetal blood vessels, and fetal blood are absent (Table 42–2). Traditionally, this was typically seen and diagnosed in the second trimester, but because of early detection, hydatidiform moles are now often suspected in the first trimester. Early-gestation complete moles lack the characteristic hydropic villi. Instead, they demonstrate villi with characteristic redundant bulbous terminal villi, hypercellular myxoid stroma, budding typically with nonpatchy trophoblastic hyperplasia, stromal karyorrhectic debris, and collapsed abnormal villous blood vessels.[31]

When pathologic signatures are difficult to detect, cytogenetic techniques may be used. Chromosomal banding and restriction fragment length polymorphism (RFLP) analysis of DNA allow unique chromosomal patterns of complete molar pregnancies to be identified and differentiated.[27,32] Immunohistochemistry (IHC) detection of p57,[KIP2] an imprinted gene expressed only by maternal alleles, is also helpful. A negative screen result is diagnostic for a complete mole because the placenta of all other gestations demonstrate nuclear staining of cytotrophoblast and villous mesenchyme.[33]

Partial Mole

In contrast, partial hydatidiform moles typically include hydatidiform changes of the villi accompanied by identifiable embryonic tissue or amniotic membranes. They typically have less pronounced histopathologic features such as less edema and trophoblast proliferation compared with complete moles. The hydatidiform changes to the villi tend to be focal rather than diffuse (see Table 42–2). They demonstrate patchy villous hydrops with scarred, abnormally shaped and scalloped, irregular villi with trophoblastic pseudo-inclusions and patchy trophoblastic hyperplasia. Their villous capillaries are more functional because they possess the same proportion of nucleated fetal erythrocytes as an embryo. In partial moles, hydatidiform changes occur at a slower rate compared with complete moles.

Again, chromosomal banding and RFLP may be used to identify unique chromosomal patterns of partial molar pregnancies. Chromosomal ploidy analysis may also be helpful to distinguish between partial (triploid) from complete (diploid) moles, although this cannot determine other etiologies of triploidy. This may be particularly helpful during a missed abortion that has developed hydropic villi suggestive but not diagnostic of partial mole.

TABLE 42–2 Features of Complete and Partial Hydatidiform Moles

	Complete	Partial
Fetal or embryonic tissue	Absent	Present
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Trophoblastic stromal inclusions	Absent	Present
Genetic parentage	Paternal	Biparental
Karyotype	46,XX or 46,XY	69,XXY or 69,XYY
p57KIP2	Absent	Present
Persistent β-hCG elevation (%)	20	0.5

β-hCG, β human chorionic gonadotropin.

Invasive Mole

Invasive moles demonstrate the same histologic features as complete hydatidiform moles but are characterized by enlarged hydropic villi invasion into the myometrium. They are typically diagnosed after molar evacuation when serum human chorionic gonadotropin (hCG) levels remain elevated. They can invade locally, causing hemorrhage and necrosis, although uterine perforation rarely occurs. Although metastasis is rare, hematogenous metastases may occur and when it does, it is most often to the lungs. Approximately 10% to 17% of hydatidiform moles result in invasive moles, and roughly 15% of these metastasize to the lungs or vagina.[34] Occasionally, metastatic deposits demonstrate hydropic villi rather than sheets of anaplastic cells characteristic of metastatic choriocarcinoma.

Choriocarcinoma

Choriocarcinoma is a highly malignant tumor with a distinct histology. It can arise from any type of trophoblastic tissue but rarely after a partial mole. Grossly, these tumors are bulky with hemorrhagic and necrotic areas. Genetically, highly complex karyotypes have been reported, and most have XX karyotype.[12] Microscopically, these lesions consist of disordered sheets of anaplastic cytotrophoblasts and syncytiotrophoblasts without chorionic villi, with frequent mitoses and multinucleated giant cells. There is often direct invasion into the myometrium, which may result in disease found in the fallopian tubes and ovaries as well. Additionally, it is often accompanied by vascular invasion and thus may result in distant metastasis, such as in the lungs, brain, or liver.[3]

Placental Site Trophoblastic Tumor

PSTT is an extremely rate tumor that most often develops after nonmolar pregnancies but can also develop after the evacuation of a complete mole.[35,36] These tumors occur at the placental implantation site. Grossly, it appears as a white-tan to yellow nodular mass in the endomyometrium, with half the cases invading deep into the myometrium.[12] Histologically, it demonstrates monophasic extravillous trophoblast, which dissects between bundles of smooth muscle, sometimes with syncytial elements.[37] Intermediate trophoblastic cells have oval nuclei with abundant eosinophilic cytoplasm, and no chorionic villi are present. Syncytiotrophoblasts and cytotrophoblastic populations are also absent. PSTT has a nonaggressive behavior with less vascular invasion, necrosis, and hemorrhage than choriocarcinoma.[37] Even though it is usually a uterine-confined tumor, metastatic disease may occur, likely because of its propensity for lymphatic metastasis.

Molecular analysis may be performed. IHC staining reveals diffuse presence of cytokeratin, human placental lactogen, MUC-4, HSD3B1, HLA-G, and Mel-CAM (CD146).[12] hCG and inhibin may be present but only focally.[12] Most cells have a low mitotic count, and the proliferation index is modestly increased, with a ki-67 index of 14%.[38] PSTT shows rare genetic imbalances and instead are typically diploid.[3,6]

Epithelioid Trophoblastic Tumor

ETT is also a rare disease derived from chorionic-type extravillous trophoblasts, often characterized as a variant of PSTT. Grossly, the tumor appears as white-tan to brown discrete nodules or cystic hemorrhage masses invading deep into the surrounding tissues. Nearly half arise in the cervix or lower uterine segment, but some in the fundus and broad ligament. It develops from neoplastic transformation of chorionic-type intermediate trophoblasts.[2,39,40] Its mitotic count ranges from 0 to 9 per 10 high-powered field.[12] Extensive or geographic necrosis is often present. ETT often exists with other trophoblastic disease and is rather chemoresistant.[38] Most present many years after a full-term delivery.[2,39,40]

CLINICAL PRESENTATION

Complete Moles

The classic signs of a molar pregnancy were once vaginal bleeding in the absence of fetal heart sounds and a uterus larger than expected for gestational age.[6] However, because of the rise in early diagnosis from routine use of ultrasonography, these signs and symptoms occur less frequently. Nonetheless, 80% to 90% of complete hydatidiform moles present with vaginal bleeding between 6 to 16 weeks of gestation.[2]

For patients who do present at a later gestation, they may exhibit a constellation of signs and symptoms historically associated with molar pregnancy. Patients with complete moles often demonstrate a pre-evacuation hCG level greater than 100,000 mIU/mL. They may present with abdominal pain related to the enlarged uterus or the pathognomonic prune juice–like vaginal discharge produced from the liquefaction of intrauterine blood clots. Because of heavy and recurrent bleeding, patients may also present with iron-deficiency anemia more severe than expected for a normal pregnancy, and 50% of patients had symptomatic anemia at the time of diagnosis. Patients may also develop theca lutein cysts, which are ovarian cysts caused by hCG-induced hyperstimulation. Bilateral cysts occur in 15% of cases[2] and may cause pelvic pressure and fullness. Typically, these cysts regress spontaneously after uterine evacuation, but their rupture or tension can cause acute abdominal symptoms that may require surgical intervention.

A variety of other signs and symptoms can be identified at the time of diagnosis. Pregnancy-related hypertension may occur in the first or second trimester. Historically, 20% to 30% of patients present with early preeclampsia, thought be to precipitated by the release of large amounts of vasoactive substance from necrotic trophoblastic tissue.[41] Seizure activity is rare. Roughly 10% of patients may present with hyperemesis gravidarum, and 7% present with hyperthyroidism because of the structural analogy of hCG to thyroid-stimulating hormone.[42,43] Thyroid storm has been reported. Other rare presentations include respiratory distress, disseminated intravascular coagulation (DIC), or microangiopathic hemolytic anemia. Many of these symptoms were more common in the past before the routine use of early ultrasound examination in the first and second trimesters of pregnancy.

Partial Moles

Aside from vaginal bleeding seen in 75% of patients with partial hydatidiform moles, the clinical presentation is otherwise different compared with a complete mole. Patients with partial moles often have symptoms related to an incomplete or missed abortion, and diagnosis is made solely after histologic evaluation of the curettage specimen. Other symptoms such as excessive uterine enlargement, hyperemesis, hypertension, preeclampsia, hypothyroidism, and theca lutein cysts occur less frequently in partial hydatidiform moles.[42] Fewer than 10% of patients with partial moles present with an enlarged uterus.

An intact fetus can coexist with a partial mole, although this occurs in fewer than 1 in 100,000 pregnancies. A minority of patients, fewer than 10%, have a pre-evacuation hCG levels greater than 100,000 mIU/mL.[2] Thus, hormonal symptoms are less common for patients with partial moles compared with patients with complete moles.

Malignant Gestational Trophoblastic Disease

After surgical evacuation, 80% of patients with GTD demonstrate spontaneous remission. However, all patients should be observed closely for malignant transformation by monitoring for symptoms, signs, and serum hCG levels. Malignant GTN is diagnosed after evacuation by a rising or plateaued hCG level, evidence of metastatic disease, tissue diagnosis of choriocarcinoma, or postevacuation bleeding not caused by retained tissue.[6,12,44]

Metastatic GTN occurs in roughly 20% of patients after molar evacuation. It most often arises from choriocarcinoma, a highly vascular tumor with hematogenous spread. It can demonstrate extensive metastasis with spontaneous hemorrhage and subsequent symptoms. Some of these metastases may histologically appear identical to molar disease, but the vast majority are histologically more similar to choriocarcinomas.

As described earlier, 50% of GTN cases are found after a complete molar pregnancy, but it may also develop after a normal pregnancy, ectopic pregnancy, or abortion. For nonmetastatic GTN, patients may present with recurrent symptoms such as irregular vaginal bleeding, theca lutein cysts, asymmetric uterine enlargement, or persistently elevated serum β-hCG levels. Although rare, perforation by the tumor into the myometrium can cause intraperitoneal bleeding. Vaginal bleeding caused by tumor invasion into the uterine vessels, a vascular uterine mass, or vaginal metastasis may be a presenting symptom. Patients rarely may also present with sepsis and abdominal pain, particularly because the uterine mass may be a nidus for infection.[6]

Pulmonary metastases occur in 80% of patients with metastatic disease, arising from trophoblastic tissue that entered the circulation by uterine venous sinuses[45] (Table 42–3). This occurs spontaneously but may also happen after molar surgical evacuation. Because of its vascular nature, hemoptysis is common with lung involvement, but patients may also demonstrate chest pain, dyspnea, and cough. Pulmonary hypertension and pleural effusions may also develop. More commonly, patients are asymptomatic, and these are only be detected following diagnostic imaging such as a chest radiography or computed tomography (CT) scan. On imaging, these findings may be subtle and include alveolar, nodular, and military patterns.[46]

TABLE 42–3 Common Metastatic Sites in Gestational Trophoblastic Neoplasm

Lungs	80%
Vagina	30%
Pelvis	20%
Brain	10%
Liver	10%
Bowel, kidney, or spleen	<5%
Other	<5%
Serum[a]	<5%

[a]Persistent human chorionic gonadotropin after hysterectomy
Data from Berkowitz RS, Goldstein DP. Pathogenesis of gestational trophoblastic neoplasms. *Pathol Annu.* 1981;11:391-411.

However, when extensive, pulmonary metastases can in extreme cases cause respiratory failure and death.

Other sites of metastasis may include the vagina (30%), pelvis (20%), brain (10%), liver (10%), or gastrointestinal (GI) tract (<5%)[47] (see Table 42–3). Vaginal metastasis may cause bleeding or may be visualized as bluish deposits upon vaginal examination. In a patient with known or suspected GTD, it is important to not biopsy vaginal lesions because they can be highly vascular and lead to hemorrhage, which can be difficult to control. Patients may experience right upper quadrant pain with hepatic metastasis caused by stretching of the Glisson capsule. GI lesions can cause severe hemorrhage or perforation with peritonitis, both of which would require emergent surgical intervention. Biopsy of these metastatic lesions is contraindicated because uncontrolled bleeding may occur.

Central nervous system (CNS) metastasis suggests widespread disease. This occurs in 7% to 28% of patients with metastatic choriocarcioma.[45,46] Patients often present with headache, hemiparesis, vomiting, dizziness, coma, grand mal seizures, visual disturbances, aphasia, and slurred speech. Weight loss and anorexia may also occur. Of note, in one third of cases with CNS metastasis, there is no vaginal bleeding.[6]

PSTT and ETT present in similar ways as invasive moles and nearly always demonstrate abnormal vaginal bleeding because the disease typically remains localized to the uterus.[35] These tumors produce only small amounts of hCG relative to their size, and in some cases, hCG levels may even be normal.[6] Human placental lactogen may be elevated in PSTT and ETT and in some patients may be a better tumor marker. Lymphatic metastasis may occur but is rare, occurring in 5% of PSTT cases.[13]

DIAGNOSIS

Diagnosis of a hydatidiform mole is made by histologic examination of a surgically excised specimen,

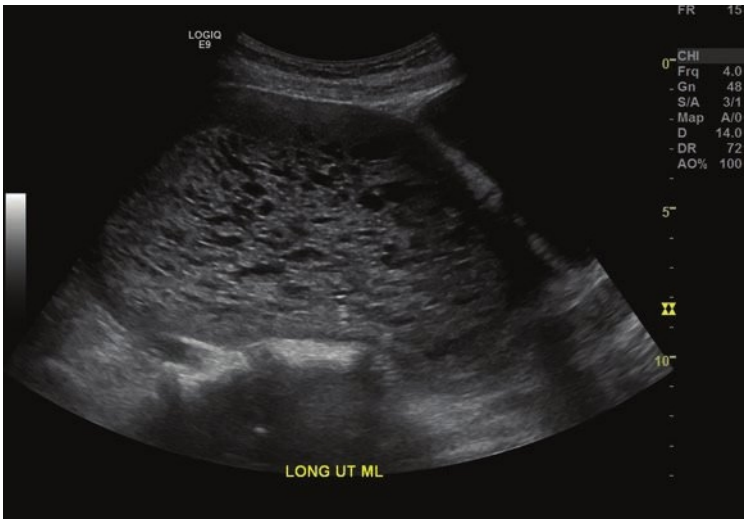

FIGURE 42–1 **Pelvic ultrasound of patient with complete hydatidiform mole. Note the classic "snowstorm" appearance caused by numerous chorionic villi with diffuse hydatidiform swelling.**

typically a curettage specimen. After curettage, the patient is monitored with serial hCG levels. The diagnosis of persistent GTN or malignant GTN is then made by plateauing or rising hCG levels during this surveillance.

Histologic diagnosis of extrauterine metastases from an invasive mole or choriocarcinoma should never be attempted because a biopsy can cause massive, life-threatening hemorrhage. Instead, hCG levels are sensitive and adequate to make the diagnosis of malignant GTN without histologic confirmation.

Because PSTT and ETT do not typically arise after molar pregnancy, their diagnosis is usually made upon examination of the curettage, biopsy, or hysterectomy specimen.[6]

Radiologic Imaging

Pelvic ultrasonography plays a central role in assisting in diagnosis but is not diagnostic of GTD. Upon sonographic evaluation, a complete hydatidiform mole has heterogeneous intrauterine material with multiple cysts, or the classic "snowstorm" appearance, because of numerous chorionic villi with diffuse hydatidiform swelling[48] (Fig. 42–1). In contrast, an early complete mole may appear similar to an embryonic death, an incipient pregnancy, or blighted ovum on ultrasonography.[49] But as gestational age increases, molar pregnancies may take on a more classic appearance of a complete hydatidiform mole on ultrasound. As a result, the rate of ultrasound detection of complete moles increases with gestational age. Additionally, theca lutein cysts on the ovaries may also be seen on pelvic sonographic evaluation, often when hCG levels are high.[50] The presentation of partial hydatidiform moles on ultrasonographic evaluation is also dependent on gestational age, and these may be more difficult to evaluate because of the presence of fetal parts mimicking an early pregnancy. Thus, partial moles may be typically suspected later in the first trimester, when a thickened placenta is visualized.[49]

After the diagnosis of malignant GTN, additional imaging is imperative for staging purposes and to determine the presence or absence of metastatic disease. The most common site of metastatic disease is the lung, and thus a chest x-ray examination should be performed in all patients. This is able to detect lung metastases larger than 1 cm and that present as multiple, well-defined, dense, and rounded opacities.[49] Although a normal chest x-ray examination does not necessarily need to be followed by a chest CT, given modern CT scans with lower dosages, a CT of the chest, abdomen, and pelvis is also appropriate and in higher resource settings is recommended because it can assess for pulmonary as well as abdominal and pelvic metastases all at once (Fig. 42–2). When using a chest CT for staging, though, only those greater than 1 cm should be counted because micrometastases are not associated with change in prognosis for patients[51,52] (Fig. 42–3).

If initial chest imaging findings are abnormal with an elevated hCG, further evaluation should be undertaken to assess for additional metastasis such as in the liver and brain. If not already done, this should include CT of the abdomen and pelvis, and CT or magnetic resonance imaging (MRI) of the brain. Although brain metastases can be seen by brain CT, it is better assessed using MRI.[49] Although MRI is not routinely used for the extracranial evaluation of GTN, it may be helpful as an ancillary tool in an atypical presentation,

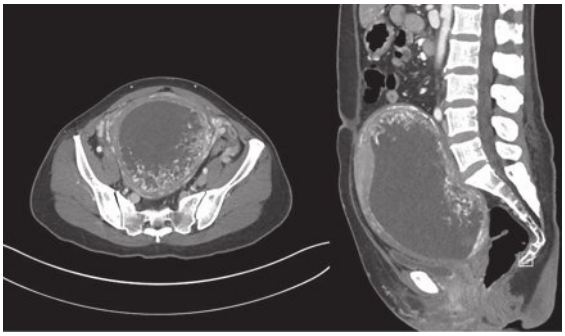

FIGURE 42–2 Computed tomography scan of the pelvis of a patient with gestational trophoblastic disease. Note the enlarged uterus. A. Axial section of the pelvis. B. Sagittal section of the pelvis.

recurrent disease, or PSTT or ETT or to evaluate the primary tumor and local disease invasion in patients who are undergoing surgical treatment.[49]

Laboratory Tests

During pregnancy, syncytiotrophoblasts secrete chorionic gonadotropin, a glycoprotein hormone that is essential for the maintenance of the corpus luteum and thus the pregnancy itself. This hormone is composed of an α subunit, which is identical to the α subunit of the pituitary hormone, and a β subunit (β-hCG), which is unique to trophoblastic tissue and confers its specific biologic activity. The hormone becomes detectable 8 days after ovulation, and its level doubles every 2 to 4 days, reaching its peak at 10 to 12 weeks of gestation followed by a steady decline. Because all trophoblastic tumors secrete β-hCG, its level serves as an excellent biomarker for tumor activity in nonpregnant patients.[6,53]

In a normal pregnancy, hCG is hyperglycosylated with both subunits in the first trimester. However, in GTD, hCG can exist in a variety of forms, such as a free β-subunit, nicked free β-subunit, c-terminal peptide, β-core, or hyperglycosylated form.[54] Because the assay used to detect and monitor hCG levels in the setting of GTD must recognize all these possible forms, home pregnancy tests are not recommended; instead, commercial assays should be used.[3,6] Even so, some commercial assays may only detect pregnancy-related hCG and thus are unreliable for detecting GTD-related isoforms, leading to false-negative readings. Alternatively, assays may be ineffective if they cross-react with heterophile antibodies, leading to false-positive results.[3,6] Of note, heterophile antibodies are large and filtered in the renal glomerulus and thus not able to pass through into the urine. As a result, urine pregnancy tests may be useful to exclude a false-positive test result from heterophile antibodies.

Overall, a patient's hCG level correlates with burden of disease in both hydatidiform moles as well as GTN. Because of this, the diagnosis of postmolar GTN is determined by β-hCG levels. Based on the International Federation of Gynecology and Obstetrics (FIGO) criteria, the diagnosis of postmolar GTN based on hCG levels occurs when[55–57]

- Weekly hCG levels plateau (remain within 10% of the previous result) over a 3-week period
- hCG levels increase more than 10% across three values recorded over a 2-week duration

This in turn assists in determining the need for additional therapy. Of note, elevations in hCG levels should also prompt an evaluation and work-up to rule out a new pregnancy. After initiating chemotherapy, monitoring of serial β-hCG levels is mandatory throughout treatment to ensure adequate therapy. Because the level of β-hCG is considered proportional to the tumor burden, it is a direct measurement of how efficacious the current therapy is.

Other biomarkers may be helpful for correlation of tumor burden as well. Previously, the ratio of β-hCG in the serum compared with that in the cerebrospinal fluid was used to detect brain metastases in GTD, with a ratio of less than 10:1 considered a positive predictor for brain metastases.[58] However, now with the availability of MRI, this is rarely used.

In the setting of GTD, other laboratory tests may be used during evaluation and treatment. CA-125 may have a role as a marker for GTD, particularly with its elevation in the development of persistent GTD.[59] Human placental growth hormone is also detected in variants of GTD and has been postulated as a potential biomarker for diagnosis.[25] The complete blood count is helpful to determine anemia and thrombocytopenia because bleeding is a common symptom. DIC is an uncommon presentation but may occur in patients with excessive blood loss. With DIC, clotting times may be prolonged, and coagulation factors may be consumed. Hepatic and renal impairment is rare. Thyroid function studies should be performed in patients with a clinical history or physical examination concerning

for hyperthyroidism. Thyrotoxicosis, although rare, can occur in patients with very high β-hCG levels (<100,000 IU/L) and if present can make surgery risky. If the patient is to undergo surgical management and thyrotoxicosis is present, prompt coordination with anesthesia before any procedure is important, including a dilation and curettage.[60]

PHANTOM HUMAN CHORIONIC GONADOTROPIN SYNDROME

Phantom hCG syndrome, otherwise known as phantom choriocarcinoma syndrome or pseudohypergonadotropinemia, is a persistent mild elevation of hCG when no true hCG or trophoblastic tissue exists. This is because of the presence of heterophile antibodies that interfere with the detection assay. Phantom hCG syndrome is clinically significant because it may lead to unnecessary treatment after primary evacuation or after successful chemotherapy for GTN.

Heterophile antibodies cause false-positive test results because they are able to mimic hCG immunoactivity in the sandwich enzyme-linked immunosorbent assay. They bind both the capture and tracing antibody, thereby causing a false-positive result. Because large heterophile antibodies are filtered at the level of the glomerulus, the urine hCG test is negative in the setting of a heterophile antibody. Thus, urine pregnancy tests should be used to rule out false-positive assay results and aid in the diagnosis of phantom hCG.

Aside from urine pregnancy tests, serial dilutions may also be used to determine phantom hCG syndrome. Nonlinearity in serial dilutions suggests the presence of heterophile antibodies and interference in the assay. Other differential diagnoses for elevated hCG may be considered, which include all forms of GTD, germ cell tumors, any cancer that has undergone trophoblastic differentiation (including epithelial cancers), and very rarely, familial elevated hCG.[13] If both urine and serum hCG test results are positive, then real hCG is present, and occult malignant GTD must be excluded.

STAGING AND PROGNOSIS

There are many staging and prognostic systems used to characterize GTD. These systems determine prognostic groups to direct optimal therapy options to ensure the highest possible cure rate. More specifically, it predicts the potential for development of resistance to single-agent chemotherapy with methotrexate or dactinomycin. Patients are classified based on individual risk factors such as histologic subtype, extent of disease, hCG titer before treatment, duration of disease, nature of antecedent pregnancy, and extent of prior treatment. The most commonly used system is the FIGO 2000 staging system (Table 42–4), which was developed from the World Health Organization (WHO) scoring system (Table 42–5). A score of 0 to 6 suggests low-risk disease or low risk of resistance to single-agent chemotherapy, and thus treatment with single-agent chemotherapy is most likely appropriate.[55] Patients with a score greater than 6 have high-risk disease or a higher risk of developing resistance to monotherapy and are best treated using combination therapy.[6,55]

TABLE 42–4 International Federation of Gynecology and Obstetrics 2000 Staging System for Gestational Trophoblastic Disease[a]

Stage	Description
I	Tumor confined to the uterus
II	Tumor extends to other genital structures (ie, ovary, fallopian tube, vagina, broad ligaments) by metastasis or direct extension
III	GTN extends to the lungs with or without known genital metastases
IV	All other metastases

[a]Stage should be followed by World Health Organization score (eg, stage I:3 or stage IV:12).
GTN, gestational trophoblastic neoplasia.

More than 50% of patients with scores of 5 or 6 will fail single-agent therapy and require combination chemotherapy. Despite this, single-agent therapy is still used initially for these patients to spare patients who do respond to the more toxic effects of combination therapy.[61]

Other factors have also been identified that may assist in predicting drug resistance and prognosis. These include pulsatility index, which uses Doppler ultrasonography, measures uterine vascularity, and predicts methotrexate resistant disease.[61] Additionally, hCG regression nomograms and kinetics may assist in predicting early onset of resistance with a single-agent therapy.[62] None of these is as studied or widely accepted as the WHO criteria.

MANAGEMENT

Each patient is considered individually based on the FIGO 2000 scoring system. The following outlines the general diagnostic and therapeutic approaches used at the University of Texas MD Anderson Cancer Center.

TABLE 42–5 World Health Organization Prognostic Scoring for Gestational Trophoblastic Disease

WHO Score	0	1	2	4
Age (years)	**<40**	**≥40**	**—**	**—**
Antecedent pregnancy	Hydatidiform mole	Abortion	Term	
Interval months from index pregnancy	<4	4 to <7	7 to <13	≥13
Pretreatment serum hCG level (IU/mL)	$<10^3$	10^3 to $<10^4$	10^4 to $<10^5$	$\geq 10^5$
Largest tumor size (including uterus)	<3 cm	3 to <5 cm	≥5 cm	-
Site of metastases	Lung	Spleen, kidney	GI	Liver, brain
Number of metastases	—	1 to 4	5 to 8	>8
Previous failed chemotherapy	—	—	Single drug	Two or more drugs

Low risk ≤6; hgh risk ≥7.
This combination of the modified World Health Organization (WHO) risk factor scoring system with the International Federation of Gynecology and Obstetrics (FIGO) Cancer Staging and Nomenclature Committee in September 2000 and ratified in June 2002 with the FIGO announcement.
GI, gastrointestinal; β-hCG, β human chorionic gonadotropin.

Molar Pregnancy

Primary Treatment

Hydatidiform mole is curable and treated with surgery. Suction evacuation and curettage, often performed under ultrasound guidance, is the preferred method of treatment to ensure removal of all molar tissue and avoid uterine perforation.[3] If the uterus is greater than 16 weeks in size, there is an increased risk of pulmonary embolization of molar tissue, and thus care at a referral center should be considered if possible.[6] Bleeding is variable, but the overall risk of hemorrhage increases with uterine size, so available blood products for transfusion should be available if the uterus is greater than 16 weeks.[12] The use of intravenous oxytocin infusion with the onset of the surgery may be considered to limit blood lost, but caution is necessary in patients with comorbidities because of the risk of hyponatremia and fluid overload.[63] Rh-negative patients with partial hydatidiform moles should be appropriately given anti-D immunoglobulin prophylaxis.

If the patient has completed childbearing and no longer desires future fertility, hysterectomy to remove the uterus with the mole intact is reasonable (Fig. 42–4). The ovaries should be preserved, even if theca lutein cysts are present. Removal of the uterus allows for permanent sterilization while also decreasing the possible need of subsequent chemotherapy because of persistent disease.[45]

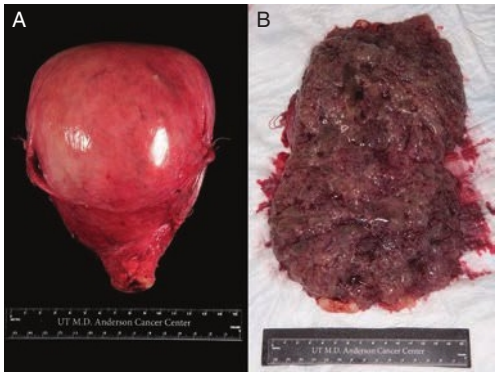

FIGURE 42–4 Gross specimen of complete molar pregnancy removed with hysterectomy. A. Enlarged uterus. B. Uterus opened demonstrating diffuse trophoblastic tissue within the cavity.

Postsurgical Care and Indications for Chemotherapy

After primary surgical treatment, weekly serum β-hCG levels should be obtained until three consecutive weekly assays are normal. This typically occurs within 8 weeks, but roughly 20% of patients continue to have elevated β-hCG levels for 14 to 16 weeks after surgical evacuation. Patients with complete molar pregnancies and normalization of β-hCG levels should continue to be monitored with monthly serum β-hCG levels for 6 months. Because of the risk of subsequent GTN is

much lower in those with partial molar pregnancies (0.5%-1%) and because when hCG normalizes, this risk falls to 1 in 3000, most centers follow-up women with partial hydatidiform moles that normalize without chemotherapy with serial hCG levels until they have two normal values.[6,44,61]

Although historically, guidelines recommended use of contraception to avoid pregnancy for 12 months after normalization of hCG levels, more recent data have demonstrated that there is no increased risk of recurrent molar pregnancy between 6 and 12 months.[13] Thus, most experts recommend only 6 months of contraception.[6] There is a relative contraindication to intrauterine devices because of the potential risk of uterine perforation.[64,65] Oral contraceptive pills are considered the contraception of choice because they are also helpful to suppress luteinizing hormone, which may interfere with the detection of low levels of hCG. Currently, there is no evidence in regard to use of etonogestrel implants or Depo-Provera injection for contraception in this patient population.

The majority of patients after surgical evacuation do not need any further therapy, but 20% will develop malignant disease requiring further management.[66–68] Pathology from these patients include complete hydatidiform mole (78%), partial hydatidiform mole (9%), and choriocarcinoma (8%).[67] Most of these patients (81%) have low-risk disease based on FIGO 2000 criteria (see Table 42–5), 18% have high-risk disease, and 1% have PSTT. Malignant disease requiring further therapy is based on the following criteria[6,44,55–57]:

- Weekly hCG levels plateau (remain within 10% of the previous result) over a 3-week period
- hCG levels increase more than 10% across three values recorded over a 2-week duration
- Persistence of detectable serum hCG for more than 6 months after a molar evacuation
- Tissue diagnosis of choriocarcinoma
- Evidence of metastatic disease
- Elevation of β-hCG level after a normal result
- Postevacuation bleeding not caused by retained tissues

Of note, an elevated but downtrending hCG level 6 months after molar evaluation does not mandate chemotherapy because hCG levels often spontaneously normalize in these patients,[69] but restaging with imaging and close monitoring is important. However, a level greater than 20,000 IU/L for more than 4 weeks after evacuation does prompt use of chemotherapy because the risk for uterine perforation and hemorrhage is high.[3,6] It is imperative to use effective contraception and to exclude any new pregnancy during this surveillance period rather than assume development of GTN.

Prophylactic Chemotherapy

Prophylactic adjuvant chemotherapy after molar evacuation is controversial and not recommended because the risk outweighs the benefit, except in rare occasions when follow-up compliance is not possible in low-resource settings.[6,70] Overall, surveillance is mandatory for all patients, and unnecessary chemotherapy exposes many women to medication toxicity and may induce drug resistance.[71,72]

Malignant Gestational Trophoblastic Disease

After diagnosis of malignant disease, patients should be appropriately evaluated to determine staging and scoring. For patients diagnosed via hCG monitoring, examination should include history, physical examination, serum hCG level, pelvic ultrasonography (to exclude pregnancy, measure uterine size, and exclude any pelvic metastasis), and chest radiography. If disease is seen on chest x-ray imaging to suggest pulmonary metastasis, chest CT should be obtained, but only lesions seen on chest radiography should be used for scoring.[6,55] If possible, especially in high-resource settings, initial radiologic evaluation should probably be with CT of the chest, abdomen, and pelvis. As stated earlier, though, pulmonary nodules smaller than 1 cm in size should not be counted in staging and scoring purposes. Routine brain imaging is probably not necessary, but if there is evidence of pulmonary metastasis, brain imaging with CT or MRI (MRI preferred) is necessary.

For patients diagnosed with malignant diseased based on pathology demonstrating choriocarcinoma or suspected GTN after a nonmolar pregnancy, full-body imaging should be obtained because of the potential for aggressive disease. This should include CT of the chest and abdomen, MRI of the brain and pelvis, and pelvic ultrasound.[6]

After evaluation, patients are stratified and staged based on the FIGO 2000 staging incorporating the modified WHO scoring system (see Tables 42–4 and 42–5). This determines the patient's initial treatment plan. Patients are stratified to the low-risk group, or a score of 0 to 6, who have a low risk of developing resistance to single-agent chemotherapy, or they are stratified to a high-risk group, or score of greater than 6, indicating a high risk of resistance to single-agent chemotherapy requiring use of combination therapy.

Low-Risk Disease

The overall prognosis for patients with low-risk disease is exceptional because current therapies result in a cure rate close to 100%, despite the presence of metastatic disease or resistance to first- or second-line therapy.[61] For patients who no longer desire fertility,

hysterectomy can be the primary treatment, although this may not eliminate the need for additional chemotherapy. However, most patients are of reproductive age and desire future fertility and thus should receive chemotherapy as first-line therapy for low-risk disease. Because of a low WHO score, these patients are suitable for single-agent chemotherapy (Table 42–6).

Both methotrexate, with or without folinic acid, and dactinomycin are suitable single-agent therapies for patients with low-risk disease (see Table 42–6). Several studies have evaluated various schedules for these therapies, with a variety of inclusion criteria, which makes them difficult to compare for a superior regimen.

One randomized trial was completed comparing low-dose, weekly methotrexate (30 mg/m^2) with 14-day dactinomycin. This study found that dactinomycin was superior with a complete response rate of 53.3% compared with 69.7%, respectively.[73] The major flaw of this study is the use of a known inferior methotrexate regimen. Despite these results, many still favor the use of methotrexate, possibly because of a better side effect profile, with no alopecia, less nausea and vomiting, and less myelosuppression compared with dactinomycin use.[13] There are a lot of retrospective as well as registry data that show high efficacy for other methotrexate regimens. These multidose regimens use folinic acid rescue and have efficacy rates that equal single-agent dactinomycin. On the other hand, dactinomycin arguably has superior efficacy with a less frequent dosing schedule.[6] To add, efficacy of these regimens may also differ within this low-risk disease group depending on WHO score. In the Gynecologic Oncology Group study mentioned earlier, weekly intramuscular methotrexate is successful in 70% of patients with WHO scores of 0 or 1,[73] but this drops to 40% in patients with WHO scores of 2 to 4 and then 12% in patients with WHO scores of 5 or 6.[74] As a result, many do not recommend or use weekly methotrexate regimens or, at best, suggest that weekly methotrexate should be reserved for patients with WHO scores of 2 or less, and biweekly pulsed dactinomycin or multiday methotrexate regimens should be the preferred treatment for women with WHO scores of 5 or 6.

Treatment of patients with low-risk disease confined to the uterus may also consider a second suction curettage. One prospective study found that 38% of patients treated with a second curettage instead of a single-agent chemotherapy demonstrated normalization of hCG levels without significant morbidity.[75] Routine use of second curettage should be avoided. In patients who wish to avoid chemotherapy and have low WHO scores, it can be considered with careful counseling about the high likelihood of needing chemotherapy anyway as well as the fact that the course of treatment might be prolonged.

During treatment, patients should be monitored with every 1- to 2-week serum hCG levels to determine response. If a persistent elevation over 3 consecutive weeks is demonstrated or an increase over 2 consecutive weeks lasting more than 2 weeks, resistance to first-line therapy is demonstrated.[6] However, if levels are low, phantom hCG syndrome should be ruled out.

Rescoring of patients who develop resistance to primary chemotherapy is not always necessary unless levels remain persistently elevated over a long period of time and PSTT or ETT is suspected.[61] Restaging imaging can also be considered in patients with low-risk disease who have plateaued or rising β-hCG levels to determine if they have now become high-risk and require multiagent therapy or can switch to another single-agent regimen. Hysterectomy is offered if disease is confined to the uterus; however, if the patient wishes to retain fertility, alternative chemotherapy is recommended. Patients initially treated with methotrexate with low hCG levels may consider

TABLE 42–6 Chemotherapy Regimens for Low-Risk[a] Gestational Trophoblastic Disease

Drug	Administration	Cycle[b] (days)
Methotrexate and folinic acid	50 mg IM on days 1, 3, 5, and7 15 mg PO on days 2, 4, 6, and 8	14
Methotrexate and folinic acid	1 mg/kg (≤70 mg) IM or IV on days 1, 3, 5, and 7 0. 1 mg/kg IM or IV on days 2, 4, 6, and 8	14
Methotrexate	0.4 mg/kg IM or IV daily for 5 days	14
Methotrexate	30–50 mg/m^2 IM	7
Dactinomycin	10 μg/kg (maximum, 0.5mg) IV daily for 5 days	14
Dactinomycin	1.25 mg/m^2	14

[a]Therapy based on World Health Organization risk criteria.
[b]Withhold treatment for marrow recovery if necessary.
IM, intramuscular; IV, intravenous; PO, oral.

dactinomycin if hCG level is less than 300 IU/L.[61,76] Patients who fail initial single-agent therapy with higher levels of hCG should be treated with combination etoposide, methotrexate, and dactinomycin alternating weekly with cyclophosphamide and vincristine (EMA-CO) chemotherapy.[61]

When hCG levels have normalized (<5 IU/L), three additional treatments of chemotherapy past normal are recommended to minimize the potential for recurrence.[6,77] Two additional cycles may be adequate in low-risk patients.

High-Risk Disease

High-risk disease is unlikely to be cured with single-agent chemotherapy. Additionally, these patients are at highest risk of treatment failure. Instead, these patients should be treated with combination therapy, first-line regimen being EMA-CO[78] (Table 42–7). The survival rate for patients with high-risk choriocarcinoma using this regimen is 83%.[79] It is generally well tolerated with toxicity including alopecia, mild anemia, neutropenia, and stomatitis. Reproductive function is preserved in 75% of patients. As for patients with significant tumor burden, rapid tumor necrosis may result in hemorrhage, and thus consideration may be given to a lower dose induction therapy first. After normalization of hCG, three additional consolidation cycles (6 weeks) of EMA-CO are administered.

EMA-CO is considered first-line therapy for high-risk disease (see Table 42–7). Other regimens such as EMA-EP (etoposide, methotrexate, dactinomycin, cisplatin) or the ACE regimen (dactinomycin, cisplatin, and etoposide) appear to be effective but are usually used only in special circumstances or as salvage therapy after failing EMA-CO.[80] Patients should be treated until β-hCG normalizes and then given three postnormalization consolidative cycles of chemotherapy.

Metastases Requiring Special Care

For patients with advanced metastatic disease, certain considerations may need to be taken. For patients with significant vaginal bleeding, resuscitation with blood products may be required until resolution of bleeding may occur, typically within 3 or 4 days. Other temporizing measures to consider may include embolization, hysterectomy, and arterial ligation.[81] Overall, though, death is rare with appropriate resuscitation and management.

Patients with widely metastatic disease, sometimes referred to as being at ultra-high risk, as noted with a WHO score greater than 12, may be at significant risk for pulmonary, intraperitoneal, and intracranial hemorrhage (Fig. 42–5). Therefore, lower dose induction chemotherapy should be considered first followed by full-dose combination chemotherapy to decrease morbidity and mortality. This includes use of induction low-dose etoposide 100 mg/m^2 and cisplatin 20 mg/m^2 (EP; days 1 and 2, every 7 days) to reduce early deaths before starting EMA-CO. In one study, EP induction was given to 23.1% of high-risk patients (33 of 140)

TABLE 42–7 EMA-CO: Preferred First-Line Chemotherapy Regimen for High-Risk[a] Gestational Trophoblastic Disease

Drug Regimen		Administration
Course I (EMA)		
Day 1	Etoposide	100 mg/m^2 IV over 30 minutes
	Methotrexate	300 mg/m^2 IV over 12 hours
	Dactinomycin	0.5 mg IV bolus
Day 2	Etoposide	100 mg/m^2 IV over 30 minutes
	Folinic Acid	15 mg IV/IM/PO every 6 hours for four doses, beginning 24 hours after start of methotrexate
	Dactinomycin	0.5 mg IV bolus
Course II (CO)		
	Cyclophosphamide	600 mg/m^2 IV over 30 minutes
	Vincristine	0.8 mg/m^2 (up to 2 mg) IV bolus
Repeat each regimen in sequence every 14 days as toxicity permits.		

[a]Therapy based on the World Health Organization risk criteria.
[b]In case of central nervous system metastases, the dose of infused methotrexate is increased to 1000 mg/m^2 IV over 12 hours after alkalization of the urine. Increase the number of folinic acid doses to eight given every 6 hours. This regimen is called "high-dose methotrexate EMA-CO."
IV, intravenous; PO, oral.

with large disease burden for one to four cycles, and the early death rate was reduced to only 0.7% compared with 7.2% before its use.[82]

Pulmonary metastases can be extensive and concerning for respiratory failure and death.[83] Some factors associated with respiratory compromise or early death include cyanosis, pulmonary hypertension, dyspnea, anemia, tachycardia, extensive (>50%) lung opacification, mediastinal involvement, bilateral pleural effusion, and an elevated WHO prognostic score.[84] For patients with extensive pulmonary disease, induction chemotherapy, as described earlier, has been suggested to decrease the risk of respiratory failure, although this strategy may not protect against pulmonary failure and death.[84]

Patients with CNS metastasis require additional unique considerations (see Fig. 42–5). These patients may need neurosurgical intervention acutely to manage any bleeding or concern for increased intracranial pressure. Whole-brain radiotherapy may be considered (3000 cGY or radiotherapy over 10 fractions), but this is controversial because no evidence currently exists to support improved long-term outcomes, and instead this may increase risk of memory impairment and secondary cancers.[13] Other centers recommend initiating induction EP repeated weekly for 1 to 3 weeks until stabilized followed by a high-dose methotrexate EMA-CO chemotherapy unless the WHO score is 13 or greater or if other poor prognostic factors are present.[85] In this regimen, the methotrexate dose is increased to 1 mg/m.^{2} Alternatively, intrathecal methotrexate 12.5 mg may be considered with CO, but this should not be concurrently administered with whole-brain radiotherapy because of the risk of multifocal leukoencephalopathy.[86] Intrathecal methotrexate should only be given in a multidisciplinary setting at centers experienced with intrathecal chemotherapy.

For patients with WHO scores of 13 or greater, EP-EMA should be considered instead of EMA-CO with increased methotrexate dose.[82,87] Intrathecal methotrexate may also be given with EP.[86]

At the end of chemotherapy, stereotactic radiotherapy or gamma-knife treatment may be considered to treat any residual unresectable lesions.[61] The overall survival rate in patients with CNS metastasis is as low as 67% with the use of whole-brain radiotherapy combined with chemotherapy,[85] but a cure rate of 88% has been reported with use of chemotherapy alone.[88] Again, patients with CNS metastases should be ideally managed in a multidisciplinary manner at a high-volume center.

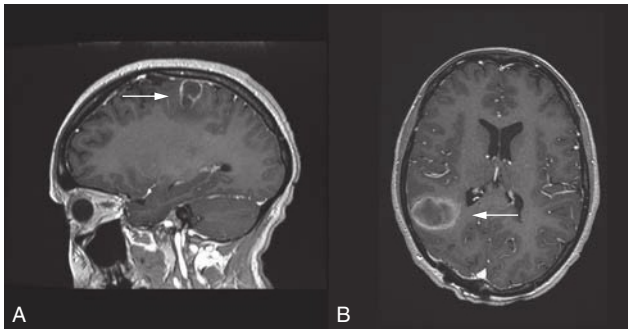

FIGURE 42–5 Magnetic resonance imaging scan of the brain of a patient with metastatic choriocarcinoma. A. Sagittal section of the brain. B. Horizontal section of the brain. *Arrows* demonstrate a metastatic lesion.

Patients in First Remission

Patients in first remission with high risk of recurrence are monitored closely with serum β-hCG levels and posttreatment baseline radiologic imaging. Patients with lung metastases should have a repeat high-resolution CT scan at the end of chemotherapy to serve as a baseline for follow-up. Often, these patients may have residual nodules seen on imaging indicating fibrous scar tissue. Similarly, patients with brain metastases should have MRI of the head obtained at the end of therapy, and patients with liver metastases should have a CT scan of the abdomen. If the uterus remains in place, a baseline MRI of the pelvis should also be considered. This is because modest increases in β-hCG levels signifying relapse may be accompanied by subtle changes in previously "sterile" lesions seen on initial posttreatment images. In certain situations, these solitary or oligometastatic "resistant" lesions may be amenable to surgical resection. If the imaging obtained after chemotherapy reveals suspicious nodules or masses while β-hCG levels are normal, a positron emission tomograph (PET)–CT scan may be warranted to serve as a baseline.[89] If the β-hCG level rises during follow-up, PET-CT helps identify any active disease.[89]

Salvage Therapy

Although most patients with GTN re cured with standard therapy, 20% to 25% of patients with high-risk metastatic disease will have persistent or recurrent GTN. For these patients, surgical resection, alternative chemotherapy often with a platinum-based regimen (Table 42–8), and immunotherapy should be considered.

The most commonly used chemotherapy regimen is EP-EMA, with omission of day 2 etoposide and dactinomycin and alternating weekly with etoposide and cisplatin. This has a cure rate greater than 75% but is associated with significant toxicity[64,90] (see Table 42–8). Some evidence suggests that TE/TP (paclitaxel and etoposide alternating weekly with paclitaxel and cisplatin) may be equally as efficacious but with less toxicity.[6,91] Other therapies may include ACE; VIP (etoposide, ifosfamide, and cisplatin); BEP (bleomycin,

TABLE 42–8 Common Salvage Therapies for Gestational Trophoblastic Disease

Drug Regimen		Administration
EP/EMA		
Course 1 (EP)	Etoposide	150 mg/m² IV over 1 hour
	Cisplatin	25 mg/m² IV over 4 hours
	Cisplatin	25 mg/m² IV over 4 hours
	Cisplatin	25 mg/m² IV over 4 hours
Course 2 (EMA)	Dactinomycin	0.5 mg IV bolus
	Etoposide	100 mg/m² IV over 1 hour
	Methotrexate	300 mg/m² IV over 12 hours
	Folinic acid	15 mg PO/IV every 12 hours for four doses starting 24 hours after start of methotrexate
EP alternates with EMA every 7 days.		
TE/PT		
Course 1 (TE[a])	Paclitaxel	135 mg/m² IV over 3 hours
	Etoposide	150 mg/m² IV over 1 hour
Course 2 (PT[a])	Cisplatinum	60 mg/m² IV over 2 hours
	Paclitaxel	135 mg/m² IV over 3 hours
TE alternates with PT every 14 days.		

[a]Given with premedications dexamethasone 20 mg orally (PO) 12 hours before paclitaxel, dexamethasone 20 mg PO 3 to 6 hours before paclitaxel, ranitidine 50 mg intravenous (IV) bolus 30 to 60 minutes before paclitaxel, and chlorphenamine 10 mg IV bolus 30 to 60 minutes before paclitaxel.
Data from Newlands ES, Mulholland PJ, Holden L, et al: Etoposide and cisplatin/etoposide, methotrexate, and actinomycin D (EMA) chemotherapy for patients with high-risk gestational trophoblastic tumors refractory to EMA/cyclophosphamide and vincristine chemotherapy and patients presenting with metastatic placental site trophoblastic tumors, J Clin Oncol 2000 Feb;18(4):854-859 and Wang J, Short D, Sebire NJ, et al: Salvage chemotherapy of relapsed or high-risk gestational trophoblastic neoplasia (GTN) with paclitaxel/cisplatin alternating with paclitaxel/etoposide (TP/TE), *Ann Oncol* 2008 Sep;19(9):1578-1583.

etoposide, and cisplatin); cisplatin, vincristine, and methotrexate; PVB (cisplatin, vinblastine, and bleomycin); PEBA (cisplatin, etoposide, bleomycin, and doxorubicin); ICE (high-dose ifosfamide, carboplatin, and etoposide); and combinations with gemcitabine or capecitabine.[90] Outcomes vary, and response rates range from 20% to 75%.

PET-CT may be used to detect isolated metastases, which may benefit from surgical resection.[92] For example, in one study, 39% of patients underwent resection of resistance foci of disease with a long-term survival rate of 82%.[93]

Furthermore, immunotherapy is currently being investigated as a novel approach to treatment in patients with multidrug-resistant GTN. Programmed cell death ligand 1 (PD-L1) is a transmembrane protein that binds to programmed cell death protein 1 (PD-1), a checkpoint molecule that transmits an inhibitory signal to T-cells. Monoclonal antibodies against PD-L1 and PD-1, examples of checkpoint inhibitors, have demonstrated impressive clinical response in patients with a variety of cancer types. PD-L1 is strongly expressed in patients with GTN,[94–96] and thus use of checkpoint inhibitors has been investigated as a potential therapeutic for this malignancy.

This preclinical data are further supported by a small case series of four patients with drug-resistant GTN treated with an anti-PD-1 monoclonal antibody, in which three of the four demonstrated remission.[97] Currently, a multicenter phase II clinical trial, TROPHIMMUN (NCT03135769) is underway to evaluate the use of avelumab, an anti-PD-L1 monoclonal antibody in patients with GTN resistant to monochemotherapy or polychemotherapy. Preliminary results suggest that immunotherapy in this disease may be effective and better tolerated than standard chemotherapy.[98]

However, the risk of permanent fertility impairment caused by lasting antitrophoblast immunity is a concern that requires further investigation before immunotherapies can be recommended for patients with GTN, particularly as an earlier line therapy. A case report regarding a patient from the TROPHIMMUN trial presents the first report of a healthy baby born after use of this immunotherapy treatment for GTN, providing some promise for the use of immunotherapy in GTN while still preserving fertility.[99]

Placental Site Trophoblastic Tumor

PSTTs are rare tumors that often occur after a nonmolar gestation. Serum hCG is not uniformly helpful in

diagnosis, treatment, or follow-up.[100] PSTTs are often aggressive with a poor prognosis and generally thought to be less chemosensitive. They present with lung metastasis in 10% to 29% of cases, and an additional 10% will develop metastases during follow-up.[100] One study reported that the overall mortality rate for PSTT is roughly 16% to 21%[67]; however, advanced-stage disease may be more concerning because another study demonstrated that 88% of patients with early disease were disease free at 28 months after diagnosis compared with 11% of patients with advanced-stage disease.[37]

FIGO scoring is not helpful to determine treatment. Instead, treatment is dictated by the presence of metastatic disease and years since antecedent pregnancy. For patients with nonmetastatic disease who present less than 4 years after an antecedent pregnancy, the primary treatment is hysterectomy with ovarian conservation.[100] Routine lymphadenectomy is of limited utility, and only sampling and removal of suspicious lymph nodes is recommended.[37] For patients with metastatic disease who present less than 4 years after antecedent pregnancy, EP-EMA is recommended with subsequent surgical resection of residual disease and hysterectomy if there is demonstrated response.[90] Patients with unresectable recurrent disease may require radiation or combination chemotherapy with EMA-CO or TE/TP.[90]

Patients who present more than 4 years after a prior pregnancy have a worse prognosis, with a 100% mortality rate compared with 98% long-term survival of patients presenting within 4 years.[100] As a result, these patients should consider high-dose chemotherapy or clinical trials regardless of extent of disease.[100]

Epithelioid Trophoblastic Tumor

ETT is a rare disease and is generally more aggressive than PSTT and choriocarcinoma. It is also considered less chemosensitive than choriocarcinoma, and thus surgical treatment is incorporated into management. Patients are treated similar to those with PSTT.

CO-TWIN PREGNANCY

It is estimated that a healthy co-twin pregnancy developing alongside a complete or partial hydatidiform mole occurs in 1 in 20,000 to 100,000 pregnancies.[3] Co-twin pregnancies may typically be detected by pelvic ultrasound, but additional tests such as amniocentesis and chromosome analysis may be necessary. This has been demonstrated in both spontaneous as well as in vitro fertilization pregnancies. However, this may presumably increase with the increase use of ovulation induction agents.[101] Some suggest termination of the pregnancy because of the low probability of a successful outcome and possible increased risk of development of malignant disease.[102] However, recent studies have suggested that 38% to 57% of women delivery a healthy baby, without increase risk of malignant transformation of the hydatidiform mole.[103] Other potential risks associated with these pregnancies include severe complications such as preeclampsia, hemorrhage, and thyrotoxicosis, which typically occur in the second trimester.[104] Preterm delivery is also a concern. Overall, the decision on any therapy should be made after thorough discussion with the patient in conjunction with a perinatologist and gynecologic oncologist with careful risk assessment for both the mother and the fetus.

FUTURE CHILDBEARING AND SURVIVORSHIP

Women successfully treated for molar pregnancy have a 1% risk of future molar pregnancy.[41] Furthermore, women with complete moles have higher risk of recurrence compared with women with partial moles.[105] After 6 months of surveillance with no elevation in β-hCG levels, patients may consider conception. However, future pregnancies should be monitored closely because of the higher risk of repeat molar disease. For women who underwent chemotherapy, 83% are able to conceive despite prior therapy, and most patients are able to carry a pregnancy to term with a successful live birth.[41]

In terms of effects of chemotherapy, EMA-CO has been shown to induce menopause 3 years earlier than anticipated for women.[61] The evidence to support risk of secondary primary malignancy, such as acute myelogenous leukemia and thyroid carcinoma, is inconclusive.[3] Additionally, survivorship concerns center around issues of sexual dysfunction and reproductive quality of life and disproportionately affect socially disadvantaged patients.[6,106]

CONCLUSION

GTD represents a wide spectrum of neoplastic disease that arises from placental trophoblastic tissue after abnormal fertilization. Patients are stratified into prognostic groups based on the FIGO 2000 staging system incorporating the modified WHO scoring system. This integrates factors such as tumor histologic subtype, extent of disease, hCG titer level, duration of disease, nature of antecedent pregnancy, and extent of prior treatment. Each patient should receive individualized treatment after careful stratification under the care of a multidisciplinary team. Surgery and chemotherapy play important roles in effective management of these patients. Additionally, careful follow-up with regular laboratory tests of β-hCG levels is essential to success.

MD ANDERSON PRACTICE TIPS

- Hydatidiform moles are curable and treated with surgery. Suction evacuation and curettage under ultrasound guidance is recommended; patients who have completed childbearing may undergo a hysterectomy.
- Patients with low-risk GTN (score 0–6) may be treated with single-agent therapy such as methotrexate or dactinomycin.
- Patients with high-risk GTN (score >6) are recommended to undergo combination therapy, most often with EMA-CO as first-line treatment. If at all possible, these patients should be cared for either at or in conjunction with a referral center with experience with GTN.
- Patients with widely metastatic disease at risk of significant risk of pulmonary, intraperitoneal, or intracranial hemorrhage should be considered for induction chemotherapy (etoposide and cisplatin) followed by full-dose combination chemotherapy.
- For the 20% to 25% of patients with persistent or recurrent GTN, a variety of salvage therapy options are available, including surgical resection, alternative platinum-based chemotherapy regimens, and immunotherapy.
- Patients with GTD should use reliable contraception throughout surveillance, during treatment, and for 6 to 12 months after normalization of hCG levels.

KEY CONCEPTS

- The International Metastatic RCC Database Consortium (IMDC) and Memorial Sloan Kettering risk scores have become important tools to aid in the selection of first-line treatment of patients with metastatic clear cell renal cell carcinoma (RCC). The IMDC risk score includes the following risk factors: elevated serum corrected calcium level, anemia, Karnofsky performance score less than 80, systemic treatment for metastatic disease within 1 year, absolute neutrophil count greater than the upper limit of normal (ULN), and platelet count greater than the ULN.
- As of 2020, contemporary first-line treatment options for metastatic RCC (mRCC) include nivolumab plus ipilimumab, pembrolizumab plus axitinib, avelumab plus axitinib, and cabozantinib. The only first-line treatments to demonstrate improved overall survival (OS) compared with sunitinib are nivolumab plus ipilimumab (CheckMate 214) and pembrolizumab plus axitinib (KEYNOTE-426).
- Contemporary second-line or later treatment options for mRCC include cabozantinib, nivolumab, lenvatinib plus everolimus, and axitinib. There is limited prospective evidence for treatment sequencing after contemporary first-line therapies, which presents a challenge for clinicians.
- Patients with metastatic non–clear cell RCC have inferior outcomes compared with patients with metastatic clear cell RCC, and treatment outcomes vary by histologic subgroup of non–clear cell RCC. In general, patients with metastatic non–clear cell RCC should be referred to a tertiary cancer center for enrollment in clinical trials.
- Adjuvant treatment for locally advanced RCC is not currently standard of care. Adjuvant treatment with vascular endothelial growth factor (VEGF)–targeted therapy has not consistently improved OS. Adjuvant treatment with checkpoint inhibitors is currently being evaluated in prospective clinical trials.
- The efficacy and timing of cytoreductive nephrectomy (CN) for patients with intermediate- or poor-risk mRCC receiving VEGF-targeted therapy were called into question by the CARMENA and SURTIME trials. At MD Anderson Cancer Center, CN is not recommended for patients with poor-risk disease, and in most patients with intermediate-risk disease, we begin with systemic therapy and reserve CN for patients with a response to treatment and good performance status.

INCIDENCE AND DIAGNOSIS

According to the World Health Organization Global Cancer Observatory (GLOBOCAN) database, there were estimated to be 60,336 new cases of kidney cancer in the United States in 2018, and 15,333 patients were projected to die as a consequence of disease progression.[1] Renal cell carcinoma (RCC) is the most common histology found in kidney tumors, with clear cell RCC (ccRCC) being the most common histologic subtype (Fig. 43–1). Non–clear cell RCC (nccRCC) subtypes include chromophobe, papillary, oncocytoma, collecting duct carcinoma, renal medullary carcinoma (RMC), translocation, and unclassified RCC.

In a 2015 analysis of multiple international databases, the incidence of RCC varied significantly worldwide, and in general, the incidence of RCC has steadily increased for several decades, including in the United States.[2] In contrast, the mortality rate for RCC has steadily declined since the 1990s in high-resource countries, such as those in North America, Europe, and Australia. In the United States, the rising incidence of RCC is largely attributed to increased detection of localized tumors. In an analysis of the Surveillance,

Photomicrographs of a type 1 papillary RCC (C) showing papillae lined by short cuboidal cells and a type 2 papillary RCC (D) showing papillae lined by tall columnar cells, with eosinophilic cytoplasm and high-grade nuclear features. (Used with permission from Pheroze Tamboli, MD.)

Epidemiology, and End Results database from 1988 to 2006, whereas the incidence of localized RCC has increased rapidly, the incidence of distant RCC has declined.[3] Many have speculated that increased use of computed tomography (CT) imaging may be contributing to this finding.

STAGING, GENETIC AND CLINICAL RISK FACTORS

The eighth American Joint Commission on Cancer (AJCC) Tumor, Node, Metastasis staging system for RCC was updated in 2017.[4] In this staging schema, T1 and T2 tumors are limited to the kidney, T3 tumors extend into major veins or perinephric tissue, and T4 tumors invade beyond Gerota's fascia. N and M stage refer to the presence of regional lymph nodes or distant metastatic disease, respectively. Major staging categories are as follows: stage 1 is a T1N0 cancer, stage 2 is a T2N0 cancer, stage 3 can be T3N0-1 or T1-2N1 cancer, and stage 4 refers to any T4 or M1 cancer.

The link between germline genetic mutations and the development of RCC is well established and applies to a small but biologically important subset of RCC cases.[5] Known hereditary kidney cancer syndromes include hereditary papillary renal cancer (*c-MET* gene), hereditary leiomyomatosis and RCC syndrome (*fumarate hydratase [FH]* gene), Birt-Hogg-Dube syndrome (*FLCN* gene), tuberous sclerosis complex (*TSC1* and *TSC2* genes), von Hippel-Lindau

disease (*VHL* gene), and hereditary BAP-1-associated RCC (*BAP1* gene).[6] Although these genomic alterations play an important role in the biology of RCC in both familial and sporadic cases, environmental factors also contribute to the risk of developing a renal neoplasm. Smoking is associated with an increased risk of developing RCC. In a meta-analysis of 24 studies, current smokers had a relative risk (RR) of RCC incidence of 1.36, and the RR was lower but still elevated for former smokers (1.16).[7]

Obesity or increased body mass index (BMI) has also been linked to increased risk of developing RCC. Several studies have demonstrated a higher incidence of obesity or increased BMI in patients with RCC, suggesting an epidemiologic linkage.[8,9] However, studies have also shown that patients with high BMIs have a more favorable prognosis after surgery and improved survival in patients with metastatic disease who are treated with angiogenesis-targeted therapy, coined "the obesity paradox."[10,11] Additional possible risk factors for RCC include hypertension, diabetes mellitus, acquired polycystic kidney disease in dialysis patients, and occupational exposures (eg, cadmium, petroleum byproducts, asbestos).

RISK ASSESSMENT AND MOLECULAR BIOMARKERS

The natural history of RCC widely ranges depending on both tumor genetic factors and clinical prognostic factors. For patients who present with localized disease, nephrectomy can be curable, but a subset of patients who undergo a nephrectomy with curative intent will go on to develop metastatic disease. Additionally, some patients with RCC present with metastatic disease, and mRCC generally carries a poor prognosis. The traditional measures of performance status, tumor stage, and tumor grade each demonstrate good correlation with clinical outcome.[8] A variety of additional clinical, pathologic, and molecular features are associated with prognosis (Table 43–1).[9,10] In the localized setting, several nomograms incorporate histopathologic factors to predict the risk of recurrence, such as the Memorial Sloan Kettering (MSKCC) postoperative nomogram; the stage, size, grade, and necrosis (SSIGN) score for RCC; and the UCLA Integrated Staging System for RCC.[12–14] Furthermore, multigene panels have been developed to assist in prognostication of localized RCC at the time of surgery, including ClearCode 34 and the 16-gene recurrence score.[15,16]

Prognostic Models for Risk Assessment in Metastatic Renal Cell Carcinoma

In 1999, Motzer et al[17] identified five risk factors (elevated serum corrected calcium level, anemia, lactate dehydrogenase >1.5 times the upper limit of normal [ULN], Karnofsky performance score [KPS] <80, and primary tumor in place) that segregated patients into three risk groups (good, zero factors; intermediate, one or two factors; and poor, three or more factors).[17] In 2002, an updated version, now referred to as the MSKCC risk criteria (also referred to as the "Motzer criteria"), was published with the original four risk factors, with the fifth being treatment with interferon within 1 year of diagnosis.[18] For clinical trial purposes, the fifth factor is often considered time to initiation of systemic therapy within 1 year from initial diagnosis of RCC. With the introduction of targeted therapy, the

TABLE 43–1 Prognostic Factors in Metastatic Renal Cell Carcinoma

Patient- or Treatment-Related Factors	Laboratory Studies	Tumor-Related Factors	Molecular Markers
Performance status	Lactate dehydrogenase	Site or number of metastatic sites	*ClearCode 34, cell cycle progression score, 16-gene RS*
Age, gender, race	Alkaline phosphatase	Disease-free interval	*BAP1, SETD1,* and *PBRM1* mutations
Symptoms: weight loss, fatigue, pain, loss of appetite, fever	Calcium	Metastasis-free interval	Carbonic anhydrase IX expression
Overweight	Albumin	Tumor burden	p53 overexpression
Prior nephrectomy	Liver dysfunction	Histologic type	IMP3 expression
Prior therapy	Anemia, neutrophilia	Sarcomatoid dedifferentiation	
	Thrombocytosis	Ploidy	

International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) was formed, and a modified prognostic scoring system was put forth in 2009 and externally validated in 2013.[19,20] The IMDC prognostic scoring system (also referred to as the "Heng score") has six risk factors (elevated serum corrected calcium level, anemia, KPS <80, systemic treatment for metastatic disease within 1 year, absolute neutrophil count >ULN, and platelet count >ULN). Similar to the MSKCC scoring system, good risk is defined as zero risk factors, intermediate risk as one to two risk factors, and poor risk as three or more risk factors. Although other systems have been proposed, the MSKCC and IMDC remain the most widely used (Table 43–2).

Molecular Pathogenesis and Biomarkers

ccRCC is characterized by early loss of *VHL,* a tumor suppressor gene that encodes a protein responsible for ubiquitination and proteasomal degradation of hypoxia-inducible factor (HIF). When there is a loss-of-function alteration to *VHL,* accumulation of HIF results in increased expression of vascular endothelial growth factor (VEGF), platelet-derived growth factor subunit B, and other proteins that mediate glucose transport, proliferation, and angiogenesis.[21] In The Cancer Genome Atlas (TCGA) study of patients with ccRCC, the most common genomic alterations were found in *VHL* (55%), *PBRM1* (38%), *SETD2* (13%), *KDM5C* (7%), *BAP1* (11%), and *PTEN* (5%).[22] Of note, *VHL*, *SETD2* (a histone methyltransferase), *BAP1* (histone deubiquitinase), and *PBRM1* (part of chromatin remodeling complex) all lie on chromosome 3p.

Interest in predictive and prognostic genomic biomarkers for RCC has grown as next-generation sequencing technology has become widely available; however, genomic biomarkers are not routinely used to guide treatment selection for patients with mRCC and remain an area of active research. *PBRM1*, *TP53*, and *BAP1* consistently appear to be prognostic across studies of single-gene biomarkers for RCC. In a study of 145 patients with localized RCC, mutations in *BAP1* were associated with poor survival (median overall survival [OS], 4.6 years), bit mutations in *PBRM1* were associated with improved OS (median OS, 10.6 years).[23] In a separate TCGA study of 538 patients with ccRCC, *BAP1*, *TP53*, and *CDKN2A* were associated with inferior OS.[22] Finally, in a retrospective analysis of the COMPARZ and RECORD-3 trials, mutations in TP53 or BAP1 and absence of mutation in PBRM1 were prognostic of inferior OS.[24] Single-gene alterations have not been shown to predict response to treatment in patients with mRCC. However, gene expression signatures of angiogenesis have shown promise in predicting response to VEGF-targeted therapy in three separate studies.[25–27] Programmed cell death ligand 1 (PD-L1) expression does not appear to predict response to immune checkpoint inhibitors in patients with mRCC.

MANAGEMENT OF NONMETASTATIC RENAL CELL CARCINOMA

With the introduction of improved cross-sectional imaging, the detection of renal masses has increased substantially. At present, the majority of renal masses

TABLE 43–2 The Memorial Sloan Kettering Cancer Center (MSKCC) Modified Risk Score for Metastatic Renal Cell Carcinoma and the International Metastatic Renal Cell Database Consortium (IMDC) Risk Score with Survival by Risk Stratification

MSKCC 2002 Factors (1 point each)	Risk Group (points)	Overall Survival (months)	IMDC Risk Score (1 point each)	Risk Group (points)	Overall Survival (months)
Anemia	Good (0)	30	Anemia	Good (0)	43
Elevated calcium			Elevated calcium		
KPS <80	Intermediate (1–2)	14	KPS <80	Intermediate (1–2)	22.5
Metastatic treatment within 1 year of diagnosis			Metastatic treatment within 1 year		
LDH >1.5× ULN	Poor (3–5)	5	Platelet count >ULN	Poor (3–6)	7.8
			Neutrophil count >ULN		

KPS, Karnofsky performance score; LDH, lactate dehydrogenase; ULN, upper limit of normal.

are detected incidentally and not through the classic triad of palpable mass, hematuria, and flank pain. When evaluating a patient with a renal mass, cross-sectional imaging with a CT renal mass protocol is most useful to delineate anatomical nuances that could help determine the surgical approach in appropriate patients. Magnetic resonance imaging is not routinely used but is particularly helpful in evaluating patients with indeterminate renal cystic lesions, in patients with limited renal function when no contrast can used, and in patients with renal mass and inferior vena cava (IVC) tumor thrombus.

By definition, a small renal mass (SRM) is any mass in the kidney that is 4 cm or smaller in size (cT1a). These SRMs could represent benign renal tumors (~20%), malignant renal tumors, metastatic tumors to the kidney, and rarely an infectious process. Management of patients with a SRM depends on a multitude of patient and tumor factors, including age, comorbidities, concurrent malignancies, renal function, size of the mass, rate of growth of the mass (if known), and biopsy results (if known). Most patients do not require a renal mass biopsy (RMB). For patients with SRM, an RMB (multiple core biopsies, not fine-needle aspiration) is generally performed when the results of such an intervention could result in a change in patient management. RMB has an acceptable very low complication rate and a good diagnostic rate (~90%).[28] In the setting of patients with concurrent malignancies, it is important to carefully review the imaging because tumors metastatic to the kidney generally have a different appearance than RCC, especially when small in size. Metastases to the kidney are generally ill-defined and more infiltrative and mainly occur in the presence of metastases to other organs as well. If indicated, an RMB can be done in this setting, especially when the renal mass is isolated without other evidence of disease.

Active surveillance is now an established approach for managing well-selected patients with SRM. Generally, these are patients with multiple comorbidities and concurrent active malignancies receiving systemic therapy. Several retrospective series, meta-analyses, and prospective cohort studies note that the rate of developing metastatic RCC while on active surveillance is encouragingly low (<2%).[29–32] These patients can be followed every 3 to 6 months initially for the first 2 years, with imaging tailored for individual patient situations. For patients with concurrent active malignancies, the imaging for active surveillance of the SRM can be combined with the primary tumor imaging, granted that IV contrast is needed, because noncontrast CT (eg, in positron emission tomography–CT) is not helpful for the purposes of active surveillance.

Percutaneous thermal ablation—with radiofrequency ablation, cryoablation, and more recently microwave ablation—is another treatment modality for select patients with SRM. Traditionally, thermal ablation has been used in patients who are older and with comorbidities, but more recent results from centers of excellence with longer follow-up period are expanding the use of this treatment modality beyond this population. In a retrospective cohort of more than 1400 patients with SRMs, local recurrence-free survival was similar among partial nephrectomy, cryoablation, and radiofrequency ablation, but metastases-free survival was better with partial nephrectomy or cryoablation compared with radiofrequency ablation. Not surprisingly, patients treated with partial nephrectomy were younger and healthier compared with those treated with thermal ablation, and their OS was higher.[33] Generally, the smaller the tumor, the higher the likelihood of success of thermal ablation techniques.[34] The main advantages of thermal ablation are the low rate of serious adverse events, the short recovery period after the procedure, and preservation of renal function. The main disadvantages include need for long-term follow-up and potential need for repeat biopsy if a recurrence is suspected on imaging. In addition, if a local recurrence is detected and repeat ablation is not deemed feasible, salvage surgery (partial or radical nephrectomy) is generally difficult because of postablation desmoplastic reaction.

Partial nephrectomy is still the gold standard for treating the majority of patients with SRM. It provides an accurate diagnosis, ascertains a complete resection, preserves renal function, and can provide the best curative potential in the majority of patients (>95%). Partial nephrectomy is mainly done with robotic-assisted laparoscopic approach at present, although it can also be done using a traditional open surgical approach or pure laparoscopic approach in selected patients. The robotic-assisted laparoscopic approach has the advantage of lower blood loss, lower postoperative complications, shorter hospital stay, and quicker recovery and return to normal activity compared with the open approach, although the vast majority of studies to date are retrospective and subject to selection bias.[35–37] An ongoing clinical trial (the OpeRa trial) is currently comparing these two partial nephrectomy approaches, with an expected study completion date of 2022 (NCT03849820).

Radical nephrectomy is generally considered for patients with SRM in rare cases when partial nephrectomy is deemed technically not feasible even with expert centers or urologic oncologists.[38]

For most patients with cT1b masses and for almost all patients with cT2 and higher tumors, radical nephrectomy is generally indicated, with some exceptions. Radical nephrectomy is generally performed with a minimally invasive approach (robotic-assisted laparoscopic or pure laparoscopic), with open radical nephrectomy reserved for patients with very large tumors or locally advanced tumors involving the IVC or adjacent organs. Patients with IVC tumor thrombus (cT3b and cT3c)

without evidence of metastatic disease should undergo prompt surgical resection by an experienced urologic oncologist with the assistance of vascular or thoracic surgery as needed. These patients should generally not undergo biopsy (as to not delay care), not receive any neoadjuvant systemic therapy (unless on a clinical trial or if the patient is not a surgical candidate after review in a multidisciplinary setting), and not undergo preoperative renal artery embolization. Patients with cT4 disease are rare (~1% of patients undergoing radical nephrectomy) and generally have poor prognosis, although some patients can be cured with multidisciplinary care and aggressive surgical resection.[39] If these patients are suspected to have sarcomatoid dedifferentiation based on imaging features, a biopsy should be obtained, and consideration should be given for neoadjuvant immunotherapy given the poor outcomes of patients with cT4 and sarcomatoid dedifferentiation.

Generally, ipsilateral adrenalectomy is performed when there is radiographic evidence of tumor involvement and not as a routine part of radical nephrectomy.[40] Similarly, lymph node dissection is generally performed when there is suspicion for lymph node involvement on preoperative imaging or intraoperatively because the rate of positive lymph nodes (pN1) is low in the setting of cN0.[41]

Patients with local recurrence after definitive therapy with thermal ablation, partial nephrectomy, or radical nephrectomy can still be potentially cured in the absence of concurrent metastatic disease by repeat thermal ablation, salvage partial nephrectomy or radical nephrectomy, or salvage surgical resection of local recurrence in appropriate surgical candidates.[42–44]

Adjuvant Treatment for High-Risk Localized or Locally Advanced Renal Cell Carcinoma

Because of the poor prognosis of mRCC, four clinical trials have assessed adjuvant VEGF-targeted therapy in patients with locally advanced RCC, and four trials are currently investigating adjuvant immunotherapy. The S-TRAC, ASSURE, PROTECT, and ATLAS trials have produced mixed results in regard to disease-free survival (DFS), but none has significantly improved OS. S-TRAC was a phase III clinical trial that randomized 615 patients with high-risk RCC to adjuvant sunitinib or placebo for 1 year or until disease recurrence.[45] High-risk RCC was defined as T stage 3 or greater, regional lymph node involvement, or both. Adjuvant sunitinib improved DFS by 24% (6.8 vs 5.6 years; hazard ratio [HR], 0.75; 95% confidence interval [CI], 0.59–0.98), but OS did not significantly differ between the two arms (HR, 0.92; 95% CI, 0.66–1.28).[45] Furthermore, grade 3 or higher adverse events were more frequently reported in patients who received adjuvant sunitinib (63.4% vs 21.7%).

In the phase III ASSURE trial, 1943 patients with pathologic T stage 1b or greater were randomized 1:1:1 to sunitinib, sorafenib, or placebo.[46] No significant differences in DFS or OS were observed between sunitinib and placebo (DFS HR, 1.02; 95% CI, 0.85–1.23; OS HR, 1.17; 95% CI, 0.90–1.52) or sorafenib and placebo (DFS HR, 0.97; 95% CI, 0.80–1.17; OS HR, 0.98; 95% CI, 0.75–1.28). In a subgroup analysis of high-risk patients using the definition established in the S-TRAC trial, there remained no difference in DFS or OS between sunitinib or sorafenib versus placebo.[47]

PROTECT was a phase III trial that evaluated pazopanib versus placebo in 1538 patients with high-risk locally advanced RCC.[48] Pazopanib did not significantly improve DFS compared with placebo (HR, 0.86; 95% CI, 0.70–1.06), and it caused frequent alanine aminotransferase and aspartate aminotransferase elevations.

Finally, 724 patients with pathologic T stage 2 or greater or node-positive disease were randomized to axitinib or placebo for 1 to 3 years in the phase III ATLAS trial. The trial was discontinued because of futility at a preplanned interim analysis (DFS HR, 0.87; 95% CI, 0.66–1.15).[49] In a pooled meta-analysis of the S-TRAC, ASSURE, and PROTECT trials, adjuvant VEGF-targeted therapy was not significantly associated with improved DFS or OS, and it significantly increased the odds of grade 3 to 4 adverse events.[50]

Four clinical trials are currently evaluating immune checkpoint inhibitors as adjuvant therapy for high-risk localized or locally advanced RCC. KEYNOTE-564 and IMmotion010 are randomizing patients to pembrolizumab and atezolizumab, respectively, or placebo for 1 year after nephrectomy or metastasectomy. In CheckMate 914, 800 patients with high-risk localized RCC are being randomized to nivolumab plus ipilimumab or placebo for 6 months after nephrectomy. Finally, PROSPER RCC is assigning 805 patients with high-risk localized RCC to nivolumab or placebo, and patients will receive two doses as neoadjuvant treatment proceed to nephrectomy and then finish 1 year of adjuvant therapy. At MD Anderson Cancer Center (MDACC), we do not routinely use adjuvant VEGF-targeted therapy for patients with high-risk localized RCC, and we await the results of ongoing clinical trials before using adjuvant immunotherapy.

METASTATIC DISEASE WITH CLEAR CELL HISTOLOGY

Role of Cytoreductive Nephrectomy in Metastatic Disease

Surgical resection of the primary tumor, cytoreductive nephrectomy (CN), has been shown to improve OS in select patients with mRCC. In the cytokine era

of high-dose interleukin-2 (HDIL-2) and interferon-α (IFN-α), two phase III clinical trials, SWOG 949 and EORTC (European Organization for Research and Treatment of Cancer) 30947, found that IFN-α plus CN improved OS compared with IFN-α alone.[51,52] A pooled analysis of these two trials demonstrated an improvement in median OS from 7.8 months to 13.6 months with IFN-α plus CN.[53] Questions regarding the benefit of CN reemerged after the introduction of targeted therapies for mRCC. In a retrospective analysis of the IMDC database, patients treated in the targeted-therapy era appeared to benefit from CN if they had three or fewer IMDC prognostic risk factors, whereas those with four or more factors did not appear to benefit.[54] In a systematic review of 10 observational studies that evaluated CN in the targeted-therapy era, all of the point estimates for OS favored CN.[55]

CARMENA is the only randomized clinical trial to compare CN followed by sunitinib with sunitinib alone in patients with MSKCC intermediate or poor-risk mRCC, and it was designed as a noninferiority trial.[56] In CARMENA, sunitinib alone was noninferior to nephrectomy followed by sunitinib for OS, and survival was longer in the sunitinib alone group. Although CARMENA is the only level I evidence available for CN in the targeted-therapy era, the trial has several limitations. CARMENA planned to enroll 576 patients, but it only accrued 450 patients over an 8-year period, resulting in an underpowered study. There was also high crossover in both directions between the two treatment arms. Finally, guidelines do not recommend CN for patients with poor-risk mRCC, yet CARMENA enrolled a high percentage of patients with MSKCC poor-risk disease (43%). SURTIME is a phase III clinical trial performed during the targeted-therapy era that sought to evaluate whether a period of sunitinib before nephrectomy improved outcomes compared with immediate CN followed by sunitinib.[57] Deferred CN did not improve the primary endpoint of progression-free rate, but deferred CN significantly improved OS (32 vs 15 months). The improved OS seen with deferred CN may be due to the higher percentage of patients who received sunitinib in the deferred arm (98% vs 80%). At MDACC, CN is not recommended for patients with IMDC poor-risk disease, and in most patients with IMDC intermediate-risk disease, we begin with systemic therapy and reserve CN for select patients with a response to treatment and good performance status.

Role of Metastasectomy

In carefully selected patients, metastasectomy plays an important role in the multidisciplinary treatment of patients with mRCC. Retrospective series have found survival benefit in resecting oligometastatic disease from multiple sites. Interpretation of these results is limited because of the highly selected and retrospective nature of these studies. In a pooled analysis of 56 retrospective studies, metastasectomy was associated with a significantly lower risk of death compared with patients who did not receive a metastasectomy.[58] Prognostic factors for OS after metastasectomy included complete resection of metastases, DFS after nephrectomy, primary tumor characteristics, number of metastases, and performance status. Lung metastasectomy was associated with the best survival benefit compared with other anatomic locations. Patients with no measurable disease after metastasectomy are at an increased risk of recurrence. Eastern Cooperative Oncology Group (ECOG)-American College of Radiology Imaging Network (ACRIN) 2810 (NCT01575548) compared 1 year of pazopanib 800 mg with placebo in patients with no evidence of disease after metastasectomy.[59] Pazopanib did not improve the primary endpoint, DFS, compared with placebo, and there was a statistically significant trend toward inferior OS with pazopanib compared with placebo. At MDACC, we strongly believe in a multidisciplinary approach to optimally manage patients with oligometastatic disease, and we do not use systemic therapy for patients without evidence of measurable disease after metastasectomy.

An algorithm to select candidates for metastasectomy and for the approach to postmetastasectomy systemic treatment is shown in Figure 43–2.

SYSTEMIC THERAPY FOR METASTATIC CLEAR CELL RENAL CELL CARCINOMA

Historical Overview

Over the past 15 years, systemic treatment of patients with metastatic ccRCC has evolved from nonspecific cytokine therapies to molecularly targeted therapies and now includes immune checkpoint inhibitors. Beginning in the 1990s until 2005, treatment of patients with mRCC was limited to nonspecific cytokine therapies, IFN-α and HDIL-2. Cytokine therapy, specifically HDIL-2, has the potential to produce durable complete responses (CRs) in a small percentage of patients, but it is limited by the potential of severe toxicity and lack of clinical benefit for the majority of patients who received it.[60] Then from 2005 through 2012, seven targeted therapies were approved to treat patients with mRCC, five against the VEGF pathway (sorafenib, sunitinib, bevacizumab, pazopanib, and axitinib) and two inhibitors of mammalian target of rapamycin

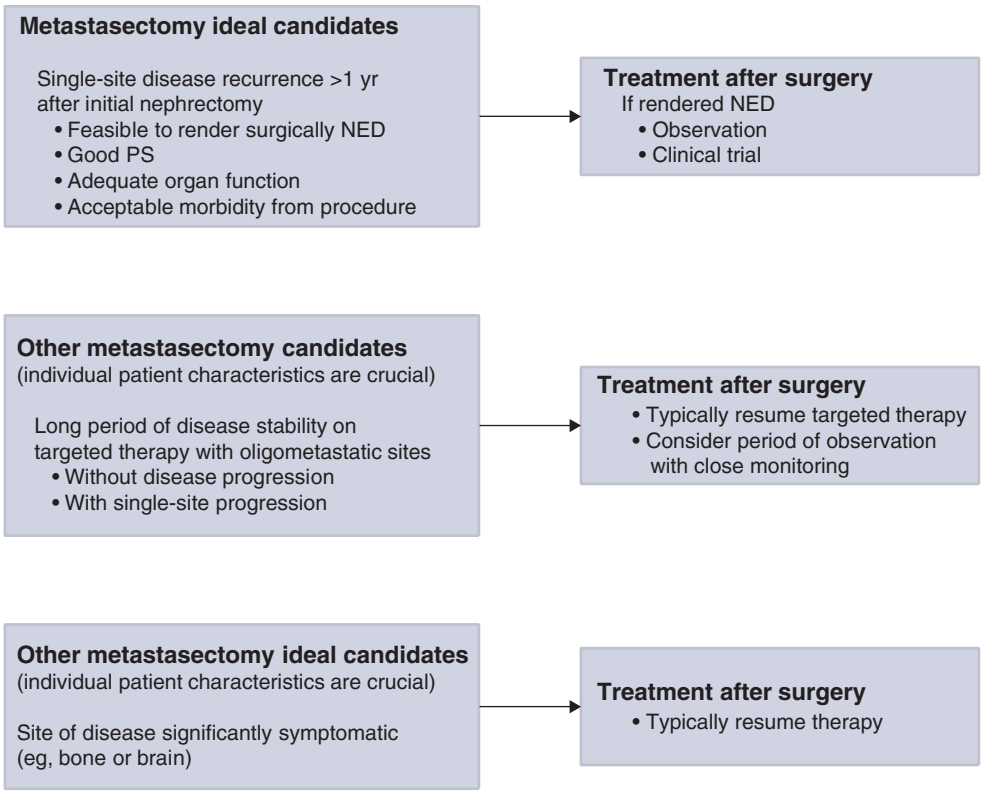

FIGURE 43–2 **Metastasectomy candidates and treatment after procedure. NED, no evidence of disease; PS, performance status.**

(mTOR (mammalian target of rapamycin), temsirolimus, and everolimus).[61–65] Most recently, the introduction of immune checkpoint inhibitors, multitargeted tyrosine kinase inhibitors (TKIs), and incorporation of the MSKCC and IMDC risk scores into clinical decision making has significantly improved outcomes for patients with mRCC.

First-Line Treatment of Metastatic Renal Cell Carcinoma

Nivolumab plus ipilimumab and pembrolizumab plus axitinib are the only first-line therapies to significantly improve OS compared with sunitinib. Nivolumab and pembrolizumab are immune checkpoint inhibitor antibodies against programmed death 1 (PD-1), and ipilimumab is an antibody against anti–cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4). Nivolumab plus ipilimumab was approved as first-line treatment on the basis of CheckMate 214, a phase III clinical trial that randomized patients to nivolumab plus ipilimumab or sunitinib.[66] At 30 months of follow-up, nivolumab plus ipilimumab significantly improved OS (Not reached [NR] vs 26.6 months; HR, 0.66), progression-free survival (PFS; 8.2 months vs 8.3 months; HR, 0.77) and overall response rate (ORR) (42 vs 29%) in the primary cohort of patients with IMDC intermediate- or poor-risk disease (Table 43–3).[67] Notably, 11% of intermediate- or poor-risk patients achieved a CR with nivolumab plus ipilimumab compared with 1% with sunitinib. In the intention-to-treat population, nivolumab plus ipilimumab also significantly improved OS (NR vs 37.9 months; HR, 0.71), PFS (9.7 months vs 9.7 months; HR, 0.85), and ORR (41 vs 34%). However, sunitinib resulted in numerically longer OS (NR vs NR; HR, 1.22), PFS (13.9 months vs 19.9 months), and higher ORR (39 vs 50%) in a subgroup analysis of patients with IMDC favorable-risk disease. In regard to toxicity, nivolumab plus ipilimumab resulted in fewer grade 3/4 adverse effects compared with sunitinib, yet more patients had to discontinue treatment because of adverse events with nivolumab plus ipilimumab, which is likely attributable to the unique toxicity profile of immune checkpoint inhibitors. Also, 29% of patients treated with nivolumab plus ipilimumab required at least 40 mg of prednisone to manage immune-mediated adverse events.

Pembrolizumab plus axitinib was approved as first-line treatment for patients with mRCC on the basis of the KEYNOTE-426 trial.[68] KEYNOTE-426 was a phase III clinical trial that randomized patients to pembrolizumab plus axitinib or sunitinib, and in contrast to CheckMate-214, all IMDC risk cohorts were included in the primary efficacy cohort. At first interim analysis,

TABLE 43–3 Pivotal Trials for First-Line Treatment of Metastatic Renal Cell Carcinoma

Agent(s)	Trial Design	Primary Efficacy Cohort	Patients (*n*)	Median PFS[a] (HR, 95% CI)	Median OS[a] (HR, 95% CI)
Nivolumab + ipilimumab	Nivolumab + ipilimumab vs sunitinib	IMDC intermediate- or poor-risk groups	847	8.2 vs 8.3 (0.77, 0.65–0.90)	NR vs 26.6 (0.66, 0.54–0.80)
Pembrolizumab + axitinib	Pembrolizumab + axitinib vs sunitinib	All IMDC risk groups and PD-L1 status	861	15.1 vs 11.1 (0.69, 0.57–0.84)	NR vs NR (0.53, 0.38–0.74)
Cabozantinib	Cabozantinib vs sunitinib	IMDC intermediate- or poor-risk groups	157	8.6 vs 5.3 (0.48, 0.31–0.74)	26.6 vs 21.2 (0.80, 0.53–1.21)
Avelumab + axitinib	Avelumab + axitinib vs sunitinib	All IMDC risk groups, PD-L1 positive	886	13.8 vs 7.2 (0.61, 0.47–0.79)	N/A (0.78, 0.55–1.08)
Sunitinib	Sunitinib vs IFN-α	All IMDC risk groups	750	11 vs 5 (0.42, 0.32–0.54)	26 vs 22 (0.82, 0.67–1.0)
Pazopanib	Pazopanib vs placebo	All IMDC risk groups	435	9.2 vs 4.2 (0.46, 0.34–0.62)	23 vs 21 (0.91, 0.71–1.16)

[a]All progression-free survival (PFS) and overall survival (OS) values listed are in months.
CI, confidence interval; HR, hazard ratio; mRCC, metastatic renal cell carcinoma.

pembrolizumab plus axitinib significantly improved OS (NR vs NR; HR, 0.53), PFS (15.1 months vs 11.1 months; HR, 0.69), and ORR (59 vs 36%). The benefit of pembrolizumab plus axitinib over sunitinib was observed across all IMDC subgroups and irrespective of PD-L1 expression. The incidence of grade 3/4 adverse events was similar between the two treatment arms (76 vs 71%), as was treatment discontinuation (11% vs 14%).

Cabozantinib, avelumab plus axitinib, sunitinib, and pazopanib have improved PFS but not OS as first-line treatment of mRCC, so these agents may have a role for defined patient populations. CABOSUN was a phase II clinical trial that randomized 157 patients with IMDC intermediate- or poor-risk mRCC to cabozantinib versus sunitinib.[69] Cabozantinib is a multitarget TKI that inhibits VEGF, Mesenchymal Epithelial Transition (MET), and AXL. At 34.5 months of follow-up, cabozantinib significantly improved PFS (8.6 vs 5.3; HR, 0.48) and ORR (20 vs 9%) compared with sunitinib, but the improvement in OS was not statistically significant (26.6 months vs 21.2 months; HR, 0.80).[70] The rate of grade 3/4 adverse events and treatment discontinuation because adverse events was similar between treatment arms. At MDACC, we reserve first-line cabozantinib for patients with IMDC intermediate- or poor-risk disease who are ineligible for immune checkpoint inhibitors.

Avelumab is an immune checkpoint inhibitor antibody against PD-L1. Avelumab plus axitinib was studied against sunitinib in the phase III JAVELIN Renal 101 trial.[71] In contrast to CheckMate 214 and KEYNOTE-426, the primary endpoint was evaluated in patients who were PD-L1 positive, which was defined as 1% or greater expression on immune cells. At first interim analysis, avelumab plus axitinib significantly improved PFS in the PD-L1 positive cohort (13.8 months vs 7.2 months; HR, 0.61) and the intention-to-treat (ITT) cohort (13.8 months vs 8.4 months; HR, 0.69) when compared to sunitinib. OS data were immature at the reported interim analysis, and OS was numerically higher with avelumab plus axitinib but not statistically significant. Avelumab plus axitinib also significantly improved ORR compared with sunitinib in the PD-L1–positive cohort (55% vs 26%) and the ITT cohort (51% vs 26%). However, the CR rate with avelumab plus axitinib was lower than was seen with nivolumab plus ipilimumab (3.4% in ITT cohort). Finally, avelumab plus axitinib was well tolerated with similar grade 3/4 adverse events (71% vs 71%) and treatment discontinuation (7% vs 13%) compared with sunitinib. At MDACC, we do not routinely use first-line avelumab plus axitinib because it has not shown a significant improvement in OS, whereas pembrolizumab plus axitinib and nivolumab plus ipilimumab have. This would likely change if future analyses demonstrate a significant improvement in OS with this combination.

Although the first-line therapies that we have discussed demonstrated superiority in the ITT populations, sunitinib and pazopanib still play a role in the first-line treatment of favorable-risk mRCC, specifically in patients ineligible for immune checkpoint inhibitors. Sunitinib was

approved as first-line treatment on the basis of a phase III trial that randomized patients to sunitinib and IFN-α. In that trial, median PFS was significantly improved with sunitinib (11 months vs 5 months), but median OS did not significantly differ between the two groups (26 months vs 22 months).[72,73] The insignificant difference in OS between the two groups was thought to be secondary to crossover from IFN to sunitinib and salvage therapy after protocol. Pazopanib was another VEGF TKI approved on the basis of a phase III clinical trial that compared pazopanib with placebo in patients who previously received nonspecific cytokine therapy but no other systemic treatment.[74] In that study, pazopanib significantly improved PFS (9.2 months vs 4.2 months; HR, 0.46), but OS was not significantly improved with pazopanib (23 months vs 21 months; HR, 0.91). In a similar fashion to the sunitinib trial, there was high crossover from the placebo arm to pazopanib, which confounded the OS data.[75]

Second-Line or Later Treatment of Metastatic Renal Cell Carcinoma

For patients with progressive disease, contemporary second-line or later treatment consists of nivolumab, cabozantinib, lenvatinib plus everolimus, axitinib, or previously unused combinations of immune checkpoint inhibitors (Table 43–4). Second-line or later nivolumab monotherapy was approved in 2015 on the basis of CheckMate 025, which was a phase III trial comparing nivolumab with everolimus.[76] In CheckMate 025, nivolumab significantly improved OS (25 months vs 20 months; HR, 0.73) and ORR compared with everolimus (25% vs 5%). There was no significant difference in PFS between nivolumab and everolimus (4.6 months vs 4.4 months; HR, 0.88). Nivolumab was well tolerated with less grade 3/4 adverse events (19% vs 37%) and treatment discontinuation because of adverse events (8% vs 13%) than everolimus. The efficacy of nivolumab after prior PD-1 axis inhibition is unclear because CheckMate 025 did not include patients who received first-line immune checkpoint inhibitors, so at MDACC, we generally use second-line nivolumab for patients who received first-line VEGF TKI monotherapy.

The METEOR trial was a phase III clinical trial that compared cabozantinib with everolimus after progression on prior VEGF TKI.[77] Cabozantinib significantly improved the primary endpoint of PFS (7 months vs 4 months; HR, 0.51), as well as OS (21 months vs 17 months; HR, 0.66) and ORR (17% vs 3%) compared with everolimus.[78] In a subgroup analysis of efficacy by prior treatment received, cabozantinib improved survival across all prior treatments, including sunitinib, pazopanib, or immune checkpoint inhibitor.[79] In another subgroup analysis, the efficacy of cabozantinib was maintained in patients who had bone metastases at enrollment.[80] Accordingly, we commonly use second-line or later cabozantinib for our patients with bone metastases at MDACC.

Lenvatinib is a multitarget TKI that inhibits VEGFR, fibroblast growth factor receptor (FGFR), platelet-derived growth factor receptor (PDGFR), rearranged during transfection (RET), and KIT, and it is approved in combination with everolimus for second-line or later treatment of mRCC. Lenvatinib plus everolimus was evaluated in a phase II trial that randomized 153 patients to lenvatinib, everolimus, or lenvatinib plus everolimus.[81] In that trial, lenvatinib plus everolimus significantly improved PFS (14.6 months vs 5.5 months; HR, 0.40) and ORR (43% vs 6%) compared to everolimus. At the time of primary analysis, lenvatinib plus everolimus did not significantly improve OS compared with everolimus, but a post-hoc analysis performed 6 months later found that lenvatinib plus everolimus significantly improved OS compared with everolimus (26 months vs 15 months; HR, 0.51). Lenvatinib plus everolimus produced more grade 3/4 adverse events than everolimus (71% vs 50%), and the most common grade 3/4 adverse events were diarrhea, fatigue, hypertension, and anemia.

Axitinib is a VEGF TKI that is now primarily used in combination with pembrolizumab or avelumab, yet it is also approved as monotherapy for second-line or later treatment of mRCC on the basis of the AXIS trial, which was a phase III trial that compared second-line axitinib with sorafenib.[63] In AXIS, axitinib significantly improved median PFS (7 months vs 5 months; HR, 0.67) and ORR (19% vs 9%) compared with sorafenib. Median OS was not statistically different between the two groups (20 months vs 19 months; HR, 0.97).[82]

Treatment Selection for Patients with Metastatic Renal Cell Carcinoma

Optimal treatment selection and sequencing has become increasingly complicated because of the rapid development of novel therapies for patients with mRCC. To date, only one trial has directly compared contemporary first-line treatments, the COMPARZ trial.[83] Furthermore, the different primary efficacy cohorts used in CheckMate 214 (IMDC intermediate or poor risk), KEYNOTE-426 (all IMDC risk groups), and JAVELIN Renal 101 (≥1% PD-L1 expression in all IMDC risk groups) limits the value of network meta-analyses to indirectly compare treatments.[84] At MDACC, we use IMDC risk group, sites of metastasis, and burden of metastasis to tailor treatment selection and sequencing for patients with mRCC. Furthermore, we offer clinical trial enrollment to all eligible patients.

For patients with IMDC intermediate- or poor-risk disease, we often use the following agents: first-line nivolumab plus ipilimumab, first-line pembrolizumab plus axitinib, second-line or later cabozantinib, and

TABLE 43–4 Pivotal Trials for Second-Line or Later Treatment of Metastatic Renal Cell Carcinoma

Agent(s)	Trial Design	Prior Treatment	Patients (*n*)	Median PFS[a] (HR, 95% CI)	Median OS[a] (HR, 95% CI)
Nivolumab	Nivolumab vs everolimus	1–2 antiangiogenic treatments	821	4.6 vs 4.4 (0.88, 0.75–1.03)	25.0 vs 19.6 (0.73, 0.57–0.93)
Cabozantinib	Cabozantinib vs everolimus	≥1 antiangiogenic treatment	658	7.4 vs. 3.9 (0.51, 0.41–0.62)	21.4 vs 16.5 (0.66, 0.53–0.83)
Lenvatinib + everolimus	Lenvatinib + everolimus vs lenvatinib vs everolimus	≥1 antiangiogenic treatment	153	14.6 vs 5.5 (0.40, 0.24–0.68)	25.5 vs 17.5 (0.55, 0.30–1.01)
Axitinib	Axitinib vs sorafenib	≥1 approved treatment	723	6.7 vs 4.7 (0.67, 0.54–0.81)	20.1 vs 19.2 (0.97, 0.80–1.17)

[a]All progression-free survival (PFS) and overall survival (OS) values listed are in months.
CI, confidence interval; HR, hazard ratio; mRCC, metastatic renal cell carcinoma.

second-line or later lenvatinib plus everolimus. We prefer to begin with first-line nivolumab plus ipilimumab for most patients with IMDC intermediate- or poor-risk disease because it produced higher CR rates, and retrospective data show higher ORRs with VEGF-targeted therapy after nivolumab plus ipilimumab.[85] If a patient needs a response to upfront treatment because of high-volume disease or a high-risk site of metastasis, we begin with pembrolizumab plus axitinib because of its higher ORR. For second-line or later treatment, cabozantinib remains a viable treatment option after progression on axitinib because it also targets MET and AXL. Nivolumab plus ipilimumab and pembrolizumab plus axitinib have not been studied as second-line treatments, but both are listed on the current National Comprehensive Cancer Network guidelines as second-line treatment options.[86] Furthermore, a retrospective study evaluated second-line or later combinations of immune checkpoint inhibition and VEGF-targeted therapy in 36 patients with mRCC and demonstrated an ORR of 35%.[87]

In patients with IMDC favorable-risk disease and a low volume of metastases, we generally consider the following agents in sequential order: sunitinib–pazopanib, nivolumab with or without ipilimumab, cabozantinib, and lenvatinib plus everolimus. In this population, we begin with sunitinib or pazopanib based on the efficacy findings for favorable-risk disease reported in CheckMate 214.[66] Physician preference can guide selection between sunitinib and pazopanib because the COMPARZ trial showed that pazopanib was noninferior to sunitinib for PFS and OS.[83] In patients with IMDC favorable-risk disease and a high volume of metastases, we often begin with pembrolizumab plus axitinib, instead of sunitinib–pazopanib, and then proceed to cabozantinib and lenvatinib plus everolimus. The treatment algorithms discussed earlier should be tailored to individual patients, and a summary can be found in Figure 43–3.

Management of Adverse Events by Drug Class

Blockade of VEGF results in class adverse effects, which include hypertension, fatigue, proteinuria, increased risk of bleeding, wound dehiscence, and thromboembolic events (Table 43–5). All of the VEGF-targeted therapies cause these side effects to varying degrees. Sunitinib, pazopanib, cabozantinib, and lenvatinib are also inhibitors of other receptor tyrosine kinases and thus commonly induce hand–foot syndrome, diarrhea, dysgeusia, and hypothyroidism. In some cases, sunitinib can also result in cardiomyopathy with decreased ejection fraction.[88–90]

Adverse events caused by VEGF-targeted therapies can often be managed with a combination of supportive care, dose reductions or interruptions, and alternative dosing schedules. Table 43–6 summarizes the standard dose-reduction algorithms used in the registration trials of VEGF-targeted therapies. In addition to dose interruptions and dose reductions, a change in schedule may be beneficial for some patients receiving sunitinib. In registration trials, sunitinib was administered as 4 weeks on, 2 weeks off, but a phase II trial evaluated an alternative schedule of 2 weeks on, 1 week off (2/1) in 77 patients with mRCC.[91] Although the trial did not meet its primary endpoint of decreased grade 3 adverse events, it did show that sunitinib 2/1 was associated with fewer grade 4 adverse events and treatment discontinuation.

Symptom control is also essential for patients receiving VEGF-targeted therapies, and Table 43–7 outlines

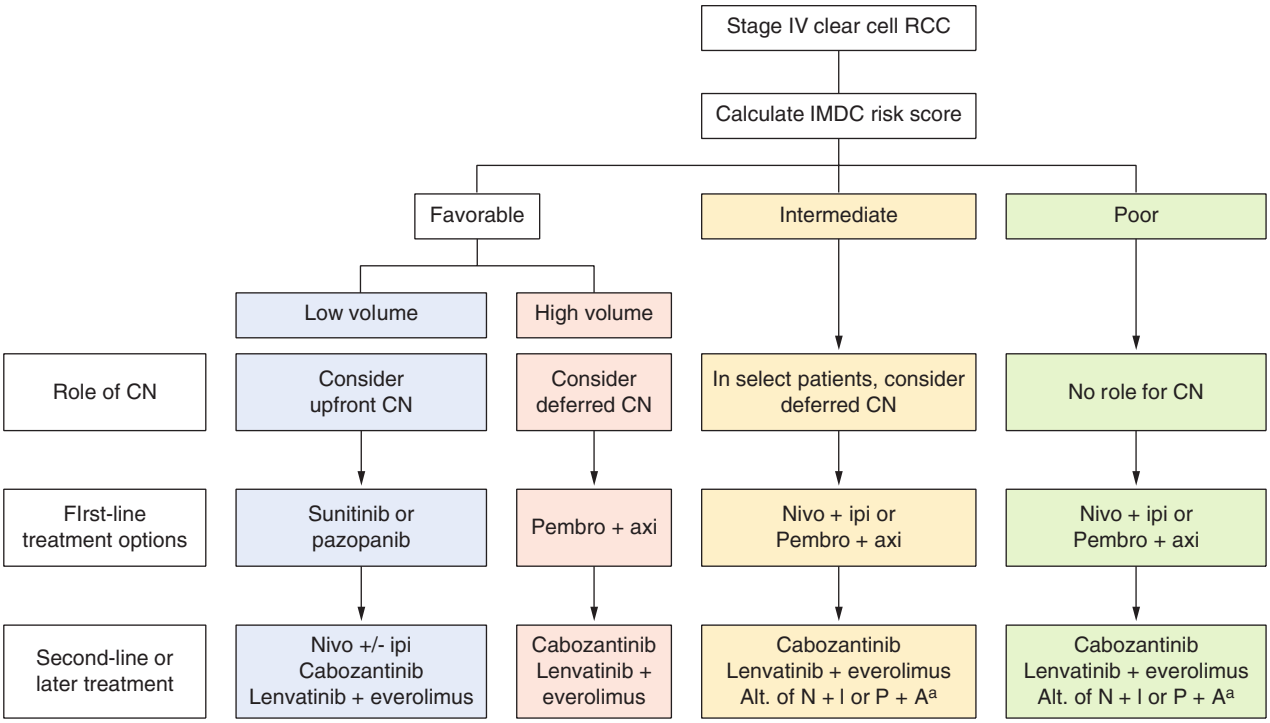

FIGURE 43–3 General approach to management of metastatic clear cell RCC, including the role of systemic therapy and cytoreductive nephrectomy (CN), in June 2020. [a]There are no prospective data to support second-line or later pembrolizumab plus axitinib, but it is currently listed in the National Comprehensive Cancer Network guidelines. alt., alternative; axi, axitinib; ipi, ipilimumab; IMDC, International Metastatic RCC Database Consortium; N + I, nivolumab plus ipilimumab; nivo, nivolumab; P + A, pembrolizumab plus axitinib; pembro, pembrolizumab.

TABLE 43–5 Summary of Side Effects of Vascular Endothelial Growth Factor–Targeted Therapy in Renal Cell Carcinoma[a]

Agent	Sunitinib	Pazopanib	Axitinib	Sorafenib
Hypertension	XX/–	XX/X	XX/X	X/X

TABLE 43–6 Dose Reduction Algorithm Used in Pivotal Trials of Vascular Endothelial Growth Factor–Targeted Therapies

Agent	Standard Dose	Dose-Reduction Schema
Sunitinib	50 mg PO daily 4 weeks on followed by 2 weeks off	Dose level 1: 37.5 mg PO daily, 4 weeks on, 2 weeks off
		Dose level 2: 25 mg PO daily, 4 weeks on, 2 weeks off
		Alternate[b]: schedule change to 50 mg PO 14 days on and 7 days off
Pazopanib	800 mg PO daily	600 mg/day (dose level 1); 400 mg/day (dose level 2)
Axitinib	5 mg PO bid	3 mg PO bid (dose level 1); 2 mg PO bid (dose level 2)
Cabozantinib	60 mg PO daily	40 mg/day (dose level 1); 20 mg/day (dose level 2)
Lenvatinib		
Sorafenib	400 mg PO bid	Dose level 1: 400 mg PO daily
		Dose level 2: 400 mg PO every other day
		Alternate[b]: dose reduction to 600 mg PO daily

[a]After patients are on therapy, there are several ways to mitigate side effects. The package inserts of each agent outline the standard algorithm for dose reduction. This table summarizes the standard dose-reduction algorithms used in clinical trials of these agents.
[b]Not prospectively validated but used empirically with good effect.
bid, twice a day; IFN, interferon; IV, intravenous; MU, million units; PO, oral; SC, subcutaneous; TIW, three times a week.

supportive care measures that can mitigate or prevent specific side effects. It is essential that the patient and health care team maintain an ongoing dialogue during each cycle of therapy to ensure that patients proactively and appropriately manage these adverse events. Successful adverse event management translates into higher drug compliance and a greater probability of achieving a successful outcome.

Immune checkpoint inhibitors, including nivolumab, pembrolizumab, and ipilimumab, are associated with unique class adverse events, which are referred to as immune-related adverse events (irAEs). irAEs are thought to be secondary to nonspecific immune system activation, and irAEs can affect any organ system. Some of the more common irAEs include rash, colitis, hepatitis, pneumonitis, endocrine involvement (thyroid, hypophysitis, adrenal insufficiency, type 1 diabetes mellitus), and arthralgias.[92] For detailed recommendations on management of irAEs, refer to the American Society of Clinical Oncology practice guideline.[93] In sum, management of irAEs varies by grade of toxicity and organ involvement. For grade 1 irAEs, immune checkpoint inhibitor should be continued, except for neurologic or cardiac toxicity. Grade 2 irAEs warrant holding the immune checkpoint inhibitor, and corticosteroids may be administered depending on the clinical scenario. Grade 3 or 4 irAEs require treatment with high-dose corticosteroids while holding the immune checkpoint inhibitor, and in the setting of grade 4 irAEs, the immune checkpoint inhibitor should be permanently discontinued. Overall, irAEs can present with a wide range of clinical manifestations at any time during treatment, so clinicians must remain vigilant for irAEs in all patients treated with immune checkpoint inhibitors.

Emerging Therapies

Novel therapies are needed for second-line or later treatment of mRCC because combinations of immune checkpoint inhibitors and VEGF-targeted therapy are now standard first-line options. Therapies targeting glutamine metabolism, HIF, and manipulation of the immune response to cancer are currently in development for patients with mRCC. RCC cells depend on glutamine metabolism, and glutaminase plays an essential role by converting glutamine into glutamate.[94] Telaglenastat is a glutaminase inhibitor that has been studied in combination with everolimus and is currently being evaluated with cabozantinib. ENTRATA was a phase II trial that compared telaglenastat plus everolimus versus placebo plus everolimus in patients who had previously progressed on at least two lines of therapy. In this trial, telaglenastat plus everolimus significantly improved PFS (3.8 months vs 1.9 months; HR, 0.64).[95] Currently, a phase II trial, CANTATA, is evaluating telaglenastat plus cabozantinib versus telaglenastat plus placebo in patients who have progressed on one or two prior treatments (NCT03428217). Primary analysis of CANTATA was anticipated in September 2020.

There is an accumulation of HIF-2α in patients with ccRCC cause of inactivation of VHL, which results in cell proliferation and angiogenesis.[21] MK-6482 (previously PT2977) is an oral HIF-2α inhibitor that was studied in a single-arm phase I/II trial of 55 patients with mRCC who progressed on at least one prior systemic therapy. In that trial, MK-6482 was well tolerated and demonstrated antitumor activity with an ORR of 24%.[96] A phase III trial is currently evaluating

TABLE 43–7 Management Recommendations for Commonly Experienced Toxicities with Vascular Endothelial Growth Factor–Targeted Therapies

Side Effect	Preventive Measures	Supportive Care Measures		
Diarrhea	In patients with prior history of diarrhea on agent, consider loperamide once daily in morning	Loperamide 1–2 tabs after diarrhea	Diphenoxylate plus atropine	1 scoop of psyllium with 1 oz of water daily
Hand–foot syndrome	Heavy emollients applied to hands and feet bid and prn	As in preventive measures, plus urea-based callus creams		
Fatigue	Regular physical activity	Consider modafinil or methylphenidate	Check thyroid function	Short naps Regular exercise Regularized diet
Hypertension		Maintain BP below 140/90 mm Hg using 1. Calcium channel blockers (amlodipine okay but not diltiazem) 2. ACE inhibitors 3. Beta-blockers		
Hypothyroidism		Levothyroxine		
Dysgeusia	Salt and soda mouthwash four times a day	Avoidance of hot and spicy foods Salt and soda mouthwash	Carafate	
Mouth sores	Salt and soda mouthwash four times a day	Xylocaine-based mouthwash		
Hyperglycemia	Scrupulous glycemic control	Scrupulous glycemic control		
Rash (sorafenib)		Dose adjustment		
		Aveeno baths		
Rash (temsirolimus and everolimus)		Topical steroids		
Noninfectious pneumonitis (temsirolimus and everolimus)		Corticosteroids		

ACE, angiotensin-converting enzyme; bid, twice a day; BP, blood pressure; prn, as needed.

MK-6482 monotherapy against everolimus as second- or third-line treatment for patients with mRCC after prior PD-1 or PD-L1 checkpoint inhibitor and VEGF-targeted therapy (NCT04195750). Finally, RCC is an immunogenic tumor with a history of responses to HDIL-2, but HDIL-2 is no longer routinely used because of high rates of toxicity, low ORR rates, and the development of immune checkpoint inhibitors. Bempegaldesleukin (NKTR-214) is a human recombinant IL-2 attached to releasable polyethylene glycol chains that is currently being studied in patients with mRCC. In a phase I trial of 28 patients with advanced malignancies, bempegaldesleukin was well tolerated and demonstrated antitumor activity in some of the patients with mRCC, so there is interest in combining bempegaldesleukin with immune checkpoint inhibitors to potentiate their activity.[97] Bempegaldesleukin is currently being evaluated in a phase III trial comparing nivolumab plus bempegaldesleukin versus investigator's choice

of cabozantinib or sunitinib in patients with treatment-naïve mRCC (NCT03729245).

NON–CLEAR CELL RENAL CELL CARCINOMA

Metastatic nccRCC comprises 25% to 30% of RCCs and is associated with a worse prognosis than ccRCC. Patients with metastatic nccRCC were excluded from registration trials, so their outcomes with approved treatments differ from reported clinical trial experiences. Furthermore, survival differs by histologic subtype in patients with metastatic nccRCC. To date, four clinical trials have evaluated systemic therapy across all histologies of metastatic nccRCC.[98–101] At MDACC, we conducted a phase II single-arm study of sunitinib in patients with metastatic nccRCC who had received up to two previous lines of treatment and reported a median PFS of 2.7 months and an ORR of 5%.[100] The ESPN trial was a multicenter, phase II trial that randomized patients with metastatic nccRCC to sunitinib or everolimus.[99] The primary endpoint was PFS after first-line treatment. The trial was stopped early because of futility of satisfying the primary endpoint, with a median PFS of 4.1 months with everolimus compared with 6.1 months with sunitinib. Everolimus and sunitinib were also compared in the phase II ASPEN trial, which randomized patients with untreated, metastatic papillary, chromophobe, or unclassified nccRCC.[98] In ASPEN, sunitinib significantly improved PFS compared with everolimus (8.3 months vs 5.6 months; HR, 1.41) These trials demonstrated that sunitinib and everolimus have modest activity in patients with metastatic nccRCC, and attention has now moved to PD-1 inhibition and multitargeted TKIs for patients with metastatic nccRCC. In KEYNOTE-427 cohort B, 165 patients were treated with pembrolizumab, and the ORR was 24.8%.[101] Multiple retrospective cohort studies have also shown that nivolumab (ORR, 19%–21%) and cabozantinib (ORR, 14%–27%) have antitumor activity in patients with metastatic nccRCC.[102–106]

Papillary Renal Cell Carcinoma

Papillary RCC (pRCC) is the most prevalent nccRCC histology, comprising 40% of patients with nccRCC. Conventionally, pRCC is split into two groups, type 1 and 2, based on light microscopy findings. Papillary type 2 carries a worse prognosis and is associated with hereditary leiomyomatosis and RCC syndrome (HLRCC), which is an autosomal dominant syndrome characterized by alterations to the *FH* gene.[107] More recently, a study from TCGA of 161 patients with pRCC showed that type 1 pRCC is associated with *MET* alterations (81%), and type 2 pRCC is associated with *CDKN2A* silencing, *SETD2* mutations, *TFE3* fusions, and increased expression of the NRF2-antioxidant response element pathway.[108] These findings suggest that the conventional groups of pRCC do not clearly delineate the underlying biology of pRCC. Because of the high prevalence of *MET* alterations in pRCC, multiple clinical trials have evaluated TKIs that target MET, including erlotinib, foretinib, crizotinib, and savolitinib.[109] However, these TKIs have demonstrated modest activity at best, so clinical development of these agents was discontinued. A single-arm, phase II trial demonstrated that axitinib has activity as first-line treatment of metastatic pRCC with an ORR of 28.6%, median PFS of 6.6 months, and median OS of 18.9 months.[110] Two clinical trials are currently evaluating cabozantinib versus sunitinib in patients with pRCC (SWOG 1500; NCT02761057), and in all patients with nccRCC (CABOSUN II; NCT03541902), which is a trial led by MDACC.

Sarcomatoid Renal Cell Carcinoma

RCC with sarcomatoid dedifferentiation (sRCC) is not a distinct histologic subtype of RCC because any RCC histology can also have sarcomatoid dedifferentiation present, and approximately 5% of all patients with RCC demonstrate sarcomatoid dedifferentiation in their tumors.[111] Varying percentages of sarcomatoid involvement can be seen, and it is difficult to determine the underlying histologic background in cases in which there is a predominance of sarcomatoid cells. Genomic analyses have shown that sRCC has increased alterations in *TP53*, *CDKN2A*, and *NF2* as well as upregulation of transforming growth factor β signaling.[112,113] Immune checkpoint inhibitors have shown promising activity in patients with metastatic sRCC. In a post-hoc analysis of CheckMate-214, patients with sRCC had significantly improved OS, PFS, and ORR with nivolumab plus ipilimumab compared with sunitinib, and it resulted in a noteworthy CR rate of 18.3%.[114] Similarly, pembrolizumab plus axitinib significantly improved all efficacy endpoints in patients with sRCC in a post-hoc analysis of KEYNOTE-426, and the CR rate was 11.6%.[101] These post-hoc analyses suggest that patients with sRCC should be offered first-line treatment with nivolumab plus ipilimumab or pembrolizumab plus axitinib because of improved survival and potential for a CR.

Collecting Duct Carcinoma

Tumors arising from the collecting duct epithelium are located in the medulla or center portion of the kidney, in contrast to RCC tumors, which arise from tubules in the cortex.[115] The diagnosis of CDC is

based on both clinical and histologic features. Sarcomatoid dedifferentiation is common, and patterns of metastasis are similar to those of a high-grade, rapidly progressive RCC. There is no established effective systemic therapy for metastatic CDC, although marginal benefit is occasionally seen with chemotherapy regimens developed for urothelial carcinoma.[116]

Renal Medullary Carcinoma

Renal medullary carcinoma (RMC) is a rare and particularly aggressive malignancy that is found in young patients with sickle cell hemoglobinopathies, usually sickle cell trait, and is associated with the loss of a tumor suppressor gene, *SMARCB1*.[117,118] Comprehensive genomic and transcriptomic profiling of RMC has shown that it is characterized by high DNA replication stress and a high number of focal chromosomal alterations.[119] RMC has a poor prognosis with a median OS of 13 months and fewer than 5% of patients living beyond 3 years in the largest retrospective cohort to date.[120] RMC is generally refractory to VEGF-targeted therapy, and the most commonly used systemic treatment is cytotoxic chemotherapy with a platinum-based regimen.[120,121] Accordingly, patients with RMC should be referred to a high-volume center for enrollment in a clinical trial specific to RMC. Currently, there are at least four clinical trials specific to patients with RMC, including trials evaluating immunotherapy (NCT03274258, NCT02496208, NCT02721732) and a proteasome inhibitor, ixazomib, in combination with cytotoxic chemotherapy (NCT03587662). In regard to nephrectomy, an expert panel led by oncologists from MDACC recommends upfront systemic therapy for all patients with RMC, even if they present with localized disease.[117]

Chromophobe Renal Cell Carcinoma

Chromophobe RCC comprises approximately 5% to 10% of all RCC cases, making it the second most common non–clear cell histology. By stage, chromophobe RCC has a better prognosis than ccRCC.[122] Chromophobe RCC is characterized by chromosome loss in chromosomes 1, 2, 6, 10, 13, 17, and 21.[123,124] In a TCGA study of 66 patients with chromophobe RCC, the authors found that mitochondrial alterations play a role in disease biology and identified unique *TERT* promoter rearrangements.[125] In the same study, the most commonly mutated genes in chromophobe RCC were *TP53* (32%) and *PTEN* (9%). Both VEGF-targeted therapy and mTOR inhibitors have antitumor activity in patients with metastatic chromophobe RCC.[98,99,126] In a subgroup analysis of the ASPEN trial, everolimus was associated with longer PFS than sunitinib in patients with metastatic chromophobe RCC (11.4 months vs 5.5 months).[98] In the small, retrospective studies currently available, nivolumab has not resulted in a partial or CR among patients with metastatic chromophobe RCC.[102–104]

Xp11.2 Translocation Carcinoma

Xp11.2 translocation carcinoma is a rare disease entity that is proportionally more common in children but can also occur in young adults.[127] A strong female predominance is observed. The *TFE3* gene located at Xp11.2 has a number of potential translocation partners leading to fusion of a novel gene. An analysis of 16 patients with translocation RCC found significant genomic heterogeneity, with 17q gain, 9p loss, 3p loss, and 17p loss being the most common findings.[128] Histologically, these tumors may resemble ccRCC or show mixed clear and papillary features. These histologic findings in a young adult should prompt further histologic and molecular characterization of the tumor. Staining for *TFE3* permits relatively specific identification of this disease entity, but if it is highly suspected, a break-apart fluorescent in situ hybridization assay should be used to increase sensitivity.[129,130] In the limited retrospective data available, Xp11.2 translocation carcinoma carries a poor prognosis, and VEGF-targeted therapy appears to have some activity. In a retrospective review of 15 adults with translocation carcinoma treated at four centers in the United States, VEGF-targeted therapy produced an ORR of 20%, with a median PFS of 7.1 months and median OS of 14.3 months.[131] Additionally, a French study of 21 patients with adult translocation carcinoma treated with VEGF-targeted therapy or mTOR inhibitors reported an ORR of 33% with median PFS of 8.2 months in first-line treatment and OS of 27 months.[132]

CONCLUSION

For patients with mRCC, immune checkpoint inhibitors and multitargeted TKIs have significantly improved survival and response to treatment. Individualized treatment selection and sequencing remains challenging in mRCC because of the lack of trials directly comparing contemporary therapies and a paucity of predictive biomarkers. In the metastatic setting, patients with nccRCC continue to have a poor prognosis, and these patients should be referred to high-volume centers where clinical trials are available. Finally, in recent years, clinical trials have demonstrated limited benefit with adjuvant TKIs after nephrectomy and questioned the role of CN for IMDC intermediate and poor-risk RCC.

MD ANDERSON PRACTICE TIPS

- Currently, molecular biomarkers are not predictive of response to treatment for patients with mRCC. For prognostication, PBRM1 is associated with a favorable prognosis, and BAP1 is associated with a poor prognosis.
- Despite the approval of adjuvant sunitinib, there is no role for adjuvant VEGF-targeted therapy for patients with locally advanced RCC. Clinical trials evaluating adjuvant immune checkpoint inhibitors are ongoing.
- The efficacy and timing of CN for patients with intermediate- or poor-risk mRCC receiving VEGF-targeted therapy were called into question by the CARMENA and SURTIME trials. At MDACC, CN is not recommended for patients with poor-risk disease, and in most patients with intermediate-risk disease, we begin with systemic therapy and reserve CN for patients with a response to treatment and good performance status.
- The IMDC risk score should be used to guide first-line treatment selection for patients with metastatic ccRCC. To date, only nivolumab plus ipilimumab and pembrolizumab plus axitinib have improved OS as first-line treatment of patients with mRCC.
- Contemporary second-line or later treatment options include cabozantinib, lenvatinib plus everolimus, nivolumab, axitinib, and referral to a clinical trial. Treatment selection depends on the prior lines of therapy received and the characteristics of a patient's disease.
- In the metastatic setting, patients with nccRCC continue to have a poor prognosis, and these patients should be referred to high-volume centers where clinical trials are available.

44 Bladder Cancer

Alexander Y. Andreev-Drakhlin
Ashish M. Kamat
Arlene O. Siefker-Radtke

KEY CONCEPTS

- Pembrolizumab has recently been approved for patients with Bacillus Calmette-Guerin (BCG)-unresponsive non–muscle-invasive urothelial cancer based on responses observed in a cohort of patients with carcinoma in situ in their bladders.
- Neoadjuvant cisplatin-based chemotherapy remains the standard of care treatment for muscle-invasive bladder cancer. Dose-dense MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin) has largely supplanted traditional MVAC because of its improved toxicity profile and shorter time to surgery.
- Immune checkpoint inhibitors have been approved frontline treatment for patients with metastatic urothelial cancer who are not eligible for cisplatin-based chemotherapy. Programmed cell death ligand 1 (PD-L1) expression is required in this setting.
- Immune checkpoint inhibitors are also approved after chemotherapy with level 1 evidence showing a survival benefit with pembrolizumab in the second-line setting and with avelumab in the maintenance setting in patients with stable disease or better for frontline chemotherapy. At the moment, there is no definitive evidence as to whether maintenance checkpoint inhibition or checkpoint inhibition at progression is the optimal treatment strategy. PD-L1 expression is not needed in the postchemotherapy setting.
- In April 2019, the Food and Drug Administration (FDA) granted accelerated approval to erdafitinib, the first-in-class fibroblast growth factor receptor 3 (FGFR3) inhibitor based on efficacy in the second-line setting. FGFR3 mutations or fusions are required for treatment.
- In December 2019, the FDA granted accelerated approval to enfortumab vedotin, the first antibody–drug conjugate approved for urothelial cancer based on efficacy in the third-line setting (postchemotherapy, postimmunotherapy). This antibody targets nectin-4, which is highly expressed in urothelial cancer, so expression levels are not necessary.

The recent approvals of checkpoint inhibitors, the first biomarker targeted therapy for fibroblast growth factor receptor 3 (FGFR3) mutations, and the first antibody–drug conjugate have reinvigorated the field of urothelial cancer. Clinical trial programs in this field are rapidly evolving, with combinations of checkpoint inhibitors with these and other novel agents showing clinical activity that appears on par with what was initially achieved with MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin) in the 1980s. Urothelial cancer is no longer just one disease. Additional developments in genomic medicine highlight the complexity and heterogeneity of urothelial cancer, providing the biologic framework for developing innovative precision therapy.

OVERVIEW

The urinary tract conveys urine from the confluence of urinary tubules in the renal papillae to the outside world. A specialized epithelial surface known as the urothelium lines this entire path and is composed primarily of transitional cells, extending from the renal pelvis through the ureters, bladder, and urethra. In males, it also lines the terminal prostatic ducts and prostatic

urethra. Although tumors arising from the urothelium can involve any organ along this path, about 90% of these cancers arise in the urinary bladder.

EPIDEMIOLOGY

Urothelial cancer is the fifth most common cancer diagnosis in the United States and is associated with cigarette smoking. In 2020, we anticipated about 85,000 new cases, with about 81,000 arising in the bladder. Altogether, these cases account for approximately 19,000 deaths.[1] These incidence figures are somewhat misleading, however, because compared with other tumors, only in the bladder are histologically bland hyperplastic lesions counted as cancers. In other sites, such lesions count as benign or at most premalignant, and thus the incidence figures include many patients with lesions that do not meet the conventional definition of malignancy. Imagine what the incidence figures for colon cancer would be if every patient with a polyp was counted as a case of colon cancer! Many such lesions recur; however, few progress to true malignancy. Thus, it is critically important to separate risk models that are designed to predict recurrence from those that predict progression, which is far more biologically significant. Because of this anomaly of classification, the literature on "risk of bladder cancer," both for incidence and recurrence, should be interpreted very carefully.

In contrast to most other carcinomas, the majority of patients with urothelial cancer (even after excluding the low-grade papillary "cancers") have early-stage, potentially curable disease at presentation. Only about 20% of patients present with disease that invades into the muscle wall. Fewer than 5% of patients present with locally advanced (ie, clinically extravesical) disease, and another 5% or so present with clinically apparent metastatic disease. When clinically metastatic, urothelial cancer is remarkably aggressive, exhibiting a natural history reminiscent of small cell carcinoma of the lungs. If untreated, the survival is measured in weeks; it is markedly chemosensitive; responses are typically short lived; the brain is a typical "sanctuary" site of relapse after response to initial therapy; and cure of patients with distant metastases, although well documented, remains *uncommon*.

The ready accessibility of urine and the fact that the urothelium itself can be accessed via minimally invasive cystoscopy make urothelial cancer an important context for understanding the processes of carcinogenesis and clonal evolution.

The current state of the art is rather sobering:

- Although immune checkpoint inhibitors targeting programmed cell death protein 1 (PD-1) and PD-L1 result in durable treatment responses in some patients, the proportion of patients responding to the therapy remains low, with most trials demonstrating an approximately 20% objective response rate in the metastatic setting.
- There are currently no reliable biomarkers to identify patients with urothelial cancer who benefit from immune checkpoint therapies.
- Fibroblast growth factor receptor (FGFR) inhibition with erdafitinib, a pan-FGFR inhibitor, results in objective treatment response in 40% of patients with FGFR-mutated urothelial cancer. However, most patients develop resistance to FGFR inhibitors within the first 6 months of therapy.

However, there is optimism in that

- Recent advances in drug development with antibody–drug conjugates show great promise in the treatment of patients with urothelial cancer.
- Further molecular characterization of urothelial cancer may have utility in guiding clinical decisions, leading to a personalized approach to care.

CLASSICAL EPIDEMIOLOGY

Malignant transformation of the urothelium parallels observations with other epithelial tumors,[2] in that it is distinctly uncommon before age 40 years and has a peak incidence in the seventh decade of life. The male:female ratio is about 3:1; the reason for this disparity is currently not clear. Malignant transformation is the result of a multistep process involving multiple genes. The appearance of clinical cancer typically follows carcinogenic exposure by decades. Fluid intake is inversely associated with risk,[3] supporting the concept that contact time of excreted carcinogens with the urothelial surface contributes to carcinogenesis.

There is a striking correlation of urothelial cancer incidence with exposure to certain environmental toxins. About half of all cases relate to smoking. Industrial exposures, especially to petrochemicals, account for another 10% to 15%. Many occupations with "chemical" exposures are linked to an excess risk of urothelial cancer. An association with aniline dye exposure was noted more than a century ago, and many aromatic amines (prototypically β-naphthyl amine) have now been shown to be potent urothelial carcinogens. Cigarette smoke is rich in both aromatic amines and the highly reactive bladder toxin acrolein. Another source of acrolein, which is strongly linked to urothelial carcinogenesis, is the metabolism of cyclophosphamide and ifosfamide. In one report, prolonged exposure to oral cyclophosphamide (as was a common intervention for some forms of cancer and for autoimmune disease in the 1970s) increased the risk of bladder cancer by a factor of nine.[4] Also noteworthy are exposures to the analgesic phenacetin and to the plant-toxin–related "Balkan nephropathy" in which the risk of upper tract tumors is increased.[5,6]

As is generally true for epithelial carcinogenesis, chronic irritation and inflammation have also been associated with malignant transformation. This is seen prototypically in settings such as staghorn calculus and other cases of chronic urolithiasis, chronic bladder catheterization (a particularly distressing complication of spinal cord injury[7] or congenital malformations), and classically, chronic schistosomiasis in the Middle East. Urothelial cancers that arise in the context of chronic irritation typically show squamous differentiation.

MOLECULAR EPIDEMIOLOGY

Assessment of genomic variations, as well as functional assessment of certain metabolic pathways, is now integrated routinely with classical aspects of cancer risk assessment. As might have been anticipated from the classical epidemiologic studies of environmental exposures, polymorphisms of various genes involved in xenobiotic metabolism are correlated with the risk of developing bladder cancer. However, these pathways are complex, and the impact of genetic changes is of course context dependent. Some examples include genes involved in carcinogen metabolism, such as glutathione S-transferase Mu 1 (GSTM1), and N-acetyltransferase 2 (NAT2).[8] Furthermore, large genome-wide association studies validated known associations for the GSTM1 deletion and NAT2 slow acetylation variant and identified additional sequence variants that can increase bladder cancer risk.[9]

TUMOR BIOLOGY

Carcinogenesis

A dual-track model has been proposed in urothelial cancer carcinogenesis (Fig. 44–1).[10] The majority of urothelial cancers, approximately 80% to 85%, arise from a hyperplastic epithelium and most commonly present as low-grade non–muscle-invasive bladder cancers (NMIBCs). Although these tumors tend to recur, they are much less likely to evolve into a more aggressive form of urothelial cancer. FGFR3 receptor alterations also follow a similar pattern, with alterations noted in over 60% of low-grade low-stage urothelial tumors.[11] The rest are nonpapillary high-grade muscle-invasive bladder cancers (MIBCs) arising from carcinoma in situ, which have a propensity to metastasize. The apolipoprotein B mRNA-editing enzyme catalytic polypeptide (APOBEC) cytidine deaminases-mediated mutagenesis mutation signature is present in both NMIBC and MIBC. However, NMIBCs are characterized by a significantly lower mutational burden.[12] Moreover, whereas NMIBCs are commonly genomically stable, MIBCs are frequently aneuploid with multiple chromosomal alterations and copy number changes.[13] These high-level differences in the mutational profiles are accompanied by significant differences in the commonly mutated genes in these two bladder cancer types.

The most common copy number alteration in NMIBC is deletion of chromosome 9 observed in approximately 50% of low-grade tumors. Chromosome 9 harbors CDKN2A, which encodes two proteins, p16 and p14ARF. Both function as tumor suppressors affecting the retinoblastoma (RB) pathway and p53 pathway.[14] This is also the location of the interferon-γ (IFN-γ) gene signature; loss of this signature has been implicated in resistance to immune checkpoint inhibitors.[15] The majority of NMIBC also contain point mutations, translocations, or amplification of FGFR3. Increased FGFR signaling leads to activation of the mitogen-activated protein kinase, resulting in increased cell proliferation and oncogenesis.[16,17] Activating PIK3CA mutations frequently co-occur with FGFR3 alterations,[18] raising the question as to whether this could be a potential mechanism of resistance to FGFR3 inhibition. In contrast, gain-of-function mutations in RAS gene family members and ERBB2 found in some NMIBCs are mutually exclusive with FGFR3 alterations.[19,20] Inactivating mutations in the cohesion complex tumor suppressor gene STAG2 are also frequently identified in NMIBC.[21] Recent targeted exon sequencing study that included 105 patients with NMIBC showed that the most frequently altered genes in NMIBC were the TERT promoter (73%), FGFR3 (49%), KDM6A (38%), PIK3CA (26%), STAG2 (23%), ARID1A (21%), and TP53 (21%). Of note, alterations in chromatin modifying genes, including KDM6A and ARID1A, are highly prevalent in NMIBC, occurring in 69% of the tumors.[20]

Multiomics efforts by many groups have provided a deep, integrative analysis of MIBC with the goal of developing new therapeutic approaches.[12,22–25] Although many genes have been shown to be altered, the majority of cases are characterized by the loss of function of key tumor suppressors, including TP53 (48%–49%), CDKN2A (22%–47%), and RB1 (13%–17%). PTEN (phosphatase and tensin homolog) deletions and MDM2 amplifications are also identified. Alterations between CDKN2A and TP53, CDKN2A and RB1, and TP53 and MFM2 tend to be mutually exclusive. FGFR3 point mutations and fusions are less frequent in MIBC compared with NMIBC and are found in up to 15% of tumors. Similar to NMIBC, epigenetic changes are highly prevalent in MIBC. A 2014 the cancer genome atlas (TCGA) study of 131 MIBCs showed that 76% of the tumors harbored an inactivating mutation in one or more of the chromatin regulatory genes, and 41% had at least two such mutations.[12]

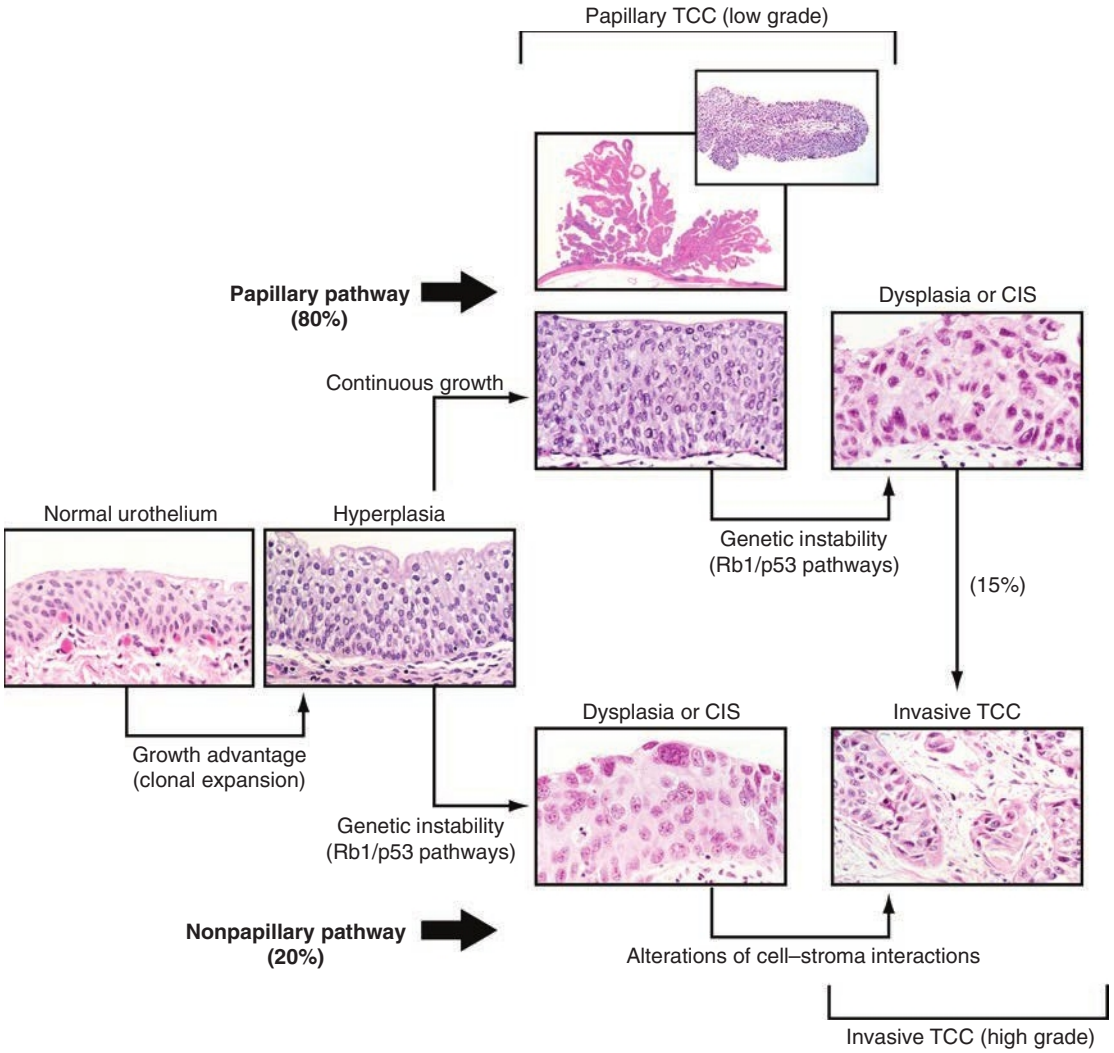

FIGURE 44–1 Dual-track pathway of urothelial cancer. CIS, carcinoma in situ; TCC, transitional cell carcinoma. (Reproduced with permission from Dinney CP, McConkey DJ, Millikan RE, et al: Focus on bladder cancer, *Cancer Cell* 2004 Aug;6(2):111-116.)

Multiple studies have focused on the molecular classification of bladder cancer. Although the Lund molecular taxonomy reported on mixed cohorts of MIBCs and NMIBCs,[25] subsequent efforts mostly focused on analyses of pure MIBC cohorts. The groups at University of North Carolina, MD Anderson Cancer Center (MDACC), and TCGA suggested several molecular classification systems of MIBC.[12,22,26] Although these studies defined different number of clusters, there was a high degree of concordance between the classifications with all tumors, at the highest level, being divided into basal and luminal subtypes. Notably, early evidence from a phase 2 clinical trial suggested that patients with the basal subtype had better outcomes when treated with platinum-based chemotherapy,[23] a finding also reported on additional retrospective tissue samples.[27] The 2017 update to the TCGA classification reevaluated the previously defined clusters and identified five subtypes that partially overlapped with the clusters defined in the prior study.[24]

A recent study analyzed the relationships between the published systems, based on 1750 MIBC transcriptomes.[28] The authors identified six consensus MIBC molecular classes with distinct oncogenic mechanisms, tumor microenvironments, and clinical associations: luminal papillary (LumP), luminal nonspecified (LumNS), luminal unstable (LumU), stroma rich, basal/squamous (Ba/Sq), and neuroendocrine-like (NE-like). LumP tumors were associated with the best survival, papillary morphology, frequent KDM6A mutations, and a strong activation of the FGFR3 signature. LumNS class tumors were enriched with older patients, micropapillary histology, and mutations in ELF3, which is a regulator of urothelial differentiation. LumU class was characterized by genomic instability, ERBB2 amplifications, mutations in TP53 and ERCC2, and the highest

tumor mutational burden. Stroma-rich tumors were associated with high levels of stromal and B-cell infiltration. Ba/Sq tumors overexpressed basal differentiation signature, had frequent TP53 and RB1 mutations, exhibited squamous histology, expressed immune checkpoint marker, and had high numbers of cytotoxic lymphocytes and natural killer cells, suggesting potential benefit from immune checkpoint inhibitors in this group of tumors. Finally, neuroendocrine (NE)-like group demonstrated neuroendocrine differentiation and strong enrichment of concurrent TP53 and RB1 inactivation and had the worst prognosis. There is a hope that this consensus classification will help the development of MIBC precision oncology by facilitating the translation of the molecular subtypes to clinical and research settings.

Novel Biologic Targets

Immune checkpoint inhibitors have transformed the world of cancer, including the field of urothelial cancer. However, the benefits are limited to a low percentage of patients with response rates at around 20%.[29–31] Attempts to select patients most likely to benefit from immunotherapy have been mostly unsuccessful. PD-L1 expression is the only biomarker currently in use in the frontline setting after a recent study suggested that patients with high–PD-L1 disease benefit from single-agent immunotherapy, and those with low–PD-L1 tumors benefitted more from frontline systemic chemotherapy.[31] Other factors, including tumor mutational burden, molecular subtype, and the IFN-γ signature, have not provided definitive benefit is selecting patients for immunotherapy.[15,29]

Approximately 20% of patients with advanced bladder cancer have activating mutations in FGFR.[24] Erdafitinib is the first-in-class FGFR inhibitor approved for the second-line treatment of patients with FGFR3-altered advanced urothelial cancer.[32] FGFR3 alterations are enriched in the immunologically cold, luminal-papillary subtype. However, there are conflicting reports on whether the FGFR3 altered urothelial tumor would benefit more from immunotherapy or FGFR3 targeted therapy.[32,33] An ongoing phase III trial, THOR, will answer this question by comparing erdafitinib with pembrolizumab in patients with FGFR3-mutated urothelial cancer. Other clinical trials, including NORSE, are investigating whether the addition of an immune checkpoint inhibitor to an FGFR inhibitor will enhance therapeutic responses in this patient population.[34]

Many other novel therapies are showing promise in the treatment of urothelial cancer. Nectin-4 is a cell adhesion molecule, which is highly expressed in more than 90% of bladder tumors. Enfortumab vedotin (EV), an antibody–drug conjugate targeting nectin-4, is the most recent addition to the treatment arsenal now approved for the treatment of metastatic bladder cancer.[35] Sacituzumab govitecan (SG) is a Trophoblast cell surface antigen-2 (trop-2)–directed antibody and topoisomerase inhibitor drug conjugate that has been granted the Food and Drug Administration (FDA) fast track designation for patients with urothelial carcinoma.[36] Sitravatinib, an oral tyrosine kinase inhibitor targeting the TAM (TYRO3, Axl, and Mer) family of receptor tyrosine kinases, is being studied in combination with nivolumab in patients previously treated with immunotherapy.[37] Bempegaldesleukin, a pegylated formulation of interleukin-2 (IL-2), has shown clinical activity in combination with nivolumab even in patients with low–PD-L1 tumors.[38]

HISTOLOGY

In the United States, approximately 90% of all urothelial malignancies are within the histologic spectrum of transitional cell carcinoma (TCC), which, in our view, merges without obvious demarcation with the "sarcomatoid" and "small cell" variants at the extreme of dedifferentiation. Most of the remainder exhibit squamous histology (especially prominent in the more distal urethra) or glandular differentiation (ie, adenocarcinoma). The finding of adenocarcinoma apart from the context of bladder exstrophy or a urachal tumor (see later) should prompt consideration of metastatic disease from some other primary site because bona fide primary adenocarcinomas originating from the urothelium are distinctly uncommon.

As noted earlier, primarily hyperplastic lesions, biologically akin to polyps in the gastrointestinal tract, account for a large portion of incident cases. In 1999, the World Health Organization (WHO) put forward a new classification of noninvasive papillary urothelial tumors in recognition of the fact that the malignant potential of these lesions varies widely[39]; even more recent updates reference these earlier recommendations.[40] The WHO terminology for these lesions, which together account for more than half of all new cases of urothelial neoplasia, is

- **Papillary urothelial neoplasm of low malignant potential.** This lesion is characterized by orderly progression of morphology within the urothelium and no cellular atypia. Recurrence occurs in about 25% of cases, but progression is rare.
- **Noninvasive papillary urothelial carcinoma, low grade.** This lesion shows some architectural variation and mild atypia. Such lesions commonly recur (in ≥50% of cases) but progression is seen in fewer than 7%.
- **Noninvasive papillary urothelial carcinoma, high grade.** This lesion shows predominantly disorganized architecture and moderate to marked

cytological atypia. Such lesions do not invade below the basement membrane, but they have substantial biologic potential, with progression to invasive, potentially life-threatening disease in up to 65% of cases. Note that in the WHO system, grades are collapsed to a two-tier system of low grade and high grade. In general, this would map to the older three-tier system as grade 1 = low grade, and grades 2 and 3 = high grade.

In contrast to these papillary cancers, some urothelial cancers exhibit dysplasia and chromosomal instability early on and constitute a "second pathway" of carcinogenesis,[10,41,42] and most of the cases with lethal potential are in this class (see Fig. 44–1). In contrast to the classic "mulberry" appearance, the nonpapillary lesions have a grossly flat or infiltrative appearance at cystoscopy. In older literature, such cancers have been known as *flat*, *sessile*, *solid*, or *tentacular*. Currently, the preferred nomenclature is simply "nonpapillary," although "flat" persists in the *AJCC Cancer Staging Manual*. These morphologic differences were noted long before an understanding of the genetic changes associated with cancer was appreciated. As expected for such distinct phenotypes, the characteristic genetic lesions have been found to be distinct.

In addition to papillary and nonpapillary variants, a *micropapillary* pattern is increasingly recognized.[43–46] The term *micropapillary* originally came from the recognition of morphologic resemblance to an aggressive variant of ovarian cancer. Indeed, this general histologic pattern has been reported in many epithelial malignancies and invariably identifies a more aggressive subset, as was first reported for bladder cancer in 1994. Gene expression profiling studies suggest these aggressive tumors are almost exclusively luminal, with enrichment of active peroxisome proliferator-activated receptor γ, suppression of p63 target genes, and activation of chromatin remodeling genes.[47] These tumors tend to be less sensitive to intravesical immunotherapy with BCG and should be treated with early extirpative surgery.[44] Thus, the biologic potential of urothelial neoplasia extends from relatively nonthreatening in papillary lesions, to potentially life threatening in nonpapillary lesions, to remarkably aggressive micropapillary lesions, all of which are recognizable as "transitional cell" cancer.

Depending on the series, about 30% (or more) of muscle-invasive urothelial cancers are found to have focal areas of squamous or glandular morphology when examined in detail. It is not clear that such "mixed" tumors have a different prognosis than "pure" TCC, and we do not consider this a meaningful subset at MDACC. Certainly, tumors with only focal areas of squamous or glandular differentiation do not exhibit the distinctive natural history of pure squamous cancers or pure adenocarcinomas. Primary nonepithelial cancers (eg, sarcomas, lymphomas, and melanomas) are exceedingly uncommon in the bladder. When they do occur, they do not appear to have a distinctive natural history or clinical management from what would be expected of similar tumors arising in more typical sites.

Urothelial cancers can dedifferentiate to include spindled ("sarcomatoid"), small cell, and plasmacytoid variants. In these cases, the clinical expression of the overall disease process is dominated by the aggressive component even if most of the primary cancer is well within the typical morphologic spectrum of TCC.

Small cell carcinoma of the urothelium is a remarkably aggressive malignancy and exhibits a similar propensity for spread to the brain as small cell carcinoma arising in other sites. Even in the setting of clinically localized disease, the prognosis with local therapy alone remains poor, reflecting the early development of micrometastases. Dysregulation of epithelial to mesenchymal transition networks and a urothelial to neural phenotypic switch appear are associated with this aggressive biology.[48] We strongly favor management of patients with cT2 or lower disease that is based on neoadjuvant chemotherapy followed by surgical consolidation.[49,50] In our hands, this provides about 70% cure.[50,51] Patients with locally advanced disease have a high incidence (8 of 16 in our series) of relapse in the brain,[51] and thus we believe these patients are candidates for prophylactic cranial irradiation. Patients with metastatic disease at presentation continue to have nearly a 100% response rate, with a 100% relapse rate and a median survival time of only 11 months.[51]

Plasmacytoid urothelial cancer is a very rare histology with very limited series reported to date.[52] These tumors typically appear mesenchymal with down regulation of E-cadherin[53,54] and consist of poorly cohesive tumor cells with perinuclear clearing reminiscent of plasma cells.[54,55] They also tend to be highly proliferative with abundant mitosis and staining for Ki-67. These tumors tend to have a unique spread pattern, often appearing as a linitis plastica with diffuse thickening of the bladder and rectum. Although plasmacytoid tumors appear to be sensitive to chemotherapy, even in the neoadjuvant setting with adequate downstaging to pathologic T0 disease, there are few long-term survivors.[52] These have also shown to have a high incidence of recurrence in the peritoneum in more than 50% of patients.[52]

Cancers arising in a urachal remnant, although not strictly "bladder cancers" in the sense of this chapter, merit a comment. These cancers typically involve the dome of the bladder and histologically are enteric-type adenocarcinomas. They are thought to reflect malignant transformation of an enteric epithelial rest within the urachal remnant, producing a cancer

readily recognized as a mucinous adenocarcinoma.[56] An early MDACC series suggested the risk of relapse was increased when an en-bloc resection was not performed and in the setting of positive margins, lymph node involvement, and tumor involving the peritoneal surface.[57] The Memorial Sloan Kettering Cancer Center (MSKCC) experience in 50 patients demonstrated long-term survival in 26 of 28 patients (93%) with pathologically localized disease, in nine of 13 (69%) patients with extension through the bladder or urachal cavity, and in none of nine patients with peritoneal involvement initially.[58] Similarly, the Mayo Clinic experience[59] in 49 patients demonstrated apparent cure in the majority of patients with confined disease and relapse in the majority with nonconfined disease, the latter group having a median survival period of only 16 months.[60] All investigators have emphasized the importance of an attempt at margin-negative, en-bloc resection that includes the umbilicus.

Urachal cancers have a tendency to recur locally, often with peritoneal carcinomatosis, and the typical metastatic sites are (about equally) lungs and liver. Although dramatic responses are infrequent, the use of modern combination regimens with activity in enteric adenocarcinoma is associated with about a 40% objective response rate. Thus, in essentially every clinical respect, urachal cancer behaves like colon cancer and based on the available data should be treated accordingly. The median survival time from the recognition of metastases was 24 months in our retrospective series of 26 patients with metastatic disease, although some patients with grossly metastatic disease have been long-term survivors.[57]

DIAGNOSIS, STAGING, AND PROGNOSIS

Presentation

About 80% of patients present with hematuria, usually painless. The "typical patient" is a smoker in his late 60s. Such patients frequently have pulmonary disease and cardiovascular disease, magnifying the morbidity of both chemotherapy and surgery. They are also at high risk for other smoking-related malignancies. A high percentage of patients have diminished renal function as a result of hypertension and obstructive nephropathy. Thus, the use of nephrotoxic chemotherapy is especially challenging in this population.

Irritative voiding symptoms, including frequency, dysuria, and dribbling, are important points in the medical history because the presence of irritative symptoms raises the possibility of extensive carcinoma in situ or large, infiltrative tumors that may be far more extensive than is revealed by the initial cystoscopy. Obstructive symptoms (nocturia, double voiding, overflow incontinence, low anterior abdominal pain) are frequent in patients with tumors of the bladder neck or prostatic urethra. Tumors in these locations are far less likely to be anatomically confined (ie, curable with surgery) than are similar MIBCs that are well away from these areas where the detrusor muscle is discontinuous.

In evaluating patients presenting with hematuria, it is mandatory to evaluate the upper urinary tracts. Even if a bladder tumor is confirmed on initial cystoscopy, excretory urography is still appropriate because synchronous or metachronous tumors of the upper tracts typically are not associated with specific symptoms.

Recently, several urine tests for cancer-associated antigens have been promulgated for diagnosis. None of these tests is yet sensitive and specific enough to replace cystoscopy and biopsy. The role of these tests for widespread screening is also not defined. Likewise, the role of urine cytology in initial diagnosis is unsettled. The yield is highly dependent on sample collection technique and the skill of the cytopathologist. As with many epithelial cancers, it is likely that DNA-based tests will eventually be widely used to find pathognomonic genetic alterations in urine and thus revolutionize the detection and clinical follow-up of patients with bladder cancer. The role of some form of surveillance in high-risk populations (eg, petrochemical workers) remains controversial. The relatively low positive and negative predictive values of cytology, even when applied to a high-risk group, make such screening difficult to justify.

Stage and Prognostic Classification

The dominant prognostic clinical variable is anatomic stage at diagnosis. Classically, this is defined by depth of invasion into the bladder wall. The currently used staging system is summarized in Figure 44–2.[61] This system is historically rooted in pathologic findings related to cystectomy specimens. As a result, it is not well suited for *clinical* staging. For example, the distinction between deep muscle invasion (T2b) and more superficial muscle invasion (T2a) cannot be reliably made by cystoscopic biopsy, and indeed the differentiation of muscle fibers in the lamina propria from muscularis propria (ie, the distinction between deep cT1 and cT2) is often problematic. Although previously categorized as stage 4 disease, a recent American Joint Committee on Cancer (AJCC) update now classifies N1-3 lymph nodes with stage 3B tumors.[61] Previous neoadjuvant trials excluded these patients from neoadjuvant trials because of the adverse impact of surgical debulking procedures on clinically involved nodes. As with most solid tumors, one must be extraordinarily

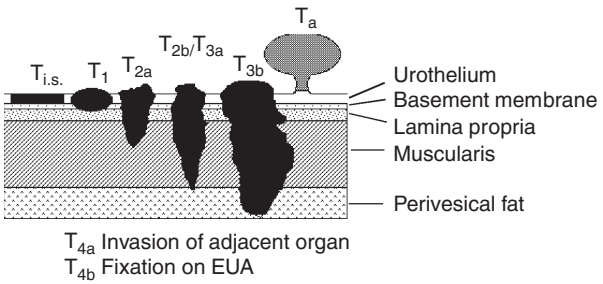

FIGURE 44–2 Current scheme for tumor (T) staging of urothelial cancer. EUA, examination under anesthesia.

careful regarding staging information, especially when comparing surgical and radiotherapy series, which necessarily rely on very different primary information.

Unfortunately, the AJCC staging system does not account for available information about tumor biology. Although "staging" has come to be understood as "prognostic assessment" for most cancers, urologic oncology lags behind in laying aside the historical notion of stage as essentially an anatomic concept. As noted earlier, the biology of papillary cancers is fundamentally different from that of nonpapillary cancers. Other biologic characteristics such as location of tumor within the bladder, the presence or absence of lymphovascular invasion (LVI), and the presence or absence of specific markers are known to influence prognosis, and thus there is a significant need to fully evaluate and standardize how such features are reported.

Although there is no official system for *clinical* staging, several important factors largely define prognosis that can be reasonably well assessed by clinical evaluation:

- The presence or absence of muscle invasion (ie, T1 vs ≥T2). This is frequently established by transurethral resection (TUR), especially if the surgeon provides deep enough samples that contain muscularis propria.
- The presence or absence of a definable mass (ie, assessable in three dimensions) by *examination under anesthesia* (EUA) after a "complete" TUR. This is the clinical definition of cT3b disease and is of critical prognostic importance. The role of cross-sectional imaging criteria for cT3b disease is controversial. We do not believe that routinely available studies can make this distinction reliably at the present time. The EUA is an essential component of the evaluation of a patient with MIBC[62] and is most informative when it is done after drainage of the bladder after the TUR has been completed. A proper EUA provides important staging information, complementing data obtained by imaging modalities such as computed tomography (CT) or magnetic resonance imaging (MRI). Whereas the presence of induration indicates deep muscle invasion, the palpation of a discreet, mobile, three-dimensional (3D) mass implies gross invasion into extravesical tissue and carries a significant risk (30%–40%) of occult lymph node metastasis. At EUA, it is possible to identify masses extending directly into the prostate in men or into the vagina in women. These findings are also associated with a high risk of occult lymph node metastasis. The finding of a mass by EUA, which extends and is fixed to the pelvic sidewall (ie, cT4b), indicates an unresectable cancer. These patients have a similar prognosis to those with overt distant metastases.
- The presence or absence of nodal disease is assessed clinically by CT or MRI imaging of the pelvis. Patients with radiographically detectable adenopathy should have a biopsy before surgery. If positive, primary chemotherapy is appropriate because distant recurrence dominates the clinical course in these patients. That being said, we advocate surgical consolidation with cystectomy and pelvic node dissection in patients with no clinical evidence of disease after chemotherapy.
- The presence or absence of LVI on the TUR biopsy specimen is also a powerful prognostic feature. The unequivocal finding of tumor cells in vascular spaces identifies a group of patients with a high risk of occult nodal involvement. In fact, LVI is associated with a risk of pN+ status of about 35%, comparable to the risk associated with a large cT3b tumor.

Other clinical factors that routinely "stay in the model" when investigators construct Cox proportional hazard models for the prognosis of urothelial cancer patients treated with cystectomy are age, gender (women consistently do worse), and time from diagnosis to definitive therapy.

From a medical oncology perspective, the most important issue is how to recognize which patients will benefit from the addition of systemic chemotherapy to definitive surgery. The current management guidelines for bladder cancer by the National Comprehensive Cancer Network (NCCN) suggest the use of neoadjuvant chemotherapy for patients with cT2 disease. In evaluating this recommendation, it should first be noted that cT2 cancers could easily be pT0 (ie, no residual disease in cystectomy specimen after initial TUR), pTis, pTa, pT1, pT2a, pT2b, or pT3a without constituting a clinical staging error. However, it is abundantly clear that the burden of residual disease (ie, the burden of disease found at cystectomy) after TUR is strongly related to the risk of disease relapse and death. In a series of 208 patients, Isbarn et al[63] demonstrated that those with residual invasive disease (ie, pT1 and pT2) were cured about 70% of the time, but all 55 of those with no residual invasive disease (pTa, pTis, or pT0) were cured.

To further highlight the enormous heterogeneity of patients with cT2 cancers, consider that we know of many features that have a dramatic influence on prognosis:

1. Cancers presenting with hydronephrosis from tumors in the region of the ureterovesical junctions (UVJs) have a very high rate of pT3b extension, occult nodal involvement, and inferior outcome. This was first reported in the 1980s and has been amply confirmed. In a study of 241 patients with cT2 disease treated by cystectomy,[64] the 5-year cause-specific survival rate (a very good surrogate for cure) was 63% for those without this feature versus 12% for those with hydronephrosis. This remained prognostically significant after accounting for pathologic stage. Similar results were obtained by Bartsch et al,[65] who observed a 68% versus a 30% survival rate, again remaining significant after accounting for pathologic stage.
2. As noted earlier, cancers exhibiting micropapillary, sarcomatoid, plasmacytoid, and small cell histology have a much more aggressive biology and inferior "stage-for-stage" outcome with cystectomy.
3. Large nonpapillary tumors (cut points range from 3–5 cm) that are muscle invasive over a broad front are much worse (ie, much more likely to be upstaged at cystectomy) than those with focal muscle invasion.
4. Cancers showing LVI, especially when appreciated in the TUR specimen, are associated with about a 30% rate of occult nodal involvement.[66]
5. In addition to these tumor characteristics, circulating levels of tumor markers are independent predictors of outcome. This has been demonstrated for human chorionic gonadotropin (hCG), cancer antigen 19-9 (CA19-9), and CA-125.[67–69]

On the basis of information that can be gathered preoperatively, it is possible to very substantially refine the clinical risk of a patient with cT2 bladder cancer. Vickers et al[70] have provided a compelling numerical analysis of just how powerful the application of a multivariate model to decision making can be and how this consistently outperforms the simple-minded notion that all patients with cT2 cancer should get chemotherapy.

In addition to these clinical features that can be ascertained preoperatively, there are surgical factors that impact outcome. For example, we know that outcome is dependent on the experience of both the surgeon and the center where surgery is performed[71,72] and that cure is consistently related to extent of pelvic node dissection,[73] and of course, patients with involved surgical margins have a higher risk of relapse.

CLINICAL MANAGEMENT

Management of Non–Muscle-Invasive Disease (cTa, cTis, N0M0)

The management of low-grade papillary disease is by TUR, and because these lesions recur but rarely progress, there is generally no thought of cystectomy except in the rare case that the bladder surface is a carpet of lesions. In such a case, just as with overwhelming colon polyposis, radical surgery to achieve appropriate tumor removal may be appropriate. After TUR, patients usually receive a single dose of immediate intravesical chemotherapy with gemcitabine or mitomycin within 24 hours of resection.[74]

High-grade noninvasive cancers present a difficult dilemma for urologists, who must balance the risk of recurrent, invasive disease (which occurs despite therapy and surveillance in at least 20% of patients) with the risk of overtreating patients not destined to have a threatening cancer. The presence of carcinoma in situ (CIS) increases the probability of both recurrence and progression. Typically, patients with either high-grade Ta disease or CIS (or both) are now treated with both TUR and intravesical immunotherapy with BCG. BCG is preferred over intravesical chemotherapy based on the results of several meta-analyses showing that BCG after TUR is superior to TUR and chemotherapy.[75,76]

Intravesical BCG was introduced in 1976, and since the first controlled trial establishing the efficacy of BCG was reported by Lamm et al in 1980,[77] it has had a remarkable impact on the clinical management of bladder cancer. It is important to note that complete responses to BCG are required for significant alteration of the natural history of the disease.[78] Partial responses should prompt referral for experimental therapy or consideration of early cystectomy. The decision to delay cystectomy in the face of less than an initial complete response to BCG is responsible for many deaths from disease that was not caught early enough, despite close surveillance.[79] In 2018, the FDA adopted the definition of BCG-Unresponsive Disease proposed by the International Bladder Cancer Group, which led to an explosion of clinical trials in this space.[80]

Until recently, treatment options were limited for cystectomy-ineligible patients with high-risk NMIBC unresponsive to BCG. In January 2020, the FDA approved pembrolizumab for the treatment of patients with BCG-unresponsive, high-risk, NMIBC with cTis who are ineligible for or have elected not to undergo cystectomy. Pembrolizumab approval was based on the results of a single-arm KEYNOTE-057 trial that enrolled 148 patients with high-risk NMIBC, two-thirds of whom had BCG-unresponsive cTis disease. The complete response rate in the cTis group was 41% with a median response duration of 16.2 months.[81]

Management of Minimally Invasive Disease (cT1, N0M0)

Patients with cancers that are invasive into the lamina propria (cT1) are at high risk of developing muscle-invasive disease. In general, patients with an invasive or high-grade component recognized on the initial TUR should have a reexcision approximately 4 to 6 weeks later.[82] A second TUR provides another opportunity to sample muscle and thus more definitively establish the status of muscle invasion, which is a key prognostic feature. In addition, the re-resection establishes which patients have persistent disease versus those who do not. Those with persistent disease have a prognosis similar to cT2 patients and should have a discussion regarding cystectomy. Conversely, a complete TUR, as demonstrated by a negative re-resection, may be adequate therapy for many patients with cT1 disease, especially if there is no CIS present and noninvolved muscle has been sampled. In the United States, most patients with cT1 disease receive BCG, and the caveats about BCG use as noted earlier apply even more strongly to this group. It is also important to recognize that tumors that overlie the ureteral orifices or involve the bladder neck are sometimes difficult to confirm as only T1 lesions and require a lower threshold for definitive surgery.

BCG Shortage

Because of increased global demand and limited supply, BCG shortage is anticipated for the foreseeable future. In the event of the shortage, treatment priority is for patients with cT1 high-grade and CIS disease. Patients who do not receive BCG may receive intravesical chemotherapy. Another alternative is to split a single dose of BCG into thirds and treat multiple patients with a single vial. Randomized trials demonstrated similar outcomes and minimally reduced recurrence rates when patients were treated with one-third dose BCG compared with full-dose BCG.[83–85] During these times of shortage, BCG induction therapy should be prioritized over BCG maintenance therapy.

Management of Clinically Localized, Muscle-Invasive Disease (cT2N0)

In the United States, radical cystectomy, which involves removal of the bladder and prostate in men and the bladder and adnexal structures in women, along with complete clearance of pelvic lymph nodes, is the standard therapy for MIBC. In older surgical series, cystectomy was curative in about half of these patients. More contemporary series typically report cure in the range of 80%, but this is on the basis of *pathologic stage*. Although it is true that in experienced centers, 80% to 85% of patients undergoing cystectomy for cancers that are found to be pathologically confined to the muscular wall of the bladder (ie, pT2b or less, N0) will be cured, it is not absolutely clear that the old figure of about 50% cure for *clinical stage* T2 patients is now obsolete. Modern series do seem to do better,[86] likely explained by better preoperative staging and patient selection, as well as better recognition of the need for an adequate lymph node dissection. Although randomized trials have not shown a benefit for extended lymph node dissection over standard lymph node dissection, we recommend that at the very least 10 lymph nodes be removed at the time of radical cystectomy.[87] Despite these advances, it must be recognized that a finding of muscle invasion signals a potentially life-threatening problem; in fact, this seems to constitute an oncologic urgency. In a study of 214 patients treated with cystectomy at the University of Michigan,[88] a cut point of 93 days from recognition of muscle invasion to surgery was associated with statistically inferior cause-specific and overall survival (OS). Specifically, about 60% of patients with timely surgery were long-term survivors versus about 40% of those with delay, even though there was no clinical or pathologic stage migration.

In view of available knowledge of prognostic features reviewed, it is clearly inappropriate in the current era to speak of "muscle-invasive" bladder cancer as though it were a single disease state with a well-defined prognosis and a single best management. We know that there are many patients with cT2 bladder cancer with such a favorable prognosis that no available systemic therapy would be expected to improve outcome over that achieved with radical cystectomy and template pelvic node dissection.[89] Likewise, we know that some patients at high risk benefit from currently available chemotherapy in addition to surgery. The challenge for clinicians, and especially for clinical investigators, is to better define those at each end of this spectrum and then continue to work on subdivision of the remaining patients in whom we currently do not know how to define the role of systemic chemotherapy. This issue of identifying the appropriate patients for systemic chemotherapy is the single most important question related to bladder cancer from a medical oncology perspective. There is no longer any question that perioperative chemotherapy can improve outcome for some patients; likewise, it is all too obvious that it can do much harm. Thus, as always, the central question for the medical oncologist is: How are we to balance risk and benefit for each patient?

Based on the impact of currently available therapy, it is our sense that patients with a 70% chance or more of cure should not be offered chemotherapy as it currently exists. Conversely, when the probability of surgical cure falls to about 40% or less, then it seems clear that chemotherapy should be offered. In between these extremes, the decision is a highly personal issue

of risk abatement versus burden of therapy. As a practical implementation that 40% cure probability is about the right threshold for chemotherapy plus surgery, we offer chemotherapy to patients with any of the following: direct invasion of the prostate or vagina (ie, cT4a disease), a 3D mass on EUA (ie, cT3b disease), LVI on TUR material, bladder neck involvement, and hydronephrosis or aggressive variant histology, including small cell, micropapillary, plasmacytoid, or sarcomatoid differentiation.

Primary Radiotherapy

In our view, radiotherapy is inferior to surgery as a local modality for bladder cancer. Available data clearly demonstrate that long-term control can be achieved in about 40% of patients with small primary tumors amenable to complete resection, not associated with CIS, not arising at the bladder neck or UVJ, and without hydronephrosis.[90] This is precisely the subset that have about an 80% cure with surgery, and claiming that the available results are "comparable" to surgical series is not justified.[91] Clearly, some patients could decide that the risks are acceptable and rationally choose radiotherapy, but this must not be presented as an option associated with a comparable outcome to surgery. When chosen as an option, we recommend the use of concomitant radiosensitizing chemotherapy.[92] Clinical trials are currently studying whether immunotherapy and radiation therapy combinations can improve the long-term control of localized urothelial cancer.

Management of Locally Advanced, Resectable Disease (High-Risk cT2N0, cT3bN0, cT4aN0)

Since the publication of the SWOG intergroup trial of neoadjuvant chemotherapy,[93] many, including the NCCN guidelines, advocate for neoadjuvant chemotherapy as the standard of care for patients with muscle-invasive urothelial carcinoma. Because in our hands, the cure fraction for patients with muscle-invasive disease only with surgery is around 85% and the use of systemic chemotherapy can be toxic in this often frail and older patient population, we have advocated for a more refined approach relying on the probability of recurrence as a guide for the use of neoadjuvant treatment. Tumors that are clinically beyond the bladder wall, (ie, those with a 3D mass at EUA) after thorough TUR of intravesical tumor carry a worse prognosis with a surgical cure rate of about 35%. Many patients with cT2 and high-risk features have a similar chance for surgical cure. The presence of LVI is associated with a high risk of nodal involvement, even in the setting of clinically negative lymph nodes on CT.

Patients with prostatic stromal involvement (from the bladder, *not* from TCC of prostatic ducts) or extension into the vaginal wall (ie, anatomic clinical stage cT4a) have a surgical cure rate in the range of 5% to 20%. A recent retrospective multicenter study of 583 patients with pT4 disease (all deemed resectable on clinical grounds) found a cause-specific survival rate of about 30%.[94] Univariate analysis confirmed female gender, LVI, nodal involvement, positive surgical margins, and pT4b substage to be associated with inferior outcome. None of these patients received neoadjuvant therapy. Collectively, these groups have what we term "locally advanced but resectable" disease, and at MDACC, they are treated primarily with chemotherapy followed by surgical consolidation as appropriate. Although this is a patient cohort with truly threatening disease, it is also true that this is the population for whom combined application of best systemic therapy and best surgical therapy has the greatest patient benefit. In the MDACC experience,[23,95,96] the benchmark outcome in this cohort is cure in about 60% of patients (by intent to treat), with about 40% having no residual invasive cancer in the resected specimen following chemotherapy (so-called "p-zero" status), which we and others[93] have noted to be a reliable indicator of long-term disease-free survival.

Recently several centers have reported on the use of dose-dense MVAC in the neoadjuvant setting for urothelial carcinoma.[23,97,98] The use of the dose-dense strategy has had multiple benefits, including a faster time to surgery with chemotherapy given on a 2-week schedule and an improved tolerance for chemotherapy. In one study, 93% of patients completed at least three cycles of neoadjuvant chemotherapy.[23] Pathologic T0 rates have been quite promising on the order of 39% with a long-term survival rate at least one center suggesting a cure fraction around 63% (Fig. 44–3).[23] Molecular characterization of urothelial tumors from the MDACC trial suggests that the basal subtype may be predictive for benefit from neoadjuvant chemotherapy,[23] a finding supported by additional retrospective evidence.[27] Further efforts in subtyping bladder cancer may yield a prognostic test available for community use that would allow us to discriminate which patients which patients are most likely to benefit from a neoadjuvant approach.

Management of Locally Advanced, Unresectable Disease (cT4b, cN1-3M0)

This group has a dismal prognosis. In our experience, patients presenting with large tumors that are clinically fixed to the rectum, pelvic sidewall, or pubic symphysis actually have a worse prognosis than patients with extrapelvic nodes or lung-only metastases. These patients are considered unresectable and are treated with chemotherapy initially and then reassessed for the possibility of surgical consolidation in light of the quality of response and their fitness for surgery postchemotherapy.[99]

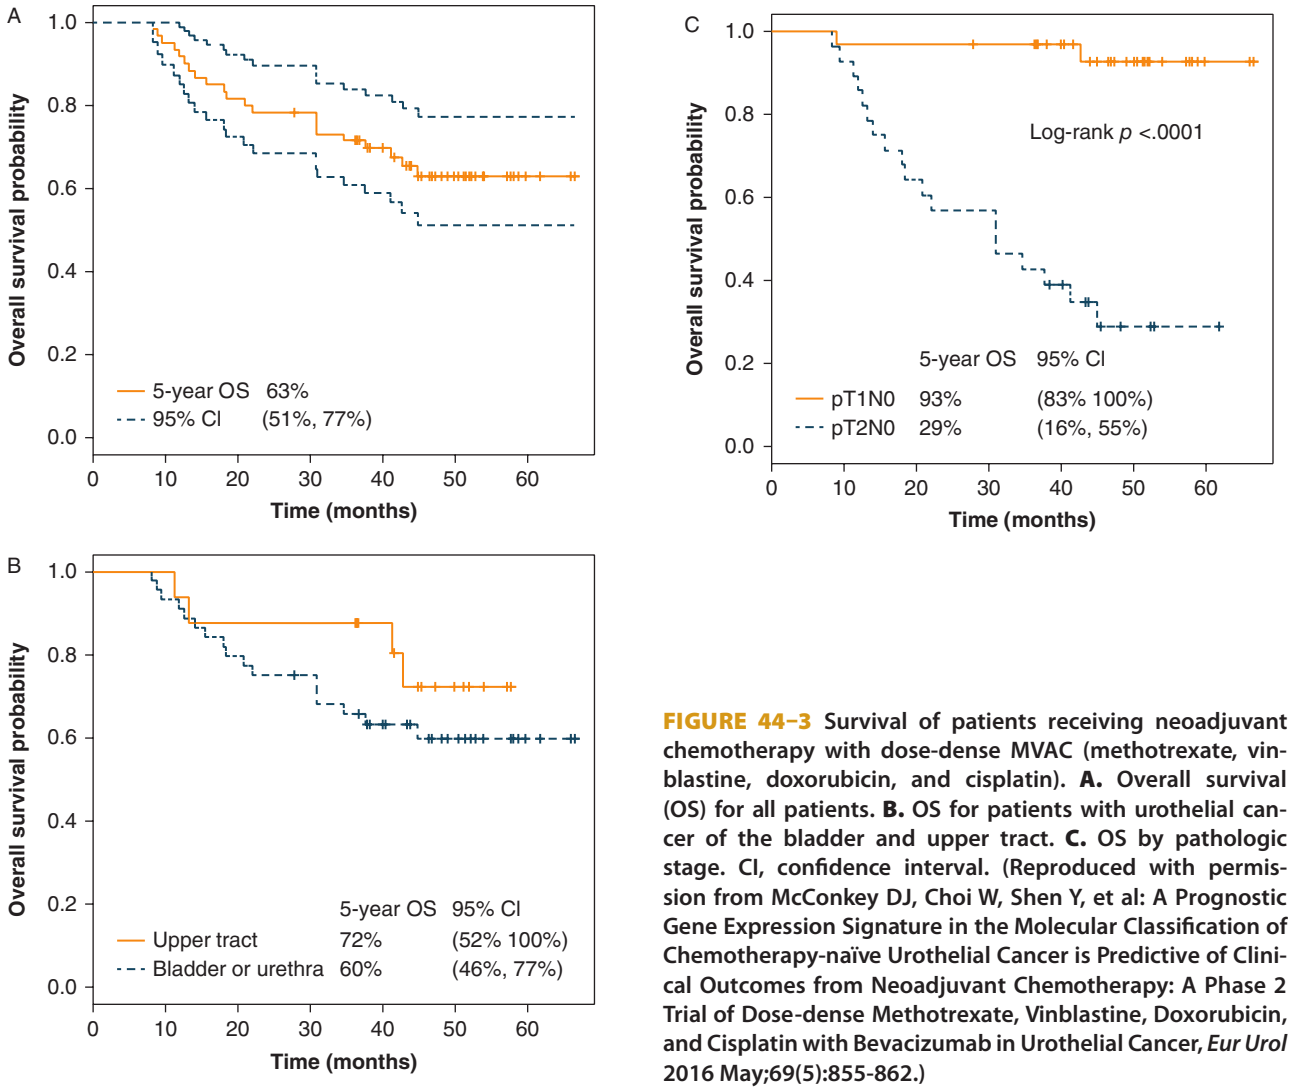

FIGURE 44–3 Survival of patients receiving neoadjuvant chemotherapy with dose-dense MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin). A. Overall survival (OS) for all patients. B. OS for patients with urothelial cancer of the bladder and upper tract. C. OS by pathologic stage. CI, confidence interval. (Reproduced with permission from McConkey DJ, Choi W, Shen Y, et al: A Prognostic Gene Expression Signature in the Molecular Classification of Chemotherapy-naïve Urothelial Cancer is Predictive of Clinical Outcomes from Neoadjuvant Chemotherapy: A Phase 2 Trial of Dose-dense Methotrexate, Vinblastine, Doxorubicin, and Cisplatin with Bevacizumab in Urothelial Cancer, *Eur Urol* 2016 May;69(5):855-862.)

Investigators from the MSKCC[100] and MDACC[101] have published their experience with this strategy. These data suggest that response to systemic therapy is the dominant prognostic feature and that surgical consolidation is both feasible and associated with long-term survival. This experience also confirmed that patients with significant residual disease after chemotherapy did not benefit from surgery, and that overall, the prognosis is still poor. Still, 22% to 40% survival rate among initially unresectable bladder cancer patients is much better than what could be expected of any single modality.

Radiotherapy has not been useful as a single modality with these large cancers. As with surgery, there probably is a role for radiotherapy in the "consolidation" of patients who show an excellent response to primary chemotherapy. It is worth emphasizing that sensitivity to chemotherapy and radiotherapy do tend to be parallel in the context of urothelial cancer. We have never seen a chemorefractory cancer respond to radiation, and we have seen some excellent long-term results from use of radiotherapy to consolidate an initially unresectable mass after an excellent response to combination chemotherapy.

Management of Distantly Metastatic Disease

Bladder cancer typically spreads first to regional nodes and then disseminates with about equal frequency to the lungs, liver, and bone. Late in the course, subcutaneous and brain metastases are common. Brain involvement is especially likely in patients who have elevated serum levels of β-hCG or variant histology, including small cell.

Even with strictly palliative goals in mind, most patients with metastatic bladder cancer should receive systemic therapy, pitched at their level of physiologic tolerance. Metastatic urothelial cancer is a very aggressive malignancy, with an untreated natural history

from the time it causes symptoms to death on the order of 3 to 4 months. Quality of life is essentially dependent on the efficacy of therapy. Even extraordinarily toxic regimens can be truly palliative in light of how rapidly (and morbidly) the disease progresses.

Since the mid-1980s, cisplatin-based combination chemotherapy has been the standard first-line therapy for advanced urothelial cancer. In the modern era with a bit of lead time bias compared with practice in the early 1980s, such treatment results in median survival of about 16 months, with few survivors beyond 3 years. This is the benchmark where therapy plateaued for more than a decade until the recent approval of five immune checkpoint inhibitors, antibody–drug conjugate EV, and erdafitinib (for patients with FGFR-mutated bladder cancer).

Surgical Consolidation

Of course, some patients with distantly metastatic disease still have disease restricted to one (or a few) anatomic areas, and one might imagine that local therapy would have a role in such a setting. However, in contrast to the situation with renal cell carcinoma, for example, surgery is almost never an appropriate initial intervention for metastatic urothelial cancer. Almost always, the disease is not really localized, and one finds rapid progression in the postoperative setting. Thus, even in cases of anatomically threatening lesions such as threatened cord compression, we generally advocate frontline chemotherapy to get the disease under some control that will then permit safe surgical intervention. Nonetheless, it is only natural to ask if there is a role for surgical consolidation after a good response to chemotherapy for (highly) selected patients with metastatic urothelial cancer. The MDACC experience with this strategy has been published in the setting of retroperitoneal lymph node metastases[99,102] and in a very small, select subset of patients with visceral metastases.[103] We have adopted the following guidelines. For patients with pelvic or retroperitoneal nodal involvement (below the renal vessels), we typically offer an extended node dissection to patients with a complete radiographic response to systemic chemotherapy. Because judging the "completeness" of response in a lymph node is problematic, we include in our working definition a negative biopsy for any node that is large enough for CT-guided biopsy. For patients with visceral involvement, we typically treat to maximum response and observe. Only when patients progress in the initially involved area (with no progression elsewhere) and then go on to have a significant response to a second course of chemotherapy do we consider surgical removal of residual metastatic disease. Just as with patients with germ cell cancers, failure of markers to normalize is nearly an absolute contraindication to surgical consolidation.

The exception to this is the rare patient with a long interval from initial management to the onset of resectable, oligometastatic visceral disease. In this setting, we typically give systemic therapy and then excise the lesions. Note that in our view, surgery without some form of systemic therapy is essentially never appropriate because these cancers have a high propensity of seeding surgical wounds. Even in the face of cord compression, chemotherapy followed by surgery is usually the preferred management.

FRONTLINE THERAPY FOR METASTATIC, SURGICALLY UNRESECTABLE UROTHELIAL CANCER

Cisplatin-Eligible Therapy

Currently, *combination therapy is standard* in the treatment of patients with metastatic TCC. The development of MVAC at MSKCC[104] was an important achievement. Subsequent landmark trials have confirmed that MVAC is superior to single-agent cisplatin[105]; the combination of cyclophosphamide, doxorubicin, and cisplatin[106]; the combination of 5-fluorouracil, IFN-α, and cisplatin[101]; and the combination of docetaxel and cisplatin.[107] In fact, there are at least nine randomized trials involving MVAC, and to date, the only challenger to even suggest improved clinical outcome was a trial of a dose-dense variant of MVAC given with granulocyte colony-stimulating factor support versus "classic" MVAC.[108] The dose-dense version was associated with markedly less mucositis, and the cycles are only 14 days (compared with 28 in the classic schedule), and thus this variant has supplanted the original. With overall response rates in the 50% to 60% range and up to 20% clinical complete response (CR) rate, there is no doubt that dose-dense MVAC provides meaningful palliation for most patients and can significantly change the natural history of the disease for a few.

In the setting of metastatic disease, for which the goals are clearly palliative, the doublet of gemcitabine and cisplatin (GC) has become a standard option. GC was compared with MVAC in a large international phase III trial.[109] This trial was negative trial that did not achieve its primary endpoint. However, the doublet was shown to be similar with respect to median survival and was associated with significantly less mucositis and neutropenic fever but more thrombocytopenia. As expected for two regimens with comparable efficacy, quality-of-life measures were not different between the two treatments despite the favorable treatment-related side effect profile of GC. In our view,

this is not a surprising finding but rather reinforces the notion that the burden of morbidity in patients with metastatic bladder cancer is far more likely to be due to the disease rather than secondary to the treatment.

Cisplatin-Ineligible Therapy

All patients considered for frontline chemotherapy should be evaluated for their ability to tolerate cisplatin-based chemotherapy. A consensus definition of patients with metastatic urothelial cancer who are unfit for cisplatin-based chemotherapy was established in 2011.[110] Based on the consensus definition, patients meeting at least one of the following are considered "unfit":

- WHO or Eastern Cooperative Oncology Group performance status of 2 or Karnofsky performance status of 60% to 70%
- Creatinine clearance less than 60 mL/min
- Common Terminology Criteria for Adverse Events (CTCAE) grade 2 or above audiometric hearing loss
- CTCAE grade 2 or above peripheral neuropathy
- New York Heart Association class III heart failure

For patients who are unfit for cisplatin-based chemotherapy but are otherwise candidates for combination chemotherapy, treatment options include a carboplatin-based therapy or a non–platinum-based combination. Carboplatin-based therapy was evaluated in the European Organization for Research and Treatment of Cancer trial 30986 that compared gemcitabine and carboplatin with methotrexate, carboplatin, and vinblastine in patients with impaired renal function of poor performance status. In this trial, carboplatin and gemcitabine therapy resulted in 41% objective response rate, 9-month median survival time, 6-month progression-free survival, and manageable toxicity with approximately 10% of patients developing grade 3 or greater adverse events.[111]

Non–platinum-based regimens present treatment options who are unfit to receive platinum-based chemotherapy. Gemcitabine and the taxanes[112,113] all have activity in urothelial cancer, and there have been many new doublets and triplets investigated over the past 10 years. From this experience, it is clear that all regimens substituting carboplatin for cisplatin show inferior results or even increased toxicity as was seen with the triplet combination of gemcitabine, paclitaxel, and carboplatin.[114]

Urothelial cancer is a disease of older adults. The lifetime accumulation of risk factors predisposing patients to bladder cancer often lead to other comorbid conditions such as coronary artery disease and chronic obstructive pulmonary disease. These diseases, in addition to other conditions, such as diabetes and hypertension, found in an aging population often contribute to poor renal function or a performance status unable to tolerate aggressive cisplatin- or ifosfamide-based therapy.

Ureteral obstruction is also a frequent factor contributing to diminished renal function, and nephrostomy tubes are an indispensable tool in the treatment of advanced bladder cancer. Nephrostomy tubes are much to be preferred over ureteral stents in patients undergoing chemotherapy for locally advanced bladder cancer. This is so because chemotherapy often engenders periods of neutropenia that can lead to chronic infection associated with foreign bodies. Nephrostomies are much more easily changed out than stents. Furthermore, stents are far more irritating and likely to bleed during periods of thrombocytopenia. It is common to have stents clog from bleeding, and this is much less problematic with nephrostomies. Finally, nephrostomies reliably decompress the kidneys, even if the cancer grows, but stents can be collapsed by tumor and even by desmoplastic reaction to therapy.

Relatively effective chemotherapy for patients with impaired renal function is now fairly easy to come by. Vinblastine, gemcitabine, taxanes, and doxorubicin can all be given safely in the context of renal insufficiency. At the present time, we favor a triplet of gemcitabine (900 mg/m^2 given over 90 minutes), paclitaxel (100 mg/m^2), and doxorubicin (30 mg/m^2) repeated every 14 days for patients with poor renal function. This regimen is reliably deliverable and has useful clinical activity.[115]

Frontline Immunotherapy

Both atezolizumab and pembrolizumab were originally approved for the frontline treatment of cisplatin-ineligible patients. The FDA then modified these recommendations, limiting their use to PD-L1–high tumors based on two frontline trials that showed patients treated with chemotherapy did better in the setting of PD-L1–low tumors. Currently, results from only one trial are available. The IMvigor130 trial compared frontline systemic platinum-based chemotherapy with chemotherapy plus atezolizumab versus atezolizumab alone. PD-L1 high was defined as immune cell expression in 5% or more of the specimen.[31] Survival favored atezolizumab monotherapy over platinum-based chemotherapy, with stratified hazard ratio (HR) for death of 0.68 (96% confidence ratio [CI], 0.43–1.08).

Frontline Maintenance Immunotherapy

Giving checkpoint inhibitors with frontline platinum-based chemotherapy has not shown evidence of definitive survival benefit. A recent "maintenance" strategy yielded positive results. Patients who received four to six cycles of platinum-based frontline chemotherapy and had stable disease or better were randomized to

either avelumab or best supportive care after a treatment-free interval of 4 to 10 weeks after the last dose of chemotherapy. The avelumab treated arm had a significantly improved median OS (median OS, 21.4 months vs 14.3 months, respectively; HR, 0.69; 95% CI, 0.56–0.86; $P = .001$). However, only 44% of the control group received second-line treatment with an immune checkpoint inhibitor, raising the question that some of this benefit reflects an "ever" immunotherapy versus "never" immunotherapy contribution.[116] A similar yet much smaller trial randomized patients to maintenance pembrolizumab versus placebo with pembrolizumab at progression. There was no significant difference in survival, with only half crossing over to pembrolizumab at progression by the time of the data lock.[117]

SECOND-LINE THERAPY FOR UROTHELIAL CANCER

Until a few years ago, there was no effective therapy for patients with platinum-resistant urothelial cancer. This second-line cohort includes patients who progress within 1 year of their last dose of neoadjuvant or adjuvant chemotherapy because of the similar prognosis. Single-agent taxanes were typically used or alternate combination chemotherapy. We have recently seen several new agents approved for this indication, including immune checkpoint inhibitors and now the first biomarker targeted therapy erdafitinib, which has efficacy in FGFR3-altered tumors. Only pembrolizumab has comparison data showing a survival benefit compared with single-agent taxanes.

Immune Checkpoint Inhibition

Currently, there are five immune checkpoint inhibitors approved for the second-line treatment of patients with metastatic urothelial cancer: pembrolizumab,[118] nivolumab,[29] atezolizumab,[119] durvalumab,[120] and avelumab.[121] Only pembrolizumab has level 1 evidence showing not only a survival benefit (10.3 months vs 7.4 months; HR, 0.73; $P = .0022$) but also an improved response rate and toxicity profile compared with single-agent taxanes.[118] Based on multiple phase 2 results, the other four checkpoint inhibitors appear to have similar activity, reporting response rates in the range of 15% to 20%, and a median OS ranging from 7.4 to 10.3 months, with potentially minor differences appearing most likely related to patient selection rather than a statement of differential activity for PD-1 or PD-L1 inhibition. Despite this "plethora" of checkpoint inhibitors, these appear to only reflect one "line" of therapy because there does not appear to be any appreciable benefit when switching from one checkpoint to another or sequencing from PD-L1 to PD-1 or vice versa. Biomarkers, including PD-L1 expression levels, tumor mutation burden, and a variety of other immune factors, have shown an increased likelihood of benefit from immunotherapy but do not provide any definitive direction as to who should or should not receive an immune checkpoint inhibitor. As a result, these measurements are not needed for treatment with second-line immune checkpoint inhibition.

FGFR3-Targeted Therapy

FGFR point mutations and fusions are present in up to 20% of locally advanced or metastatic urothelial cancers of the bladder and up to 35% of upper tract urothelial cancers.[122] Erdafitinb has pan-FGFR3 inhibition across FGFR1-4, with IC50 in the single-digit nanomolar range. A recent phase 2 trial of erdafitinib in patients with FGFR3-altered, previously treated urothelial cancer showed evidence of clinical activity with an objective response rate of 40% and median OS of 13.8 months (Fig. 44–4), resulting in accelerated approval of erdafitinib in April 2019.[32] A retrospective look at investigator reported response to previous checkpoint inhibition found a low response rate of 1 of 22 patients, suggesting that these FGFR3 altered tumors may benefit more from an FGFR3-targeted strategy as a result of their enrichment for an "immunologically cold" tumor profile. A more recent study from the second-line nivolumab and atezolizumab trial datasets suggest that FGFR3-altered urothelial cancers do respond to immunotherapy, although long-term outcomes of benefit were not included. The THOR clinical trial[34] randomizes FGFR3 altered urothelial cancer patients to either erdafitinib or pembrolizumab and will definitively determine whether FGFR3-altered tumors benefit more from second-line immunotherapy or FGFR3-targeted therapy.

THIRD-LINE THERAPY FOR UROTHELIAL CANCER

Antibody–drug conjugates are showing promise in the treatment of urothelial cancer. EV is an antibody conjugate targeting nectin-4 expression, which is present on 94% of metastatic urothelial cancers. After selectively targeting urothelial cancer cells, the cleavable linker releases auristatin, a microtubule agent, directly into the tumor cell. This third-line trial had reported a response rate of 44% with a median survival period of around 11 months, resulting in FDA-accelerated approval in December 2019.[35] Current studies combining EV with pembrolizumab in the frontline treatment of patients with metastatic urothelial cancer are

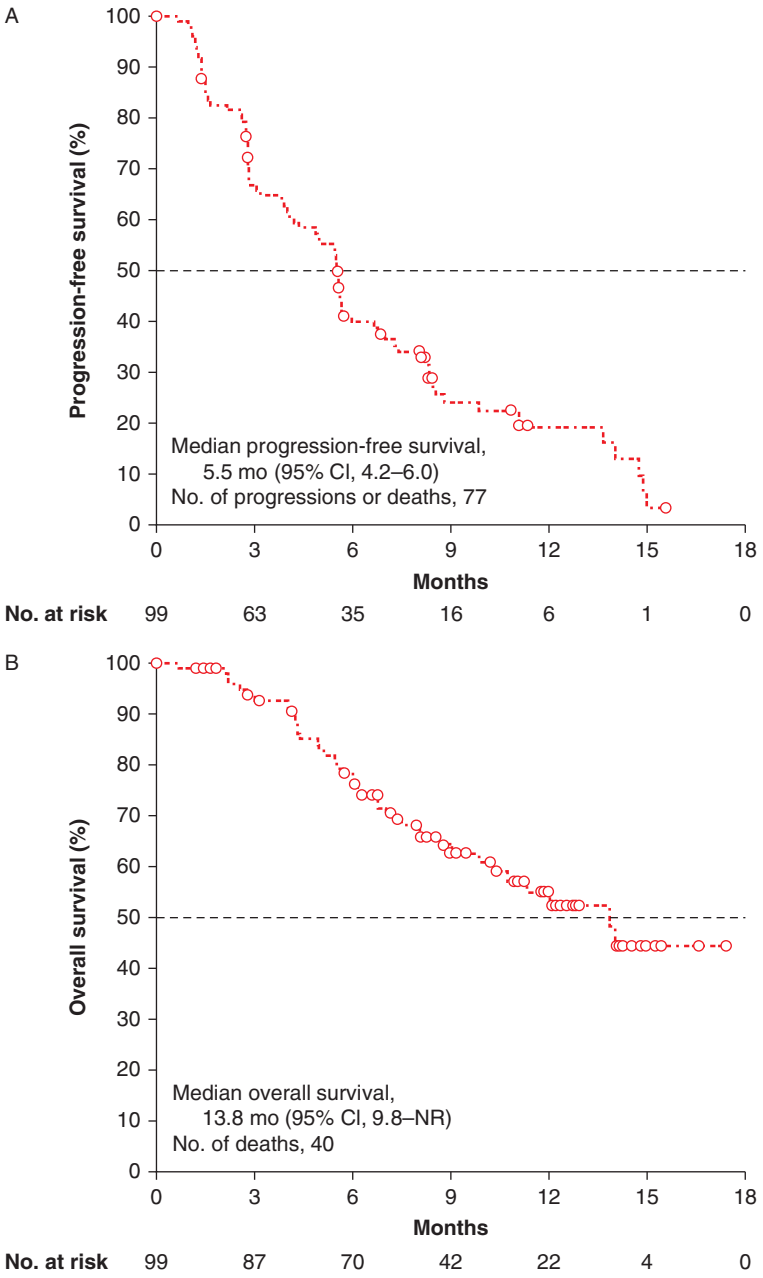

FIGURE 44–4 **Progression-free survival and overall survival of patients after continuous daily treatment with erdafitinib. (Reproduced with permission from Loriot Y, Necchi A, Park SH, et al: Erdafitinib in Locally Advanced or Metastatic Urothelial Carcinoma, *N Engl J Med* 2019 Jul 25;381(4):338-348.)**

showing impressive early evidence of clinical activity with objective responses greater than 60%, so it seems likely that we will see EV moving to the frontline setting as well.

FUTURE PROSPECTS

The future is looking bright for patients with urothelial cancer. Multiple current clinical trials are investigating the impact of combining immunotherapy with systemic chemotherapy for the treatment of patients with advanced urothelial cancer and in the neoadjuvant setting. Combinations with other checkpoint targets including anti–CTLA-4 (cytotoxic T-cell lymphocyte antigen-4) antibodies appear promising as well, with response rates around 38% with a combination of nivolumab 1 mg/kg with ipilimumab 3 mg/kg.[123] A phase 3 trial is evaluating the benefit of this combination in the frontline setting. However, it appears that many of these IO combinations have greater benefit in the PD-L1–high tumor groups.

Improving antitumor activity of checkpoint inhibitors in the "immunologically cold" PD-L1–low tumors remains an unmet need, with trials currently accruing to overcome this limitation. Bempegaldesleukin is an IL-2 analogue stimulating selective proliferation of lymphocytes associated with the immune response. Early results from an expansion cohort of a phase 1 trial reported response rates of nearly 50%, regardless of PD-L1 expression levels or CD8+ T-cell presence.[124] Another trial, NORSE, builds on the developments in FGFR3 inhibition by combining erdafitinib with the PD-1 inhibitor cetrelimab. Early results from the phase 1 portion suggest object response rates greater than 50% in previously treated urothelial cancer patients.[125] Another tyrosine kinase inhibitor, sitravatinib, targets the TAM family of receptors and when combined with nivolumab had an objective response rate (ORR) of greater than 30% in patients who progressed after treatment with a checkpoint inhibitor.[126]

Additional antibody–drug conjugates are also being developed in urothelial cancer patients. SG targets trop-2 on tumor cells, bringing a payload of a topoisomerase inhibitor to the tumor, is also showing a promising response rate in the third-line setting. Sirtratumab targeting SLTRK and others targeting Her-2 are also being explored for evidence of clinical activity. With the promising activity of EV with pembrolizumab reported earlier, it seems likely that checkpoint inhibitors will be become the backbone of multiple combinations treating patients with urothelial cancer.

Urothelial cancer is no longer just one disease. Novel agents and selection strategies have now come to this disease, with an energy and optimism that we are moving from cytotoxic strategies to immunologic and targeted interventions that will be embraced by physicians and will enhance the lives of our patients. The era of personalized medicine is indeed upon us.

MD ANDERSON PRACTICE TIPS

- It is important for pathologists to recognize the presence of variant histology because it could alter therapy. One example is the strong recommendation for neoadjuvant chemotherapy for small cell urothelial cancer.
- Although neoadjuvant chemotherapy is currently recommended for patients with muscle-invasive urothelial cancer, there is a group of "low-risk" patients who do well with surgery alone. We currently advocate for neoadjuvant cisplatin-based chemotherapy when the following high-risk features are present: cT3b disease (typically by EUA at MDACC), LVI, hydronephrosis, or variant histology, including micropapillary, sarcomatoid, or small cell. When absent, we would offer initial surgery, and adjuvant chemotherapy if upstaging occurs to pT3b or greater or N+ disease.
- Although the "consensus" definition for cisplatin eligibility includes a creatinine clearance of 60 mL/min or greater, several trials suggest one can treat to a lower clearance. At MDACC, we give full-dose cisplatin for a clearance of 50 mL/min or greater and split-dose cisplatin (35 mg/m^2 on days 1 day 2) for a clearance of 40 mL/min or greater. This strategy incorporates aggressive fluid hydration and use of nephrostomy tubes in the setting of obstruction.
- There is currently much debate as to whether maintenance immunotherapy with avelumab is better than immunotherapy at progression. Our current view is that both are good standards and reasonable to consider. This debate may disappear if immunotherapy becomes a frontline standard when considering the early evidence suggesting an excellent response rate with frontline EV with pembrolizumab.
- Erdafitinib dosing with uptitration on day 15 based on target phosphorous levels may induce a better response to erdafitinib. However, most patients cannot continue on a 9-mg/day dose indefinitely and may have their responses maintained at lower doses. We view this treatment as an "induction-maintenance" approach in which the higher dose induces a deeper response that may be maintained at lower doses of erdafitinib.
- It is important to follow fasting glucose levels before each dose of EV and hold therapy for a glucose level greater than 250 mg/dL. Increasing glucose and difficult to control diabetic ketoacidosis despite insulin drip with death occurred in earlier EV trials, which led to this recommendation. Although the mechanism is not definitively known, this author (ASR) hypothesizes it could reflect liver toxicity from auristatin impacting the ability to store glycogen. We advise caution on use of this therapy in patients with cirrhosis.

KEY CONCEPTS

- Risk categories (low, intermediate, and high) for localized prostate cancer based on T-stage, grade grouping, and prostate-specific antigen at diagnosis help guide treatment approaches. Whereas men with low-risk prostate cancer should be considered for active surveillance, men with high-risk disease should be considered for definitive therapy after confirming no evidence of distant metastatic disease. Although favorable intermediate-risk disease can also be considered for active surveillance, definitive treatment of patients with unfavorable intermediate-risk disease is recommended if life expectancy is 10 years or longer and can be considered on a patient-by-patient basis depending on comorbid conditions.
- For men with high-risk localized prostate cancer, multiple studies have confirmed the additive benefit of androgen-deprivation therapy (ADT) plus radiation over either modality alone. Furthermore, the addition of second-generation antiandrogens (eg, abiraterone acetate and prednisone) has been shown to improve disease-free survival over ADT alone when given with radiation therapy. The optimal duration of androgen ablative therapy in this setting is still under investigation.
- ADT remains the backbone of treatment for men with recurrent prostate cancer. However, prolonged ADT has high potential morbidity, and recurrent prostate cancer is a heterogeneous disease. For nonmetastatic castrate-sensitive recurrence after definitive local therapy, intermittent ADT can be considered. For metastatic castrate-sensitive disease, intermittent ADT failed to show noninferiority to continuous ADT; however, with second-generation antiandrogens being moved into the metastatic castrate-sensitive space, the treatment decision should be made on a patient-by-patient basis.
- Androgen biosynthesis inhibition as well as androgen receptor inhibitors have been moved earlier in the treatment of patients with prostate cancer with multiple approvals in the nonmetastatic castrate-resistant setting (darolutamide, apalutamide, enzalutamide) and the M1 castrate-sensitive setting (abiraterone acetate with prednisone, enzalutamide, and apalutamide). Choice of inhibitor should be based on side effect profile and the patient's comorbid conditions.
- All men with metastatic prostate cancer, as well as those with high-risk localized prostate cancer, should be considered for germline genetic testing regardless of family history. This test should include analysis for variants in *BRCA1/2*, and other DNA damage response (DDR) genes should be considered for testing. Men with localized disease that is not high risk should be considered for genetic testing if there is a strong family history of hereditary prostate cancer or concern for hereditary breast and ovarian cancer syndrome. Men with deleterious variants in *BRCA1/2* (somatic or germline) with prostate cancer who have progressed on standard-of-care second-generation antiandrogen(s) should be considered for treatment with poly (ADP-ribose) polymerase (PARP) inhibition (eg, olaparib [PROfound] or rucaparib [TRITON]). In addition, men with DDR gene alterations or hypermutated cancers (eg, high microsatellite instability or loss of mismatch repair protein expression) should be considered for immune checkpoint blockade because trials have shown these alterations can predict for response to immune checkpoint blockade (CheckMate 650).
- AVPC (androgen-indifferent) and neuroendocrine prostate cancer are molecularly characterized by aberrations in *TP53, RB1*, and/or *PTEN*. These cancers have been shown to benefit from carboplatin-based chemotherapy (eg, carboplatin with cabazitaxel). Active research is ongoing to better define and treat these aggressive prostate cancer subtypes.

Over the past decade, insight into the biological basis of prostate cancer development and progression has influenced our approach to treating patients with the disease. Although research efforts have historically focused on the prostate cancer epithelial cell, there is growing evidence that interactions between the host tissue microenvironment and the cancer epithelial cell are critical for tumorigenesis. Understanding the bidirectional cancer cell–host interaction now dominates prostate cancer research.

Prostate cancers have recognizable clinical features that allow anticipation of their clinical behavior. Fortunately, the progression from localized, androgen-dependent disease to castration-resistant disease with bone-forming metastases occurs in only a minority of patients. To conceptualize the clinical heterogeneity displayed along this continuum, patients have historically been assigned to different "clinical states" (eg, metastatic castrate vs noncastrate) to help structure treatment recommendations and therapy development.[1,2] However, this approach has been limited by the fact that patients within each state display wide biological heterogeneity and response to therapy. To address this, improved classification of the disease based on the underlying molecular mechanisms of progression is necessary. This effort will create a "marker-driven" strategy to more reliably predict prostate cancer progression, permit optimal selection of specific therapies for individual patients, and apply therapy to only those patients who need it. This tailored approach can favorably improve the outcome of selected patients threatened by their disease while avoiding unnecessary morbidity associated with treatment to the majority who are not.

EPIDEMIOLOGY AND CLINICAL FEATURES

Prostate cancer is a major health care challenge in the United States.[3] It is the second most common cancer in men (behind skin cancer) and the second leading cause of cancer-related death after lung cancer. There are several unique clinical features of prostate cancer that distinguish it from other solid tumor types:

1. Despite the high prevalence of prostate cancer, the majority of men diagnosed with the disease ultimately die from other causes.
2. Cancer of the prostate often has a prolonged natural history. This is evidenced by a high incidence of occult malignancy in autopsy series of men who die from nonprostate cancer causes and in clinically normal prostates of men undergoing cystoprostatectomy for bladder cancer. Therefore, over the course of a normal lifetime, most men will develop "clinically occult" prostate cancer that will never produce symptoms, require treatment, or cause death.
3. The incidence of detected carcinoma increases with age.
4. Androgens are a major driving force in normal prostate development and are implicated in tumorigenesis.
5. Prostate cancer is typically multifocal, commonly presenting as synchronous carcinomas arising in multiple locations, and the malignant potential is determined by the sum of the primary and secondary grades (Gleason score). Thus, biologic heterogeneity is an inherent property of each tumor.
6. Clinical prostate cancer is more prevalent in men from Western compared with Eastern societies, although incidence rates increase for men from China and Japan who immigrate to the United States. This observation implicates environmental factors (eg, diet, lifestyle, etc) in prostate cancer development.
7. Prostate cancers have a predictable rate and pattern of progression, with bone-forming metastases dominating the clinical progression in the majority of patients with advanced disease. This observation supports the hypothesis that the bone-epithelial interaction is central to the progression of prostate cancer.

Aging

It has long been recognized that prostate cancer is a disease of older adults. Epidemiologic data demonstrate that rates of prostate cancer incidence and mortality increase with age.[4] Although prostate-specific antigen (PSA) screening has led to an earlier average age at diagnosis, deaths are still largely seen in patients 70 years of age or older. As the longevity of populations increases worldwide, the burden of prostate cancer creates a significant health care challenge. This has generated a sense of urgency among physicians to refine our ability to predict cancer virulence and escalate therapy for patients who truly need it.

Endocrine

Androgens are central to the normal growth, differentiation, and function of the prostate gland, although the role of androgen-receptor (AR) signaling in prostate carcinogenesis and progression has not been fully elucidated. Even in the clinically castrate state (serum testosterone <50 ng/mL), there is growing evidence that prostate cancer cells continue to rely on AR signaling for proliferation.[5] One of the principal mechanisms

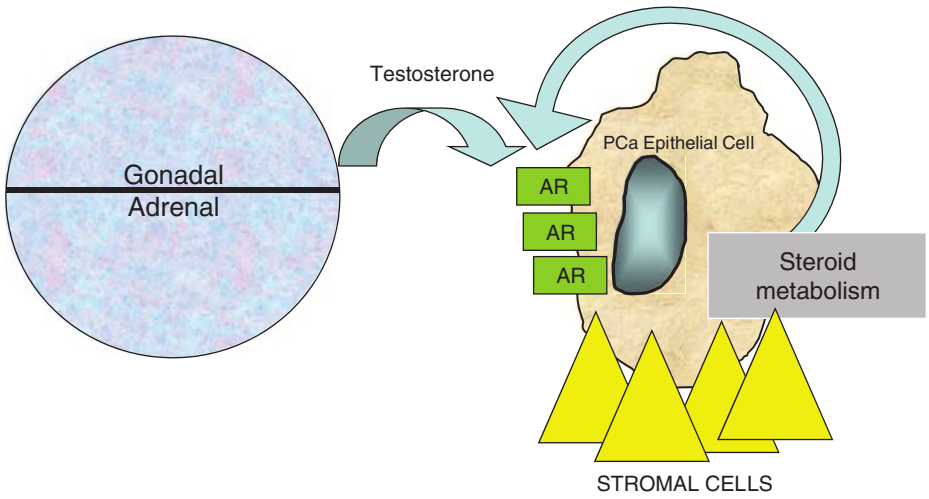

FIGURE 45–1 **Androgen sources switch from endocrine to paracrine and autocrine during disease progression. PCa, prostate cancer.**

for this involves a gradual shift from endocrine sources of androgens (ie, from the testes and adrenal glands) to paracrine, autocrine, and intracrine (ie, intratumoral) sources during prostate cancer progression (Fig. 45–1). This occurs through the peripheral conversion of adrenal steroid precursors (eg, dehydroepiandrosterone and androstenedione) in prostate and bone tissues expressing CYP17 enzymes.[6] Other mechanisms accounting for castrate resistance include intratumoral amplification of AR, mutations of AR, changes in levels of AR cofactors, and ligand-independent activation of AR (see Fig. 45–1).

Diet and Obesity

Several lines of clinical and experimental evidence support a central role of a high-fat diet, caloric intake, and obesity in the development of prostate cancer with lethal potential. Obesity, defined as body mass index (BMI) above 30, is manifested by overgrowth of white adipose tissue (WAT). Obesity has been associated with incidence, progression, and mortality of prostate cancer.[7,8] The mechanism for the association between obesity and prostate cancer progression is poorly understood. Further complicating the understanding of how obesity influences prostate cancer outcomes is studies showing that obesity and increasing adiposity in men with metastatic castration-resistant prostate cancer (mCRPC) may actually have improved clinical outcomes, a potential "obesity paradox."

A large genetic epidemiologic study of predetermined genetic variants associated with increased height, BMI, or both did not predict for prostate cancer risk; lifestyle factors such as diet and physical activity may contribute to prostate cancer development and progression. For example, a preclinical model of prostate cancer revealed that high-fat diet led to activation of MYC transcriptional program with subsequent cancer cell growth and increased tumor burden. In addition, studies have shown that WAT itself may have direct effects on cancer cell growth across a variety of cancer cell histologies.

Mechanisms linking obesity and aggressive prostate cancer include signaling through insulinlike growth factor 1 (IGF-1) and adipokines.[9] The insulin–IGF-1 axis has been widely implicated in obesity-induced tumorigenesis, including prostate cancer.[10] Primary human prostate cancer commonly expresses the insulin receptor, suggesting insulin may stimulate tumor growth.[11] Both excess body weight and a high plasma concentration of C-peptide are associated with increased prostate cancer–specific mortality.[12] In addition, the antidiabetic agent metformin has been shown to reduce all-cause and prostate cancer–specific mortality rates among men with diabetes.[13]

Beyond changes in insulin, obesity alters levels of adipokines (eg, leptin, adiponectin) because of chronic subclinical inflammation. Leptin is associated with in vitro protumor effect in human prostate cancer cell lines,[14] but epidemiologic studies have failed to consistently establish an association with prostate cancer risk and mortality.[15] In contrast to leptin, adiponectin serum levels are reduced in obesity and have largely antitumor effects.[16]

Race and Ethnicity

African American men are at higher risk of developing and dying from prostate cancer. The reasons behind why prostate cancer tends to display a more aggressive phenotype in African American men are thought to be multifactorial. A recent study of more

than 300,000 men with prostate cancer showed that Black men who were followed and treated in Veterans Affairs health system and National Cancer Institute–sponsored randomized clinical trials did not display inferior prostate-cancer–specific mortality, thus suggesting that equitable access to care and standardized treatment plays a significant role in increased mortality from prostate cancer in Black men. Genomic studies of prostate cancer tumors from Black men have revealed *ERF* deletions in 3% of primary prostate cancers and mutations or deletions in *ERF* in 3% to 5% of lethal castration-resistant prostate cancers (CRPCs), as well as frequent mutations in DNA damage response (DDR) gene pathways, including nucleotide excision repair. As discussed further later, now that clinical genetic testing includes sequencing of the entire exome of certain cancer-related genes (instead of just hot spot mutation testing), it has been shown that African American men are also equally likely to carry deleterious hereditary variants in DDR genes, such as *BRCA2*, which significantly increase the risk of developing aggressive prostate cancer.

It is imperative that clinical trials be more inclusive and representative of our diverse population, and it is also exceedingly important for further research to be done on disparities and health care access issues for minority men in terms of prostate cancer screening and treatment and to enact policy changes to resolve these systemic barriers to quality care for all.

Genetic Predisposition

Prostate cancer has been shown to cluster within families and exhibit Mendelian inheritance patterns. Family history of prostate cancer has been shown to increase prostate cancer risk whereby the risk is influenced by (1) the number of affected family members, (2) first-degree affected relatives compared with those who are more distantly related, and (3) the presence of early-onset cancers in a pedigree (typically men diagnosed at or before age 55 years). Early genome-wide linkage studies focusing on families with a history of hereditary prostate cancer resulted in the identification of a number of potential candidate loci. A recurrent mutation was identified in the *HOXB13* gene, a member of the homeobox gene family, which resulted in a nonconservative substitution of glutamic acid for glycine (G84E). Multiple studies of men with prostate cancer of European ancestry have shown that *HOXB13* G84E increases the risk of prostate cancer, with cancer onset at earlier age and more likely to be found in men with a family history of prostate cancer. However, the molecular mechanism by which *HOXB13* G84E promotes prostate cancer development remains unknown.

Deleterious variants in DDR genes, most notably in *BRCA2*, have been shown across multiple studies to significantly increase the risk of prostate cancer. Men with metastatic and high-risk localized prostate cancer are enriched (≥15%) for deleterious germline variants in cancer-related genes, particularly DDR genes, regardless of family history. Men with prostate cancer with distinct phenotypes, such as early-age onset of prostate cancer (younger than 55 years old) or multiple primary malignancy phenotype, have also been shown to be enriched for hereditary variants in cancer-related genes. These findings have led to the recommendation for universal germline genetic testing in men with metastatic or localized high-risk prostate cancer, regardless of family cancer history. In terms of which genes to test, there is consensus for *BRCA1* and *BRCA2*, with recommended testing of other DDR genes as well, with most patients receiving a panel-based test. Variants in other DDR genes including but not limited to *ATM*, *CHEK2*, and mismatch repair (MMR) genes have low to moderate penetrance in prostate cancer, with testing results often yielding variants of unknown significance; however, they should be considered in panel germline testing for patients with prostate cancer. It is imperative to perform germline testing because positive results can inform the patient's risk for other cancer types and risk of cancer for family members and can also now guide targeted treatment as discussed later in this chapter.

Cohort studies of men with hereditary *BRCA2* mutations show an increased risk for prostate cancer and for higher grade disease and shorter time to cancer progression, with these men showing a significantly reduced cause-specific survival from time of diagnosis of mCRPC. Furthermore, men with deleterious germline variants in DDR genes, including *BRCA2*, display similar outcomes to frontline chemotherapy or androgen-signaling inhibition as do their DDR-germline wildtype matched counterparts, but preliminary data suggest that mutation carriers may do better with frontline AR-signaling inhibition than with docetaxel chemotherapy. As discussed further in this chapter, men with deleterious *BRCA2* variants are most likely to derive benefit from poly (ADP-ribose) polymerase (PARP) inhibitors and possibly platinum chemotherapy.

RELEVANT HISTOMORPHOLOGY OF PROSTATE CANCER

Most epithelial cancers arise from the prostatic acinus, with fewer than 10% having a pure ductal origin. (This is the opposite of the pattern seen in cancers of the pancreas and breast, in which ductal cancers are far more common than those arising in the acinar portion of the secretory unit.) The majority show glandular differentiation (ie, adenocarcinoma) (Fig. 45–2A).

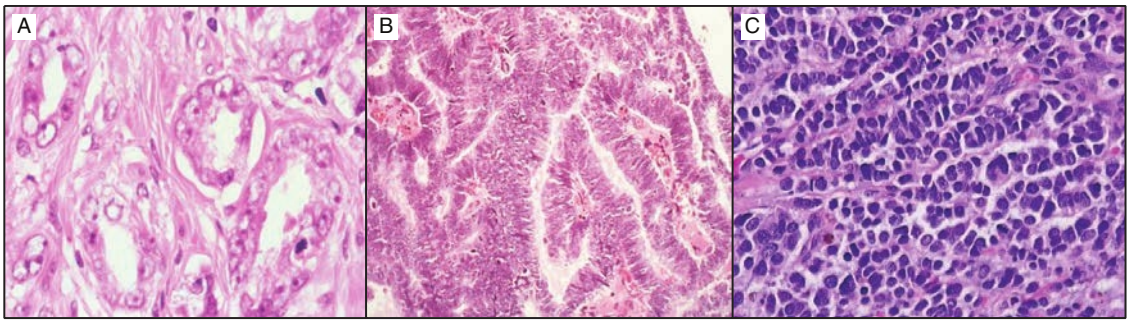

FIGURE 45–2 **A. Architecture of prostate adenocarcinoma. B. Architecture of prostate ductal carcinoma. C. Architecture of prostate small cell carcinoma.**

Importantly, mucin is essentially never seen in prostate cancer. Historically, numerous grading systems have been devised using all of the typical morphologic criteria by which pathologists can sometimes infer biologic potential. Although more than 20 systems have been put forward, prostate cancers are now almost universally graded according to the Gleason system.

Gleason Grading System

The Gleason system is unique among pathologic grading systems because it is a composite classification based on a combination of architectural and cellular features often considered in the grading of other epithelial cancers. As originally described, the Gleason system includes two components:

1. There are five patterns, or grades, ranging from normal architecture to arrays of cells without any glandular organization at all. At our institution, because unequivocal criteria for malignancy already correspond to Gleason grade 2 and the Gleason grade 1 category is rarely reported, prostate cancers are assigned Gleason grades ranging from 3 through 5.
2. Gleason score is obtained by assigning one Gleason grade to the most dominant (ie, "primary") pattern and another to the next most common (ie, "secondary") pattern. By convention, such data are expressed as a sum, with the primary pattern listed first. Thus, the Gleason score can range from 2 (ie, 1 + 1) to 10 (5 + 5). At MD Anderson Cancer Center (MDACC), these scores range from 6 to 10, reflecting our decision not to assign a Gleason grade of 1.

A major advantage of the Gleason grading system is its reproducibility and ability to distinguish different cancer phenotypes that influence clinical management. The system is most useful for tumors falling at one the extremes (eg, Gleason score ≤6 vs Gleason score 8–10). However, a major disadvantage of the system is that it does not provide a refined view of Gleason 7 tumors, the most commonly reported type. Gleason 7 cancers (ie, 3 + 4 or 4 + 3) represent a clinically heterogeneous group with variable biologic potential and clinical outcome.[17] Despite efforts to improve stratification of Gleason 7 tumors, it is clear the Gleason system is inherently limited by light microscopic methodology to evaluate morphology. Thus, most investigators are now looking to incorporate molecular characterization of tumors into the current grading system.

Assessment of Prostate Biopsies and Prostatectomy Specimens

Gleason grading is a validated system to prognosticate untreated prostate cancers sampled at initial diagnosis. However, the common practice of applying Gleason grading to treated cancers may be misleading. At MDACC, for example, pathology reports of specimens obtained after hormone ablation typically indicate "hormonal treatment effect" rather than a Gleason grade per se. Thus, Gleason scores from serial biopsies obtained pre- and posttherapy from the same patient should be interpreted with careful regard to treatment effects. To address this problem, our group has proposed a novel "posttherapy" histologic classification to introduce uniformity in analysis of treated tissue specimens.[18] If prospectively validated, this system should prove useful in prognosticating preoperatively treated prostate cancers.

An additional confounding variable is tissue sampling. We recognize that there is intratumoral heterogeneity of grade within individual prostate cancers. Thus, it logically follows that the extent and areas of sampling affect the accuracy of grading and staging. The development of techniques to obtain prostate tissue samples with ultrasound guidance and limited patient morbidity has had a major effect on stage and grade assignment. We increasingly find that the completeness of tissue sampling as measured by the number and distribution of transrectal biopsies greatly influences the adequacy of tumor staging and grading. Biopsy algorithms have been developed

to ensure adequate number and distribution of the biopsies.[19]

Many of the challenges attributed to the sampling errors that occur with needle biopsies can be overcome with proper handling of the prostate after surgery. Assigning a primary and secondary Gleason score is straightforward in a properly processed specimen. This requires great attention to detail in assessing whether the cancer has invaded beyond the prostate capsule (extracapsular) or beyond the margin of resection (margin positive). Effective communication between the surgeon and pathologist is essential to properly identify the extent and site of surgical margin involvement. As the therapeutic benefit of postoperative radiation therapy is better appreciated, the importance of these aspects has proportionally increased.

Molecular Genetics of Prostate Cancer

In prostate cancer, gene fusions between *TMPRSS2* (21q22.3), an androgen-regulated gene, and *ERG*, from the ETS family of transcription factors (21q22.2), are common.[20] However, the functional and prognostic significance of *TMRPSS2-ERG* remain poorly understood. Currently, detection and measurement of *TMPRSS2-ERG* are not performed in standard clinical practice.

Additional studies have sought to refine the diagnostic classification of prostate cancer through molecular methods. Unfortunately, no consensus yet exists about the usefulness of molecular phenotypic (or genotypic) characterization in prostate cancer. Using immunohistochemistry, we do know that expression of specific proteins in human specimens has been linked to the clinical course of the disease. For example, loss of functional PTEN (phosphatase and tensin homolog), mutations in p53, and increased expression of Bcl-2 are some of the widely reported gain- and loss-of-function changes that have been correlated with prostate cancer progression and mechanistically linked to castration-resistant growth.[21,22] Despite this link to biology and correlation with clinical outcome, the methods provide insufficient additional clinical information to justify their routine use.

Prostate Cancer Variants

Ductal Cancers

The ductal variant of prostate cancer in its pure form is unusual. More often, ductal and acinar components are mixed, and the relative contribution of the ductal variant to the clinical phenotype of the cancer is unclear. Our impression of the behavior of ductal cancers of the prostate is based on tumors that are either dominant or pure ductal in origin (Fig. 45–2B). The clinical features that lead us to suspect its presence include the lack of proportional rises in serum PSA concentrations with invasion of the base of the bladder (occasionally mistaken for urothelial cancer), soft tissue distribution of metastases, or lytic bone metastases. For localized disease, patients with pure ductal adenocarcinoma have a better clinical outcome after radical prostatectomy than patients with mixed ductal adenocarcinoma.[23] Men with de novo metastatic ductal cancers display poor outcomes with prostate cancer that is typically resistant to multiple therapies, and men with ductal features display more aggressive disease and a higher probability of developing visceral metastases than pure acinar adenocarcinomas.

Small Cell and Aggressive Variant Prostate Cancers

Small cell prostate cancer (SCPC) is a histologically defined variant demonstrating "salt-and-pepper" chromatin, neuroendocrine marker expression (ie, chromogranin, synaptophysin), and a high nuclear-to-cytoplasm ratio (Fig. 45–2C). It is androgen-indifferent and clinically virulent with higher frequency of visceral metastases (eg, liver or lung), bulky lymph node involvement, lytic rather than blastic bone metastases, and little to no PSA production. The classic clinical presentation is a patient with a precipitously enlarging prostate associated with obstructive symptoms and very little (to no) PSA production. It can arise de novo or, more commonly, as a delayed manifestation of progression in patients with a history of high-grade adenocarcinomas after therapy (hormone ablation, radiation therapy, or chemotherapy). As a result, a biopsy should be obtained from a metastatic site if atypical clinical features develop after treatment for conventional adenocarcinoma, particularly if the PSA is lower than would be expected for the volume of disease. Interestingly, the evolution to a neuroendocrine phenotype is often associated with expression of carcinoembryonic antigen, which may be a more useful monitoring tool than PSA. Tumor testing for neuroendocrine markers (chromogranin, synaptophysin, CD56, neuron-specific enolase, or bombesin) may be performed though expression is not particularly sensitive or specific for a virulent clinical course in our experience.

Increasingly, biopsies of metastatic lesions demonstrating characteristic atypical features of SCPC are found to be adenocarcinomas with variable neuroendocrine marker expression. We have termed these tumors *aggressive variant prostate cancer* (AVPC), replacing the previous term "anaplastic," which is reserved as a histologic description. AVPC clinical criteria include exclusive visceral metastases, radiographically evident

lytic bone metastases, bulky lymphadenopathy (≥5 cm) or a bulky high-grade mass (≥5 cm, Gleason ≤8) in the prostate or pelvis, low PSA (≤10 ng/mL) at initial presentation (before androgen-deprivation therapy [ADT] or symptomatic progression of castrate-resistant disease) plus high-volume (≤20) bone metastases, or short interval (≤6 months) to androgen-independent progression after initiation of hormonal therapy. Preclinical studies have found that AVPC are characterized by a molecular signature containing one or more deleterious alterations in the tumor suppressor genes *TP53, RB1,* and *PTEN.*

Candidate Premalignant Lesions

Prostatic Intraepithelial Neoplasia

The search for premalignant lesions of the prostate has resulted in the identification of two candidate morphologic lesions.[24] The first and most promising premalignant lesion is prostatic intraepithelial neoplasia (PIN). Grades I and II PIN are observed but have not been reliably associated with cancer or linked with confidence to prostate cancer development or progression. Thus, the reporting of grades I and II PIN has fallen into disfavor at MDACC and at most other leading institutions. Grade III PIN has been linked to the presence of cancer in many studies, but it does not justify a therapeutic intervention (eg, prostatectomy). Rather, its presence leads to the recommendation of a more thorough biopsy to search for coexistent cancer or a repeat biopsy within 6 to 12 months. Grade III PIN is frequently linked to the presence of established cancer in other regions of the prostate, and as a consequence, it rarely serves as a useful early predictive marker. Therein lies the difficulty of performing prevention studies targeting PIN. Most MDACC clinicians share the view that a report of multifocal PIN III is nearly identical to a report of low-grade prostate cancer but with the important caveat that there is insufficient evidence to justify routine intervention (surgery or radiation).

The second potential premalignant lesion is proliferative inflammatory atrophy (PIA).[25] Histologically, these lesions are characterized by inflammatory infiltrates associated with atrophic epithelium. Compared with normal epithelium, there is an increased fraction of proliferating epithelial cells within PIAs. These lesions are thought to provide a mechanistic link between chronic infection or inflammation and the predisposition to develop prostate cancer. However, in contrast to PINs, adenocarcinomas rarely arise from PIAs, and PIAs are often observed in prostate biopsies that have no evidence of cancer. Thus, it remains unclear if PIAs are truly precursor lesions for prostate cancer. Ongoing studies seek to address this.

Staging

It is difficult to precisely assess the extent of prostate cancer on clinical criteria alone. The major benchmark of local extent that influences treatment—organ confined versus non–organ confined—is essentially impossible to distinguish by rectal examination and is not easily appreciated by any imaging modality. Furthermore, PSA levels do not accurately inform about extraprostatic extension of disease. Thus, it is common to use an array of modalities, including transrectal ultrasonography, computed tomography, conventional magnetic resonance imaging (MRI), MRI with an endorectal receiver coil, complex biopsy strategies designed to sample the seminal vesicles and extraprostatic space, and even pelvic lymph node sampling, to determine disease extent. Clearly, each of these modalities offers a different level of sensitivity for detecting lesions and can vary markedly in efficacy. In the final analysis, the concept of clinical stage is meaningless without proper context. One must ask, What is the clinical stage by a particular set of diagnostic tests?

The Case for Prostate Cancer Screening

With the advent of PSA screening, there has been a dramatic increase in the number of younger men detected with localized disease. Along with improved outcomes for local therapy (surgery or radiation), it logically follows that PSA screening has contributed to the improved survival rates for men diagnosed with localized prostate cancer. However, the benefits of PSA screening remain controversial for clinicians and a source of confusion for patients. For clinicians, there has been a lack of level 1 evidence supporting the use of PSA screening. The two large, randomized screening trials (with >250,000 patients) has not helped clarify the issue because one trial did not show a survival benefit (the prostate, lung, colorectal, and ovarian cancer screening trial (PLCO) Cancer Screening Trial in the United States), but the other one did (the European Randomized study of Screening for Prostate Cancer (ERSPC) trial in Europe).[26,27] Although confounding factors to each study limit a definitive conclusion about PSA screening, the enormous expense and time required may discourage future PSA screening trials. Available evidence favors clinician discussion of the pros and cons of PSA screening with average-risk men aged 55 to 69 years. Other strategies to mitigate the potential harms of screening include considering biennial screening, a higher PSA threshold for biopsy, and conservative therapy for men receiving a new diagnosis of prostate cancer.

Although the US Preventive Services Task Force no longer recommends routine screening,[28] in our practice, we recommend annual PSA and digital rectal examination (DRE) for all healthy men starting at

TABLE 45–1 Rationale for Prostate Cancer Screening

• Reduction in prostate cancer mortality rates coincide with the introduction of routine PSA screening.
• Patients whose cancers are detected with PSA screening have early-stage disease.
• Long-term disease-free survival is linked to treatment of early-stage disease.
• Randomized trials demonstrate a survival advantage for early surgical intervention for early-stage disease.

PSA, prostate-specific antigen.

age 50 years or age 40 years for those at high risk (eg, men with a family history or African Americans). Early inclusion of the patient in the decision-making process is essential to optimize patient care given the ambiguities regarding the cost effectiveness and clinical value of widespread screening for prostate cancer. The rationale for routine screening that justifies routine application is outlined in Table 45–1.

PATIENT MANAGEMENT BY DISEASE STATE

Clinically Localized Disease at Presentation

As a result of widespread screening of men by PSA and DRE, the majority of patients are seen with clinically localized disease at diagnosis. Unfortunately, it is not always obvious how to match the individual patient with the most appropriate management. In an abstract sense, patients with clinically localized prostate cancer fall into one of four theoretical categories:

1. Those not destined to have any clinical manifestations of their disease. These patients are actually harmed by any intervention, including further surveillance.
2. Those destined to have a clinical manifestation of cancer but will not die of it. These patients might benefit from definitive therapy (eg, prostatectomy or radiation) but would likely benefit equally from less-morbid intervention (eg, minimally invasive surgery).
3. Those destined to have life-threatening disease for whom definitive therapy will be curative. Patients who can be cured, or for whom there will be a substantial alteration of the natural history of their disease, constitute the group that will unequivocally benefit from definitive local therapy.
4. Those destined to have life-threatening disease for whom the opportunity to cure by means of local therapy either never existed or passed. For these patients, however, control of the primary tumor could still be an important component of an overall treatment strategy that considers the probability of local versus distant progression, comorbidity, and other factors.

The common practice of urologists and radiation therapists is to assume that nearly every patient falls into the third category, and thus they recommend definitive therapy for the vast majority of newly diagnosed cases of localized prostate cancer. Unfortunately, available evidence suggests that fewer than half of patients are in category 3, so it is not surprising that understanding the role of definitive therapy in eliminating prostate cancer morbidity and mortality has been both difficult and controversial. In fact, these issues underscore the fact that overtreatment of patients with "clinically insignificant" prostate cancers certainly occurs. The significant cost and morbidity associated with local treatment also adds to the difficulty of managing these patients (whether the patient ultimately benefits from the therapy or not).

In patients with newly diagnosed localized disease, current prognostic and predictive models rely on data derived from large prostatectomy series conducted at major academic centers. For example, investigators at Johns Hopkins initially published a predictive model relating the rate of finding disease that is not confined to the prostate (by assessing the surgical specimen) as a function of three readily available preoperative clinical parameters: PSA, Gleason score from the core biopsy, and the clinical stage based on DRE.[29,30] The correlation of these features with pathologically organ-confined disease, summarized in the famous "Partin tables," provided sobering evidence that commonly encountered subsets of patients had a surprisingly high risk of disease that was not confined to the prostate. Of course, not all patients with pathologically organ-confined disease relapse, and not all patients with pathologically organ-confined cancers are cured. Thus, the importance of this particular surrogate outcome was and remains uncertain. Nevertheless, the effect of the Partin tables on clinical practice has been profound. They have driven the application of prostatectomy to patients with smaller and smaller volumes of cancer. It is clear that although more patients are remaining free of disease after prostatectomy, this comes paradoxically at the cost of operating on many patients who may not have needed surgery or not operating on many patients who would have benefited from good local control even if the surgery were not curative.

Additional models have been developed to predict outcomes after radical prostatectomy or radiation therapy. Based on the work of D'Amico et al,[31] a combination of pretherapy PSA, Gleason score, and clinical stage can be used to stratify patients into low (T1–T2a

TABLE 45–2 Rationale for Use of Predictive Nomograms

- Gleason grade, clinical stage, and initial PSA are predictive of surgical stage, risk of subsequent relapse, and risk of cancer-specific mortality.
- Improving the ability to predict outcome will inform both physicians and patients about the risks and benefits of local therapy.
- Fewer patients will undergo unnecessary or futile surgery.

PSA, prostate-specific antigen.

and Gleason score 2–6 and PSA <10 ng/mL), intermediate (T2b-T2c or Gleason score 7 or PSA 10–20 ng/mL), high (T3a or Gleason score 8-10 or PSA >20 ng/mL), and locally advanced (T3b–T4) groups that predict risk for both biochemical recurrence and survival following definitive local therapy (radical prostatectomy or radiation). Similarly, Kattan et al[32] developed postoperative nomograms for predicting prostate cancer recurrence after radical prostatectomy. These tools not only help guide recommendations for individual patients but also help stratify patients for clinical trials. For example, low-risk patients can be directed toward "active surveillance" trials, and high-risk patients can be direct toward adjuvant or neoadjuvant trials. The rationale for the use of predictive nomograms is outlined in Table 45–2.

Despite the efforts detailed previously, tumors with identical morphology and clinicopathologic characteristics often display biologic heterogeneity (ie, some "low-risk" tumors rapidly progress, but some "high-risk" tumors are relatively indolent). Thus, more refined models are needed. Recent efforts have sought to incorporate genetic tests to enhance current clinicopathologic risk stratification for patients newly diagnosed with localized prostate cancer. For example, PROLARIS (Myriad Genetics, Inc.) directly measures expression of 46 different genes in formalin-fixed paraffin-embedded tissue obtained by biopsy or prostatectomy,[33–35] including 31 cell cycle progression genes and 15 housekeeper genes that correlate with proliferation of prostate cancer. Whereas low expression is associated with a low risk of disease progression, high expression is more indicative of higher risk of disease progression, suggesting either close monitoring or additional therapy for the latter group of patients.

Other investigational approaches to improve risk stratification include assessing suspicious nodes or small-volume extracapsular extension by MRI or positron emission tomography, staging biopsies of seminal vesicles and extraprostatic tissue, and incorporation of molecular signatures. Within our group, a significant effort is under way to relate the expression of genes that may affect apoptotic threshold, invasion, angiogenesis, and AR signaling to biologic potential and ultimately clinical outcome of localized tumors. These data suggest that both loss of tumor suppressor pathways (eg, p53) and gain of oncogene–anti-apoptotic pathways (eg, Bcl-2) contributes to prostate cancer progression. In addition to these and other "epithelial" events, the importance of the host–epithelial interaction in prostate cancer progression has been supported by evidence that pathways involved in paracrine regulation of normal stromal–epithelial interactions have also been implicated in prostate cancer progression.[36–38]

Therapy

Localized Low-Stage Prostate Cancer

In patients with localized low-stage disease (generally including low- and intermediate-risk groups based on the D'Amico risk stratification groups), the options offered include active surveillance, surgery, radiation, and presurgical clinical trials. Educating the patient about his treatment options is critical to make the best decision for each individual. Patients who are undecided or request more information about treatments and side effects are seen in our multidisciplinary clinic.

Critical evaluation of the relative merits of different therapies for localized low-stage prostate cancer is difficult. This is because patients in this category have a greater than 80% chance of 10-year progression-free survival (PFS) after local therapy.[39–41] Prostate cancer has a long natural history, and 10-year data for patients with low-risk prostate cancer remain immature with respect to cause-specific and disease-free survival. The contribution of delayed hormonal therapy and the appreciation that not all patients with a delayed PSA recurrence after local therapy are threatened by their disease have made comparisons between different treatment modalities difficult. As a consequence, the modification of older therapies or the application of new ones (eg, brachytherapy, cryoablation, or proton beam therapy) is often judged by their complication profile and the rate of PSA-free survival with a relatively short follow-up. Although seemingly logical, interpreting potential benefit from "new and improved" therapies is challenged by the impact of "stage migration" on outcomes. Stage migration refers to the fact that as a consequence of awareness and PSA screening, younger patients with lower-stage cancer are diagnosed with increasing frequency. This trend of earlier therapy in younger patients with earlier-stage disease likely has an effect on the analysis of therapy efficacy and morbidity for low-stage cancer. Therefore, the practice of deriving conclusions from the comparison of nonrandomized study groups in low-stage prostate cancer is a dubious exercise.

In fact, in localized, low-stage prostate cancer, the principal therapeutic dilemma is whether to intervene at all. Increasingly, many investigators are recognizing that not all patients diagnosed with prostate cancer by histologic criteria have a disease that has lethal potential.[42] Hence, many clinicians have explored a strategy of observation followed by delayed therapy if required. This strategy has historically been called "watchful waiting," but in recent years, we have adopted the term *active surveillance*. This is because the definition of watchful waiting is ambiguous and includes the practice of not following or evaluating patients after diagnosis until they present with a prostate cancer–associated symptom(s). In contrast, active surveillance implies regular follow-ups with PSA evaluation, DRE, and repeat biopsies as indicated to inform the need for local therapy. Active surveillance acknowledges the reality that many patients with prostate cancer survive despite diagnosis and therapy, as opposed to benefiting directly from the intervention. At MDACC, the rationale for offering active surveillance is the idea that carefully monitored patients require therapy with curative intent only if accompanied by objective evidence that their cancer has become life threatening. In this way, patients with truly indolent disease can be spared the morbidities of local therapy, and patients who show progression over time to potentially lethal disease will preserve the opportunity for curative therapy.

Active Surveillance with Deferred Treatment

Two categories of patients with low-stage disease are generally considered for active surveillance: (1) men who have a higher probability of dying from a comorbid illness (eg, coronary artery disease) than from prostate cancer and (2) men whose cancer poses some risk for lethality but choose active surveillance because of concerns about consequences of therapy (eg, impotence or incontinence). The rationale for active surveillance is outlined in Table 45–3.

There are two central challenges of the active surveillance strategy. The first is that we do not yet have a validated method to anticipate progression of the disease to avoid "closing the window" on curative therapy. The second is that we lack methods to ensure reliable selection of all patients in whom the disease will be unlikely to spread while excluding all patients who will have lethal progression of the disease despite its initial morphologic appearance as low stage. Thus, this strategy, although supported by compelling logic, must be regarded as unproven. This is particularly true for patients with a life expectancy of 15 years or more. As a patient's life span shortens because of comorbid conditions, the unproven nature of this strategy has less predicted impact on outcome. Thus, outside a clinical trial, active surveillance in our practice is routinely reserved for patients with low-stage disease and an expected survival of less than 10 years because of comorbidities.

TABLE 45–3 Rationale for Active Surveillance

• A significant portion of newly diagnosed patients will not develop clinical progression.
• Complications of local therapy exceed benefits in some patients.
• Close monitoring of selected patients with serial PSA measurements may avoid or delay initiation of potentially morbid or unnecessary therapy.

PSA, prostate-specific antigen.

Active surveillance for category 1 patients is not codified, and follow-up strategies (eg, annual PSA checks) are designed by mutual agreement between the physician and patient. Select older adult patients whose cancer diagnosis was precipitated by an ill-advised PSA screening test may choose no further follow-up. In contrast, active surveillance for category 2 patients involves close observation with quarterly PSA checks and annual prostate biopsies. Often, these patients elect to undergo local therapy as the physical and emotional burden of close observation becomes more obvious. Despite the intensity of follow-up, the ability to anticipate progression of disease based on true biologic evidence as opposed to apparent progression caused by the randomness of the biopsies remains a major problem. These problems will be clarified with prospective studies accruing at several institutions.

Treatment of Low-Stage Disease with Available Therapy

Although there is much debate about the relative merits of radiation therapy and surgery for patients with localized low-stage prostate cancer, the inescapable conclusion is that both treatment groups have excellent survival, and the principal issues influencing choice are related to therapy-associated morbidity. Interestingly, competition between radiation therapy and surgery has resulted in the reduction of morbidity to both therapies. The morbidity of radiation therapy—while retaining its effectiveness—has been greatly reduced, as has morbidity related to improvements in surgical techniques. Thus, for low-stage prostate cancer, the principal therapeutic recommendation is to treat patients who have a greater than 15-year expected life expectancy. The primary recommendation is surgery or radiation therapy, with a bias toward surgery for patients with an expected longevity of more than 20 years and a bias toward radiation therapy for patients with an expected longevity of 15 years or less (Table 45–4).

TABLE 45–4 Rationale for Selection of Local Treatment Modality

• There are no clinical trials showing a therapeutic advantage of surgery over radiation therapy for localized disease.
• Either approach is associated with some risk of significant morbidity (initial impotence rates are higher with surgery).
• There is a reduction in impotence rates over time with radiation.
• Surgery provides better assessment of risk for future relapse by allowing molecular-pathologic analysis of the radical prostatectomy specimen.
• Radiation is ideally suited for patients who are physically unfit for surgery and those who have disease extending beyond the bounds of traditional surgical fields.
• Surgery improves symptom-free and overall survival in patients with localized disease.

Presurgical Trials for Low-Stage Disease

Presurgical trials facilitate the development of novel therapies and treatment strategies in prostate cancer by providing proof of "target engagement" by the drug(s) and modulation of the tumor phenotype in a therapeutically favorable manner.[43] The principal goal of a *preoperative* clinical trial is to identify short-term molecular and pathologic tissue surrogates that establish target engagement and modulation of key signaling pathways by the drug(s). Because surgery is performed before cytoreduction or significant changes in the tumor phenotype are expected (as opposed to *neoadjuvant* trials), preoperative trials provide only limited inferences about the therapeutic potential of the drug(s) being tested. However, data from preoperative trials help identify the most promising therapeutic candidates worthy of further study. Preoperative studies of low-stage prostate cancer seek to identify molecular markers that characterize response to therapy and predict tumor biology.

High-Risk and Locally Advanced Prostate Cancer

As a general principle of oncology, high-risk and locally advanced tumors are best treated with a combination of systemic therapy and aggressive local therapy. This strategy addresses occult disseminated disease while preventing local complications of the primary tumor. Despite the widely recognized poor outcomes for patients with seminal vesicle or regional node involvement, the application of optimum local control with systemic therapy has only recently become accepted.[44]

Current multimodal therapies include radiation plus hormones and neoadjuvant therapy plus surgery. It is now well established that the addition of hormones to radiation therapy is superior to radiation therapy or hormones alone for patients with high-risk and locally advanced tumors.[45] The duration and sequence of the combination are important in maximizing therapy benefit from the combination. Several lines of evidence suggest that initiating the androgen ablation 2 months before the radiation therapy is more effective than combined therapy from the outset or sequential therapy with radiation followed by androgen ablation. The available data demonstrate an increase in survival with a 3-year period of androgen ablation. However, the optimal duration of androgen ablation in the context of locally advanced prostate cancer treated with radiation remains an area of investigation. Recent data have shown that shorter durations (eg, 18 months vs 24 months) of androgen ablative therapy in the adjuvant setting after radiation may be noninferior, with biomarker-directed strategies in development. In addition, there is a general trend that earlier use of second-generation antiandrogens is warranted for men with high-risk localized prostate cancer treated with definitive radiotherapy and ADT. The Systemic Therapy in Advancing or Metastatic Prostate Cancer: Evaluation of Drug Efficacy (STAMPEDE) study assessed the use of abiraterone acetate with ADT in men with hormone-naïve prostate cancer, including a cohort of men with high-risk localized disease treated with radiotherapy. This study showed significant benefit for the abiraterone acetate arm over the ADT only arm, thus leading to NCCN guidelines including abiraterone acetate with radiotherapy and ADT as standard of care for men with high-risk localized disease.

It also appears that improved local control represents another strategy to improve overall survival (OS) in patients with T3N0M0 (tumor, node, metastasis [TNM]) tumors. Randomized controlled trials have demonstrated that adjuvant radiation therapy after radical prostatectomy for T3N0M0 tumors significantly reduces the risk of metastases and improves OS.[46] These data support the hypothesis that untreated residual disease at the primary site can act as a source for metastatic progression.

Neoadjuvant Trials in High-Risk and Locally Advanced Prostate Cancer

At MDACC, we recognize two different categories of patients with high-risk or locally advanced disease: (1) those we believe can be effectively treated with hormones and radiation therapy and (2) those we believe will not be effectively treated with this approach because of the extent of their disease, adverse histologic features of the tumor, or the relative youth and expected long survival of the patient. Patients in the second category are candidates for a novel preoperative therapy given before prostatectomy. The rationale for

neoadjuvant therapy in this setting is based on progress made in other cancer types and is described as follows: (1) in high-risk and locally advanced disease, the post-therapy pathology specimen will inform both prognosis and future treatment decisions, and (2) controlling the primary tumor is an essential part of an integrated strategy for patients with high-risk and locally advanced disease (although this strategy is not always curative).[47] We are using neoadjuvant trial designs with increasing frequency to develop novel agents (eg, angiogenesis inhibitors) in prostate cancer. Analysis of the prostatectomy specimen permits detailed analysis of molecular (eg, apoptosis) and pathologic surrogates for therapy benefit (eg, achievement of pathologic 0 stage [P0]). We believe the preoperative model will significantly enhance our ability to identify the most promising agents worthy of development in a time-efficient manner.

A promising combined modality approach has recently been reported using maximal androgen blockade of both endocrine (using luteinizing hormone–releasing hormone agonists) and paracrine, autocrine, and intracrine (using abiraterone, a CYP17 inhibitor) testosterone sources. Two recent phase 2 studies demonstrated that combination leuprolide–abiraterone was clinically superior to leuprolide alone with respect to PSA responses and cytoreduction.[48,49] A subset of patients in both trials achieved P0 (or near P0) in the surgical specimen, a relatively common phenomenon in neoadjuvant trials of other epithelial cancers (eg, breast and bladder) but essentially unprecedented in prostate cancer.

Castration-Resistant Locally Advanced Prostate Cancer

CRPC is an umbrella term that encompasses a spectrum of disease states ranging from rising PSA alone to rising PSA associated with osseous or soft tissue metastases.[1] Furthermore, patients receiving combined androgen blockade are typically screened for an antiandrogen withdrawal response before being considered castration resistant. Patients with CRPC and PSA-only recurrence are discussed in the next section.

For patients with castration-resistant locally advanced prostate cancer, clinical progression presents significant clinical symptoms (pain, hematuria, bladder outlet and bowel obstruction), but optimal management remains a difficult therapeutic problem. The critical decision is whether to offer consolidative therapy. For patients without metastatic disease, we offer neoadjuvant chemotherapy followed by surgery for consolidation. If not used as primary therapy, salvage radiation therapy is another rational strategy, particularly for patients who are not candidates for salvage surgery.

For patients with both castration-resistant locally advanced and metastatic disease, these approaches are more controversial. Nonetheless, we recognize that

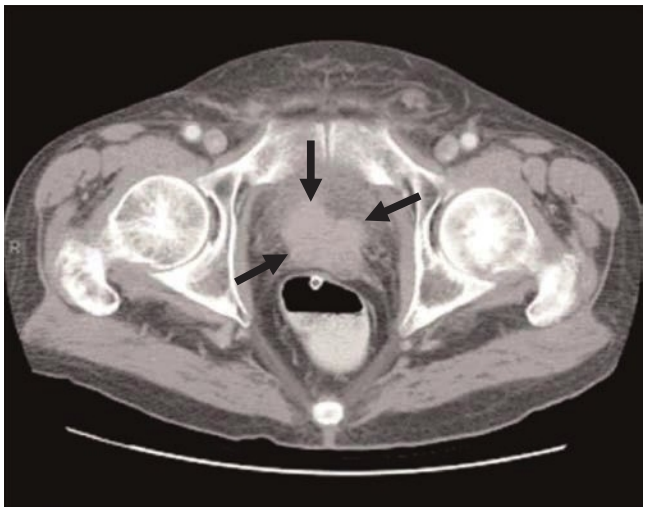

FIGURE 45–3 **Recurrent prostate cancer invading the base of the bladder.**

these patients experience significant morbidity from local tumor progression that is comparable to patients without metastases. Thus, for select candidates, we still offer consolidative therapy. As an example, consider the case of a patient who presented with metastatic prostate cancer at diagnosis and was successfully treated with androgen ablation for 10 years. He then developed castration-resistant progression and presented with invasion of his primary tumor into the bladder (Fig. 45–3). To relieve painful voiding symptoms attributed to the bladder invasion, induction chemotherapy followed by salvage cystoprostatectomy was performed. At 3-year follow-up, the patient continued to have evidence of active metastases but was free of cancer-associated local symptoms. Although this patient benefited longer than most, striking relief of intractable symptoms is common using this approach. The clinical rationale to apply chemotherapy followed by salvage surgery is summarized in Table 45–5.

Rising Prostate-Specific Antigen After Definitive Local Therapy

The utility of PSA measurements is greatest in monitoring cancer progression and effects of therapy in patients with radiographic evidence of disease. In contrast, the significance of PSA in patients without

TABLE 45–5 Rationale for Salvage Surgery

• Patients can avoid significant morbidity associated with local progression.
• Improved local control may contribute to longer overall survival.
• Patients who develop a delayed local relapse after treatment with primary radiation therapy may still have surgically curable disease.

detectable disease is less clear. Although available evidence suggests that patients with a measurable PSA after prostatectomy will eventually develop a recurrence given sufficient time, these recurrences are not uniformly fatal. Furthermore, in patients treated with radiation therapy, interpretation of PSA posttherapy is very different compared with patients treated with surgery.

Significance of Prostate-Specific Antigen After Prostatectomy

The serum PSA concentration should be undetectable using standard commercial assays within 6 weeks of prostatectomy. Persistent PSA after surgery usually indicates persistent cancer secondary to inadequate surgery, persistent cancer despite adequate surgery, or the presence of occult metastases. The experience from Johns Hopkins suggests that given sufficient time, patients with early PSA recurrence (≤2 years) or short PSA doubling time (<10 months) will develop metastatic disease within 15 years of surgery.[50–52] In contrast, patients with late PSA recurrence or a longer PSA doubling time are more likely to have a recurrence confined to the prostatic fossa. Patients who have a striking discordance between the predicted behavior of the cancer (eg, low stage) and early elevations of postoperative serum PSA may have had inadequate surgery and are considered for adjuvant radiation therapy. In patients who undergo nerve-sparing prostatectomy, consideration must also be given to the possibility that normal prostate gland left behind at surgery is producing PSA.

Significance of Prostate-Specific Antigen After Radiation Therapy

In contrast to surgery, serum PSA concentrations are not expected to become undetectable after curative therapy. In addition, the phenomenon of a PSA "bounce" is well described after radiation of the primary tumor.[53] The PSA bounce is a modest, self-limited rise in PSA concentration without evidence of cancer progression. It typically occurs within the first 18 months after completion of radiation and can last for as long as 3 months before reaching a plateau and then declining. The central clinical dilemma with PSA bounces is that their presence can only be determined with confidence in retrospect. Thus, clinicians need to be aware of this phenomenon and show restraint in introducing therapy to patients displaying delayed PSA elevation after radiation without evidence for metastases.

Management of Patients with Prostate-Specific Antigen–Only Recurrence

The scenario of the patient with PSA-only recurrence poses a therapeutic dilemma for physicians and considerable anxiety for patients, with a desire to avoid treating based just on a number but also initiate systemic therapy at the most appropriate juncture to avoid disease progression. It is clear that PSA-only recurrences do not uniformly portend morbidity or mortality from the disease. Our general approach is to offer hormone ablative therapy (commonly using an intermittent strategy) during the androgen-dependent phase of the disease.[54] Recently, darolutamide, a novel AR-signaling inhibitor, was approved by the Food and Drug Administration (FDA) for the treatment of patients with nonmetastatic CRPC based on large phase III trial data Androgen Receptor Antagonizing Agent for Metastasis-free Survival (ARAMIS) showing significant improvement in metastasis-free survival for darolutamide compared with continued ADT alone (hazard ratio [HR], 0.41; 95% confidence interval [CI], 0.34–0.50; P <.001), without a significant increase in adverse events. Subsequently, apalutamide Selective Prostate Androgen Receptor Targeting with ARN-509 (SPARTAN) and enzalutamide Safety and Efficacy Study of Enzalutamide in Patients With Nonmetastatic Castration-Resistant Prostate Cancer (PROSPER) were also approved in this setting. Subsequent data from these three trials have shown significant improved in OS in the patients treated with AR-signaling inhibition, and thus all three now can be used as standard of care in this setting. Notably, we never use chemotherapy for PSA-only recurrences that occur in the setting of CRPC.

Metastatic Cancer

Metastatic Androgen-Dependent Disease

For patients with M1 castrate-sensitive prostate cancer, there are multiple approved AR-signaling targeted therapies in recent years that provide OS benefit above ADT alone as described later. For patients with de novo metastatic disease and primary tumors in place, there are also ongoing clinical trials (eg, NCT01751438) to test best systemic therapy versus best systemic therapy plus definitive treatment (radiation or surgery) of the prostate to learn if control of the primary tumor improves the clinical outcome in patients with metastatic disease.

The role of cytotoxic chemotherapy in patients with androgen-dependent disease remains nuanced. The Chemohormonal Therapy Versus Androgen Ablation Randomized Trial for Extensive Disease in Prostate Cancer (CHAARTED) trial compared "up-front" chemotherapy plus ADT to ADT alone in men with metastatic prostate cancer. The results showed that the median OS was 57.6 months with docetaxel plus ADT compared with 44.0 months with ADT, a difference of 13.6 months (HR, 0.61; P <.001). The benefit was primarily observed in men with high-volume

disease (49.2 months vs 32.2 months), which was defined as the presence of visceral metastases or four or more bone metastases. However, men with low-volume disease did not experience a survival benefit (HR, 1.04). Arm C of the multiarm STAMPEDE trial compared ADT plus docetaxel with or without zoledronic acid with ADT alone in men with high-risk locally advanced, metastatic, or recurrent prostate cancer starting first-line, long-term hormone therapy. Compared with a median OS of 71 months with ADT alone, ADT plus docetaxel was 81 months (HR, 0.78; P = .006). The addition of zoledronic acid did not demonstrate a survival benefit.

However, in contrast to those data, other large phase 3 studies of similar design have been negative.[55,56] The GETUG-AFU 15 trial recently reported no differences in OS between patients with noncastrate metastatic disease receiving ADT plus docetaxel versus ADT alone (median, OS was 58.9 months in the group given ADT plus docetaxel and 54.2 months in the group given ADT).[56] It is likely that differences in patient populations (eg, volume of disease at baseline) and treatments after progression explain the disparate results between these trials. At our institution, although our clinical experience strongly supports the notion that some patients with metastatic disease will benefit from early application of cytotoxic chemotherapy (eg, patients with small cell or aggressive variant features or patients with high-burden of metastatic disease and associated symptoms), we make that decision collectively with the patient based on each individual's case.

Newer generation antiandrogen agents have also been studied in the castrate-sensitive setting. Both the LATITUDE study and STAMPEDE study showed that the addition of abiraterone acetate plus prednisone to ADT led to a significant improvement in OS and radiographic PFS compared with placebos plus ADT in men with newly diagnosed high-risk metastatic castration-sensitive prostate cancer (mCSPC). Apalutamide (Erleada, Janssen Biotech) is an oral nonsteroidal antiandrogen that directly binds the AR to prevent receptor translocation and activity. The TITAN trial demonstrated a significant benefit in 2-year radiographic PFS with apalutamide plus ADT compared with ADT plus placebo in mCSPC regardless of disease volume and may have received prior local therapy with or without docetaxel. Notable adverse events experienced with apalutamide include rash, hypothyroidism, fracture, and ischemic heart disease.

Enzalutamide (Xtandi, Medivation/Astellas) is an oral small molecule that directly binds the AR to competitively inhibit endogenous androgen binding and antagonize AR function. It has a higher affinity for the AR than first-generation nonsteroidal antiandrogens (eg, bicalutamide). The ENZAMET trial compared enzalutamide plus ADT versus ADT plus a first-generation nonsteroidal antiandrogen with concurrent docetaxel administration allowed in each group per physician discretion. A benefit was seen in PFS and OS at a median follow-up period of 34 months. The ARCHES trial also studied enzalutamide in castrate-sensitive prostate cancer by comparing enzalutamide plus ADT with ADT alone with stratification by disease volume and prior docetaxel use. At a median follow-up period of 14.4 months, median radiographic PFS was not yet reached in the enzalutamide group compared with 19.0 months with placebo. Notable adverse events with enzalutamide include fatigue, lowering of seizure threshold, and hypertension.

Castration-Resistant Progression

Second-Line Hormonal Therapies

During castrate-resistant progression, there is a gradual "switch" in sources of androgens that sustain tumor growth from endocrine to intratumoral (paracrine, autocrine, and intracrine). Second-line hormonal therapies that block these alternative sources have long been of interest as cancer therapeutics. For example, considerable advances have been made in developing small molecule inhibitors that block CYP17, a key enzyme involved in androgen biosynthesis expressed in testes, adrenal glands, and tumor tissues.[57] Ketoconazole is an antifungal agent with weak and nonspecific CYP17 inhibitory properties that has been available for decades. Although ketoconazole is active in prostate cancer, its application has been limited because of extremely poor tolerance. In contrast, several new agents, including abiraterone, have proven more successful. Abiraterone is a potent irreversible inhibitor of CYP17, and two large, randomized phase 3 studies have demonstrated clinical benefit in both chemotherapy-naïve and docetaxel-treated patients with mCRPC.[58,59]

The PREVAIL and AFFIRM studies have demonstrated a survival benefit with enzalutamide in chemotherapy-naïve and docetaxel-treated mCRPC, respectively. Because enzalutamide can potentially address molecular resistance mechanisms to abiraterone monotherapy, and vice versa, studies of combination abiraterone and enzalutamide are also under way. More specifically, resistance to abiraterone is associated with increased nuclear AR copy number (theoretically blocked with enzalutamide), and resistance to enzalutamide is associated with increased microenvironment testosterone levels (theoretically blocked with abiraterone).[60,61] Preliminary analysis suggested that a higher percentage of patients experience favorable PSA response profiles than seen with either agent alone, and the combination appears to be well

tolerated.[62] Despite breakthroughs in the treatment of mCRPC, approximately 20% to 40% of patients have no response to these agents (primary refractory). Furthermore, among patients who initially have a response to enzalutamide or abiraterone, virtually all eventually acquire secondary resistance. For example, the emergence of mutations (eg, a single F876L amino acid substitution) in the AR can confer resistance to enzalutamide. Antonarakis et al[63] reported detection of AR-V7 in circulating tumor cells from patients with CRPC may be associated with resistance to enzalutamide and abiraterone.

Chemotherapy

Chemotherapy is routinely applied to patients with castration-resistant locally advanced or metastatic disease. For more than a decade, patients have been treated with docetaxel-based regimens. However, although these therapies improve quality of life, prolongation in survival is modest. Faced with these challenges, the approach at MDACC has been to delay cytotoxic therapy until second-line hormonal (or experimental options) have been explored. Of course, patients with rapidly progressive disease causing (or expecting to cause) symptoms are offered chemotherapy sooner rather than later, particularly when additional hormonal manipulations are predicted to fail (eg, in patients with small cell or anaplastic tumors). The rationale for the use of chemotherapy is outlined in Table 45–6.

Given the limitations of docetaxel-based chemotherapy, there has been a global research initiative to improve on it, principally by combining docetaxel with other agents. However, these efforts have met with little success. For example, antiangiogenic drugs such as sunitinib and Avastin did not improve OS compared with placebo in docetaxel-refractory mCRPC.[64,65] Similarly, bone microenvironment targeting agents such as zibotentan, atrasentan, and dasatinib were each tested in phase III trials, and all failed to improve on standard docetaxel.[66–68] Interestingly, each of these agents showed promise in phase II studies, and some (eg, Avastin and sunitinib) did result in improvements in median PFS. These results suggest that a subset of patients did benefit and that moving forward, clinical trial designs that incorporate predictive biomarkers to enrich for patients most likely to respond will be necessary to develop novel treatment strategies.

TABLE 45–6 Rationale for the Use of Chemotherapy

- Chemotherapy palliates or prevents symptoms associated with progression of disease.
- Docetaxel-based regimens result in modest improvements in survival in patients with metastatic castration-resistant cancer.
- Other active agents in prostate cancer (eg, mitoxantrone and prednisone) can be used as second-line therapy.

Optimizing Therapy Sequence in Metastatic Castration-Resistant Prostate Cancer

The concept that patients can respond to another taxane after progressing on docetaxel is important. The recent approval of cabazitaxel by the FDA, based on the results of the phase III TROPIC study, provided further validation of this concept.[69] Cabazitaxel is a novel semisynthetic taxane developed specifically to overcome docetaxel resistance, and it is typically offered as second-line therapy for patients with mCRPC previously treated with docetaxel. There are now multiple approved therapies for men with metastatic prostate cancer that improve PFS and OS; thus, it is important to understand treatment sequencing. The recent CARD study evaluating cabazitaxel versus an androgen signaling–targeted agent in patients with mCRPC who had been previously treated with docetaxel, and the alternative androgen signaling–targeted agent (abiraterone or enzalutamide) showed significantly better outcomes for the men treated with cabazitaxel.

Beyond docetaxel and cabazitaxel, multiple chemotherapy regimens with modest activity are routinely applied in a sequential manner to patients in the salvage setting. Examples include CVD (cyclophosphamide, vincristine, and dexamethasone), KAVE (ketoconazole plus doxorubicin alternating with vinblastine plus estramustine), TEC (paclitaxel, estramustine, and carboplatin), and TEE (paclitaxel, estramustine, and etoposide). However, there is no standard chemotherapy in the salvage setting, and we do not have randomized comparisons testing whether the sequential application of therapy prolongs survival.

More recent studies have demonstrated clinical responses to platinum-based therapy in combination with taxanes.[70–72] Ross et al[73] tested the activity of docetaxel–carboplatin in patients who had progressed during or within 45 days after the completion of docetaxel. PSA declines of 50% or greater were noted in 18% of patients, and measurable responses occurred in 14% of patients. Because patients in this study would not be anticipated to respond to "rechallenge" with docetaxel alone, these results support the hypothesis that carboplatin has the potential to overcome docetaxel resistance mechanisms.

We have performed a randomized phase I/II study of cabazitaxel with or without carboplatin in patients with mCRPC (NCT01505868), showing that the addition of carboplatin improved the median PFS from 4·to 5 months (95% CI, 3.5–5.7) to 7·3 months (95% CI, 5.5–8.2; HR, 0.69; 95% CI, 0.50–0.95; P =·.018). The

combination arm did show increased side effects, most notably fatigue and cytopenias.

Precision Medicine and Targeted Therapies

Men with advanced prostate cancer have a 10% to 15% risk of carrying a hereditary, or germline, variant in a DDR gene, as previously discussed. Pathogenic or deleterious variants in these same DDR genes can also be found at the somatic, or tumor-associated level, in up to 25% of mCRPC. Precision medicine currently centers mostly on discovering these somatic aberrations through DNA sequencing to then guide targeted treatment selection for patients with advanced cancer. Compared with other solid tumors such as melanoma and urothelial cancers, advanced prostate cancer overall displays relatively low tumor mutational burden (TMB), with rare exceptions, including tumors with MMR deficiency or subsequent high microsatellite instability (MSI-H). Defective MMR genes or MSI-H is seen in about 3% to 8% of prostate cancers, with the majority being of sporadic origin and with Lynch syndrome not displaying high penetrance in prostate cancer.

BRCA2 is by far the most frequently altered homologous recombination repair (HRR) gene in the in prostate cancer, and variants in other HRR-related genes such as *BRCA1, ATM*, and *CDK12* can also be seen.

Multiple approved tumor and liquid somatic sequencing platforms are available to clinicians. Each platform may slightly differ in terms of the genes included on the panel, as well as their coverage. Currently, there are three FDA-approved therapies (pembrolizumab, rucaparib, and olaparib) for patients with advanced prostate cancer with associated DNA-based biomarkers for patient selection. Briefly, pembrolizumab, a well-known immune checkpoint blockade therapy, was approved by the FDA for treating patients with advanced MMR-deficient and MSI-high cancers, agnostic of tissue origin. Testing methods for identifying these cancers include MMR protein staining, MMR gene sequencing, MSI polymerase chain reaction testing, and TMB via next-generation sequencing. Rucaparib and olaparib, two drugs in the class of PARP inhibitors were both recently approved by the FDA for biomarker-selected, previously treated advanced prostate cancer. Rucaparib was granted accelerated approval for men with mCRPC with deleterious variants in *BRCA1* or *BRCA2* only (somatic or germline origin) based on data from the ongoing TRITON2 study (NCT02952534) showing a promising objective response rate (ORR) and duration of response for rucaparib 600 mg twice a day, with a phase III confirmatory trial pending. Olaparib was approved for men with advanced prostate cancer who previously progressed on abiraterone or enzalutamide and have a deleterious HRR gene variant (somatic or germline) based on statistically significant improvement in radiographic PFS compared with the alternative androgen-signaling directed agent, with statistically significant benefit in OS and ORR also seen in cohort A of the study that included men with *BRCA1*, *BRCA2*, and/or *ATM* variants. Although olaparib received FDA approval for a broader list of deleterious HRR genes outside of just *BRCA2*, it is evident from multiple studies that the majority of benefit from single-agent PARP inhibitor is seen in patients with deleterious *BRCA2* variants or other very closely related genes such as *PALB2*. Targeting ATM-aberrant prostate cancer warrants further research, with some preliminary promising data for the use of ATR inhibitors for these patients.

CDK12 has previously been implicated in regulating the expression of HRR genes, and loss of function in CDK12 has been shown to result in a distinct immunophenotype in prostate cancer. Thus, CDK12 alterations held promise as a potential predictive biomarker for PARP inhibition as well as immune checkpoint blockade. However, clinical data thus far have been mixed, in which CDK12 alterations more clearly portend for worse outcomes to both AR-directed therapy and chemotherapy but have yet to show clear benefit to PARP inhibitor or immune therapy.

Missense mutations in the SPOP gene are frequently seen in localized primary prostate cancer and to a lesser degree in metastatic disease. Multiple studies have shown that patients with *SPOP* variants display a better prognosis and good response to androgen-targeted therapies. The underlying biological reasoning and mechanisms for this improved response are an active area of investigation.

Androgen-Indifferent Prostate Cancer Treatment

Because of characteristic androgen indifference, pure SCPC does not respond to available androgen-directed therapies. Therapeutic recommendations are extrapolated from small cell carcinoma of the lung using etoposide plus cisplatin or carboplatin as first-line therapy. Despite platinum sensitivity, the responses are typically short-lived, and prognosis remains poor. SCPC is more commonly identified as a mixed histology with adenocarcinoma that can be treated with therapies for either histology. Approved androgen-directed therapies should not be withheld based on neuroendocrine marker expression alone in the absence of small cell histology.

The AVPC clinical and molecular criteria seem to enrich for the platinum sensitivity seen in SCPC, though responses remain short-lived. This is supported

by a phase 2 study showing a survival benefit with docetaxel plus carboplatin in tumors with atypical clinical features regardless of histology or neuroendocrine marker expression. A phase 1/2 study of cabazitaxel plus carboplatin versus cabazitaxel alone demonstrated a significant benefit with the addition of carboplatin when stratifying by presence of AVPC molecular criteria. An ongoing study is assessing the efficacy of maintenance PARP inhibition after use of carboplatin–cabazitaxel in AVPC tumors (NCT03263650), and another study is being planned to explore the addition of immune checkpoint blockade to this regimen. However, available AVPC criteria are prognostic but not predictive, and responses to platinum-based therapy remain heterogeneous. Further study is warranted to discover biomarkers that (1) define androgen-indifferent tumors regardless of morphology, (2) predict for response to current platinum-based therapies, and (3) enable development of targets for more effective therapies.

Stromal-Targeting Therapies

Bone-targeting radiopharmaceuticals are examples of stromal-targeting agents in prostate cancer. The merits of targeting the bone microenvironment have been established by the use of strontium 89 (pure β-emitter radiopharmaceutical) as a single agent or in combination with cytotoxic therapy[74] (Table 45–7). Emerging data support the view that targeting bone will prolong overall patient survival, even in those with advanced-stage disease. Samarium-153 conjugated to ethylene-diamine-tetra-methylenephosphonic acid is a β- and γ-emitter radiopharmaceutical. It was approved by the FDA in 1997 after the landmark study that showed palliation of pain associated with metastatic bone cancer using samarium-153 lexidronam.[75] However, marrow toxicity remains the principal side effect. The radioactive calcium mimetic radium-223 dichloride (Xofigo, Bayer), which specifically targets bone metastases (present in 80%–90% of patients with metastatic CRPC), is the newest treatment for patients with mCRPC. A phase III, randomized, double-blind, placebo-controlled study (ALSYMPCA) investigated the use of radium-223 in men with CRPC and bone metastases; radium-223 showed improved OS in this patient population.[76] This study led to its FDA approval for CRPC with bone metastases in 2013.

Bisphosphonates were the first class of agents investigated for prevention of skeletal-related events (SREs) in patients with mCRPC. A randomized, placebo-controlled trial of zoledronic acid in patients with hormone-refractory metastatic prostate carcinoma showed zoledronic acid reduced SREs in patients with prostate cancer with bone metastases.[77] Currently, zoledronic acid is the only bisphosphonate approved to prevent SREs in patients with mCRPC.

Denosumab is a fully humanized monoclonal antibody that binds to the RANKL (receptor activator of nuclear factor κ-B ligand), which results in inhibition of RANK-L–mediated bone resorption. A phase III study of men with CRPC with bone metastases and no previous exposure to intravenous bisphosphonate compared denosumab with zoledronic acid for prevention of SREs.[78] Denosumab was superior to zoledronic acid in delaying or preventing SREs, but there was no significant difference between treatments in survival or disease progression.[78] It was approved by the FDA in 2010 for prevention of SREs in patients with bone metastases.

TABLE 45–7 Rationale for Bone-Targeted Therapy

• Osseous metastases are the preferred site of castration-resistant progression.
• Osseous metastases significantly contribute to the morbidity and mortality of prostate cancer.
• Bone-targeting radiopharmaceuticals prolong symptom-free survival in patients with castration-resistant progression and skeletal metastases.

Immune-Based Therapies

Historically, there has been long-standing interest in stimulating a patient's immune system as a therapy strategy for prostate cancer. Despite enthusiasm for this paradigm, studies have consistently demonstrated no clinical benefit. Recently, several new strategies have emerged that reveal the potential of immunotherapy in treating prostate cancer. Randomized, placebo-controlled phase III trials demonstrated an OS benefit for men with CRPC treated with sipuleucel-T.[79] GVAX, a cellular vaccine product that uses exogenous tumor cells that secrete granulocyte-macrophage colony-stimulating factor, has shown promising activity in phase II studies,[80] although it failed to meet its primary end point of OS compared with docetaxel in a phase III study.[81,82] Ipilimumab is a humanized anti–CTLA-4 (cytotoxic T-cell lymphocyte antigen-4) antibody; data from a phase III trial of a single dose of radiation treatment followed by ipilimumab or placebo in previously treated patients showed the primary endpoint (ie, OS) was not met (ipilimumab vs placebo, 11.2 vs 10.0 months, respectively; however, there was an improvement in PFS and PSA responses).[83] Further development of these agents (and others) could dramatically change the way we treat prostate cancer in the coming decade.

FUTURE DIRECTIONS

The majority of patients with advanced prostate cancer demonstrate a predictable clinical pattern of progression. As elucidation of the biologic events responsible for prostate cancer progression evolves, better classification of the disease based on the underlying molecular mechanisms of progression will facilitate the implementation of current and emerging therapies. To reflect this, we have recently proposed a "spiral" model for prostate cancer progression that describes underlying biology to predict response to therapy[84] (Fig. 45–4). The model proposes three main phases in prostate cancer progression: (1) the dihydrotesterone (DHT)-dependent phase, (2) the microenvironment-dependent phase, and (3) the cell-autonomous phase.

The first phase is the *DHT-dependent phase*, during which the tumor is responsive to 5-α-reductase inhibitor treatments. In the PSA era, this phase typically occurs when patients are initially diagnosed with

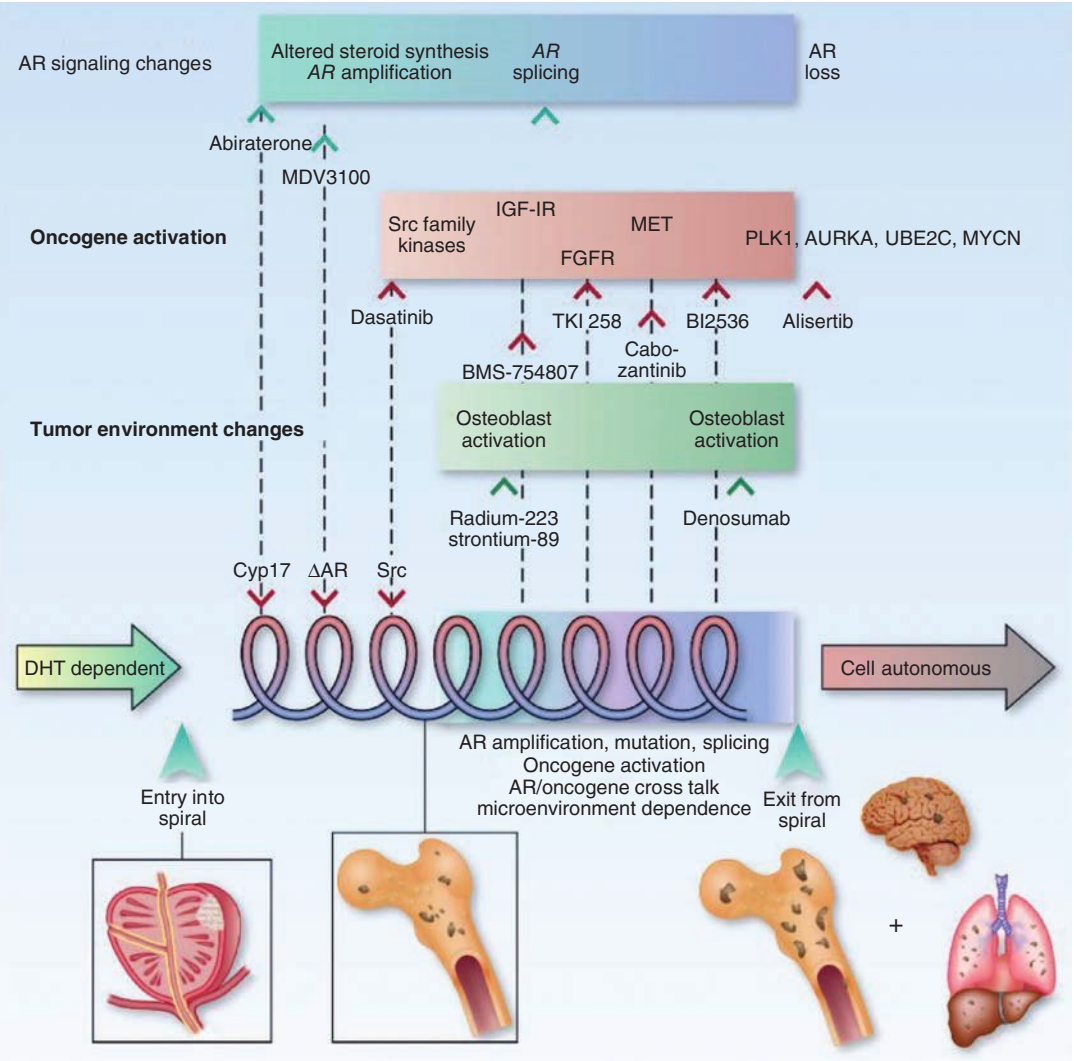

FIGURE 45–4 **Spiral model for prostate cancer progression. The first phase is the *dihydrotesterone (DHT)-dependent phase*. The second phase is the *microenvironment-dependent phase*. The third phase is the *cell-autonomous phase*. Each "turn" is defined by a predictive marker(s) that can be targeted. The pitch in each spiral reflects the duration that the tumors remain responsive to a specific therapy. The adaptive changes in tumors in response to therapy account for resistance, leading the tumor to progress to the next turn of the progression spiral, which signals additional alterations in the tumor and its microenvironment. Tumors in this new "turn" require different therapeutics that specifically target the altered properties that define the turn. Markers that reflect the biology that drives each turn can be used to guide timely therapy application in anticipation of progression. AR, androgen receptor; FGF, fibroblast growth factor; IGF, insulinlike growth factor. (Reproduced with permission from Logothetis CJ, Gallick GE, Maity SN, et al. Molecular classification of prostate cancer progression: foundation for marker-driven treatment of prostate cancer. *Cancer Discov*. 2013;3(8):849-861.)**

early-stage, localized prostate cancer. Tumors in this phase would be predicted to respond optimally to chemoprevention strategies.

The second phase is the *microenvironment-dependent phase*, when the tumor enters a progression spiral in which multiple factors, including AR-signaling changes, oncogene activation, tumor suppressor gene loss, and microenvironment changes, affect tumor progression. Tumors in this phase would be predicted to respond optimally to inhibitors of intratumoral androgen signaling (eg, with abiraterone and enzalutamide). Over time, however, adaptive changes in response to therapy promote resistance, leading the tumor to progress to the next turn of the progression spiral, which signals additional molecular alterations in the tumor and its microenvironment. Tumors in a new turn of the spiral will require different therapeutics that specifically target the altered molecular events that drive each turn (eg, inhibitors of Src, fibroblast growth factor, c-MET). Predictive biomarkers corresponding to each turn can be used to guide timely therapy application.

The third phase is the *cell-autonomous phase*, whereby cancers exit the spiral when a series of mutations arise, including the loss of AR, RB, or p53; upregulation of polo-like kinase 1 (PLK1) and Aurora kinase A (AURKA); and amplification of *MYCN*. At this stage, the prostate cancer cells are no longer regulated by the microenvironment and become tumor cell autonomous. Cancers in this phase would be predicted to respond optimally to chemotherapy.

Along with the integration of improved predictive and prognostic markers, we believe it is realistic to expect individualized treatment algorithms for prostate cancer patients as details of the spiral evolve. The application of biologically based, rational therapy is the foundation of our mission at MDACC to cure prostate cancer. Recent progress has created a strong sense of hope that we are well on our way to achieving this goal.

MD ANDERSON PRACTICE TIPS

- Men with low-risk and favorable intermediate-risk prostate cancer should be considered for active surveillance.
- Despite additive benefit of androgen deprivation and radiation for men with high-risk localized prostate cancer, there has been no benefit shown to date for adjuvant ADT after prostatectomy.
- The decision on when to initiate ADT in asymptomatic men with castrate-sensitive PSA recurrence after definitive therapy is a patient-to-patient decision that should be tailored based on the patient's age, functional status, and comorbid conditions. Rapid PSA doubling time or change in the velocity of PSA rise should prompt further investigation and consideration of initiating ADT.
- Multiple phase III studies of AR-signaling blockade in conjunction with ADT have shown clinical benefit for men with metastatic castrate-sensitive disease over ADT alone, leading to multiple FDA-approved options in this space. It is not recommended to switch to an alternative second-generation antiandrogen signaling agent after progression on one because there is cross-resistance and been shown to be inferior to switching to chemotherapy (CARD trial).
- Carboplatin with cabazitaxel should be considered for treating men with AVPC (androgen-indifferent prostate cancer), with continued ADT.
- Precision medicine in prostate cancer is actively evolving. Alterations in DDR genes (eg, *BRCA2*) at the somatic or germline level are relatively frequent in prostate cancer (≤25% of metastatic prostate cancer). A deleterious alteration in a DDR gene aids in treatment selection (eg, PARP inhibition in *BRCA2*-aberrant tumors). Tumors with MSI-H, MMR protein loss, or high TMB can be considered for treatment with pembrolizumab. Alterations in *SPOP* are associated with an overall good prognosis and display better response to antiandrogen therapy. The impact of variants in other genes on prostate cancer phenotype and treatment (eg, *CDK12*, *ATM*, *CHEK1/2*) are under active investigation.

46 Penile Cancer

Jad Chahoud
Curtis A. Pettaway

KEY CONCEPTS

- Human papillomavirus infection appears to be the possible cause of 30% to 50% of penile cancer cases and appears to have a prognostic impact on clinical outcomes among patients with advanced disease.
- Penile-preserving strategies should be strongly considered among patients with low-stage tumors, especially those limited to the skin and the distal glans penis.
- The presence and the extent of metastasis to the inguinal region are the most important prognostic factors for survival in patients with squamous cell carcinoma of the penis.
- Penile tumor T stage ≥ T1b, grade, lymphovascular invasion, and perineural invasion appear to be the most important pathologic prognostic factors for nodal spread. Their presence is used to determine the need for inguinal staging procedures among patients with no clinically apparent inguinal metastases.
- Patients with bulky lymphadenopathy should undergo a multimodal therapeutic approach to include neoadjuvant platinum-based chemotherapy with paclitaxel, ifosfamide, and cisplatin (TIP) for four cycles followed by consolidation surgical lymph node dissection among responding patients.
- Patients with relapsed or refractory penile cancer to platinum-based chemotherapy have poor outcomes with current therapy modalities, and every effort should be made to enroll these patients on novel therapeutic clinical trials.

INCIDENCE

Penile cancer most commonly affects men between 50 and 70 years of age. The tumor is not unusual in younger men; in one large series, 22% of patients were younger than 40 years, and 7% were younger than 30 years.[1] In 2018, there were an estimated 1820 new cases in the United States.[2] The annual incidence of penile cancer cases in total per year worldwide has been estimated at approximately 35,000.[3] Penile cancer accounts for less than 1% of all malignant neoplasms among men in the United States and Europe,[2,4,5] but it may represent up to 10% of cancers in men in some Asian, African, and South American countries.[1] These differences are thought to be related to the prevalence of neonatal circumcision, human papillomavirus (HPV) infection, and cultural practices. Among uncircumcised tribes of Africa and within uncircumcised Asian cultures, penile cancer may amount to 10% to 20% of all malignant neoplasms in men.1 Squamous cell carcinoma (SCC) is the most common histologic subtype, accounting for more than 95% of cases (Table 46–1).[6]

Leiomyosarcoma

RISK FACTORS

Lack of Circumcision

The risk of penile cancer varies according to circumcision practice, phimosis, HPV infection, and smoking.[7–13] Neonatal circumcision has been considered a prophylactic measure that removes many of the risks of penile carcinoma because it eliminates the closed preputial environment where penile cancer most commonly develops. This increased risk appears to be related to a history of phimosis, which is a diagnosis of circumferential fibrosis of preputial tissue leading to an inability to retract the penile foreskin over the glans penis.[11] These findings were confirmed by a systematic review and meta-analysis that found a strong protective effect of childhood circumcision on invasive penile cancer (overall survival [OR], 0.33; 95% confidence interval [CI], 0.13–0.83; three studies).[14] Phimosis is found in 25% to 75% of patients with penile carcinoma described in most large series. Epithelial atypia was found in around 30% of patients who underwent circumcision with phimosis.[15] Also, a large case series showed the protective benefit from neonatal circumcision, but circumcision delayed until after puberty was not beneficial.[16]

Human Papillomavirus

Although the etiology for penile cancer development is not unique nor clarified, it is thought that HPV infection probably plays an important factor in the development of some penile cancer, with evidence that 31% to 63% of tumors are HPV related.[17–19] The presence of HPV in tumor tissue is established using numerous methods, such as polymerase chain reaction (PCR) amplification for the detection of HPV DNA. PCR is a highly sensitive method that can detect both transient and persistent HPV infections.[20] Also, p16INK4a expression has been used as a cost- and time-efficient surrogate marker of transforming HPV infections based on the strong correlation between transcriptionally active HPV and p16INK4a overexpression in cancer cells.[21] HPV is most associated with the basaloid and warty tumor subtypes, which were found to contain HPV DNA in 80% to 100% of cases. The largest meta-analysis of the prevalence of HPV infection in 4000 penile cancer cases showed a pooled HPV DNA prevalence of 50.8% in penile cancer. Basaloid SCCs (84%) and warty-basaloid carcinoma (75.7%) had a particularly high HPV DNA prevalence.[17] They found that HPV16 is by far the most common HPV type in both penile cancer and penile intraepithelial neoplasia. This meta-analysis also assessed pooled data from 2000 penile cancer cases and 167 penile intraepithelial neoplasia (PIeN) to show p16INK4a positivity amount to 41.6% for penile cancer and 49.5% for PIeN.[17]

Patients with HPV-related penile cancer appear to have a better prognosis than those with HPV-unrelated tumors. A population-based study found that the detection of HPV DNA in penectomy specimens was associated with a significant advantage in disease-specific survival (96% vs 82%).19 Immunohistochemical detection of p16, which is a marker for HPV infection, was also associated with improved outcome.[22] Whether HPV is predictive of response to treatment (eg, chemotherapy or radiation therapy) remains unknown.

MOLECULAR FEATURES

Overview of Molecular Features

The etiology of penile squamous cell carcinoma (PSCC) is multifactorial with limited information available of any familial inheritance pattern for PSCC, and a family history of PSCC is not considered a risk factor. As of today, no cancer susceptibility syndrome is definitively linked with an increased risk of PSCC.

There has only been one large long-term follow-up study among Nordic twins, which evaluated the familial and environmental influence for 23 types of cancers that included PSCC cases. In this analysis within the Nordic Twin Study of Cancer (NorTwinCan), all of the reported PSCC cases were discordant in monozygotic twins ($n = 15$ PSCC cases) and dizygotic twins ($n = 34$ cases).[23,24]

The viral oncogenesis of HPV-related PSCC is initiated by the viral E6 and E7 oncoproteins' expression in host cells, and they are known to interact with the *RB1* and *TP53* tumor suppressor pathways.[18] These molecular events are known to play a critical role in the development of cervical cancer,[25] and a similar mechanism probably exists in HPV-related cases of penile cancer.[18,26] This leads to the degradation of the tumor suppressor p53 and the binding to the tumor suppressor gene Rb causing autonomous cell proliferation followed by a malignant transformation from the precursor lesion to invasive PSCC.[27,28] HPV-associated cancers express high levels of p16(INK4A) as a response to E7 oncoprotein expression, causing enhanced expression and cellular accumulation of p16INK4a in the basal and parabasal epithelial cells of HPV-related PSCC. On the other hand, HPV-negative PSCC carcinogenesis is poorly understood but has been linked to the tumor suppressor gene p53 mutations and other tumor suppressor genes that are discussed later in more detail.

Over the past 5 years, research efforts continue to improve our understanding of three important cornerstones of the molecular landscape of PSCC:

(1) bettering our understanding of the differences in molecular pathways implicated in the development and progression of HPV-related PSCC compared with HPV-negative PSCC,[29,30] (2) assessing the genomic similarity between PSCC and other HPV-related SCCs,[31,32] and (3) the identification of potentially targetable recurrent somatic alterations that could impact clinical trial development in PSCC.[31,32]

PATTERN OF METASTASIS

Anatomy of Lymphatic Drainage

Penile cancers have a predictable pattern of local, regional, and systemic spread. The earliest route of dissemination from the penis is metastasis to the regional inguinal and iliac nodes. The lymphatics of the prepuce form a connecting network that joins with the lymphatics from the skin of the shaft. These tributaries drain into the superficial inguinal nodes. The lymphatics of the glans join the lymphatics draining the corporal bodies, and they form a collar of connecting channels at the base of the penis that also drain by way of the inguinal lymph nodes. From there, drainage is to the pelvic nodes (external iliac, internal iliac, and obturator). Multiple cross connections exist at all levels of drainage, so that penile lymphatic drainage is bilateral to both inguinal areas.[33]

Frequency of Metastases: Prognostic Factors

Tumor grade, lymphovascular invasion (LVI), and perineural invasion appear to be the most important pathologic prognostic factors for nodal spread and mortality.[34] Other frequently cited risk factors are pathological T stage it is a known staging nomenclature (pT) classification, tumor thickness, anatomical site (proximal vs distal), pathologic subtype, urethral invasion, and positive margins of resection.

LVI in the primary tumor has significant prognostic importance. Studies have assessed its presence or absence and found that it was an important predictor of nodal metastasis.[35] Perineural invasion was present in 36% of cases analyzed in a multi-institutional dataset of 134 patients and was also a strong predictor of lymph node metastasis.[36] The pathologist should specifically comment on the presence or absence of vascular invasion, tumor grade, and perineural invasion in the surgical specimen.

Distant Metastasis and Mortality

Metastatic penile cancer is characterized by a relentlessly progressive course, causing death for most of the untreated patients within less than 2 years.[37–40] Metastatic enlargement of the regional nodes eventually leads to skin necrosis, chronic infection, sepsis, hemorrhage secondary to erosion into the femoral vessels, and failure to thrive.

Clinically detectable distant metastatic lesions to the lung, liver, bone, or brain are uncommon at initial presentation.[41] Such metastases usually occur late in the course of the disease after the local lesion has been treated. Distant metastases in the absence of regional node metastases are unusual.

EVALUATION OF THE PATIENT

Staging System

The American Joint Committee on Cancer's eighth edition[42] tumor, node, metastasis (TNM) staging system for penile cancer (Table 46–2) is used for staging in the United States since 2018 and differs from the seventh edition.[43] A major difference in the current TNM staging system compared with the previous version is the presence of perineural invasion, which was added as another factor to separate pT1a disease from pT1b disease. Another difference is the nodal category of pN1, which is now defined as two or fewer unilateral inguinal metastases with no extranodal extension. Additionally, pN2 is now defined as three or more unilateral inguinal metastases or bilateral metastases.[42]

Evaluation of Palpable Lymph Nodes

Palpable inguinal lymph nodes are found at presentation in 28% to 64% of patients with penile cancer, but not all of these represent metastatic tumor. Lymphadenopathy is caused by metastasis in 47% to 85% of these cases; the rest are secondary to inflammation.[41,44,45] Approximately 25% of patients with palpable lymph nodes have bilateral metastases. Careful note should be made of the uni- or bilateral location of palpable adenopathy, diameter, number in each inguinal area, whether they are mobile or fixed, their relationship to other structures (eg, skin) with respect to infiltration or perforation, and the presence of leg or scrotal edema.[39,46] The National Comprehensive Cancer Network (NCCN) and European Association of Urology (EAU) guidelines for penile cancer recommend fine-needle aspiration (FNA) of palpable inguinal lymph nodes.[39,46]

Staging Groin Dissection

Although treatment of the primary tumor and a period of antibiotics may be useful to help sterilize the inguinal region, this practice is no longer advocated as a

TABLE 46–2 Definitions of Tumor (T), Node (N), Metastasis (M)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Ta	Noninvasive verrucous carcinoma
T1a	Tumor is without lymphovascular invasion or perineural invasion and is not high Grade (ie, grade 3 or sarcomatoid)
T1b	Tumor exhibits lymphovascular invasion and/or perineural invasion or is high grade (ie, grade 3 or sarcomatoid)
T2	Tumor invades into corpus spongiosum (either glans or ventral shaft) with or without urethral invasion
T3	Tumor invades into corpora cavernosum (including tunica albuginea) with or without urethral invasion
T4	Tumor invades into adjacent structures (ie, scrotum, prostate, pubic bone)
Regional Lymph Nodes (N)	
Clinical Stage Definition	
CNX	Regional lymph nodes cannot be assessed
cN0	No palpable or visibly enlarged inguinal lymph nodes
cN1	Palpable mobile unilateral inguinal lymph node
cN2	Palpable mobile ≥2 unilateral inguinal nodes or bilateral inguinal lymph nodes
cN3	Palpable fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral
Pathologic Stage Definition	
PNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	≤2 unilateral inguinal metastases, no ENE
pN2	≥3 unilateral inguinal metastases or bilateral metastases
pN3	ENE of lymph node metastases or pelvic lymph node metastases, no ENE
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis[a]

[a]Lymph node metastasis outside the true pelvis in addition to visceral or bone sites.
ENE, Extranodal extension.

tool to select patients who either should or should not undergo lymphadenectomy. Patients with clinically node-negative disease, in addition to cross-sectional imaging of the abdomen, pelvis, and chest, might still receive surgical lymph node evaluation if they are in the high-risk group based on the presence of any of the following primary tumor pathological findings: (1) T2 or greater tumor,[47,48] (2) high-grade tumor,[49,50] or (3) presence of LVI or perineural invasion.[36,49] Both dynamic sentinel node biopsy and superficial or modified inguinal lymph node dissection (LND) (using either an open or minimally invasive approach (ie, laparoscopic and robotic-assisted approaches) can be used for surgical staging among patients with high-risk PSCC, whereas patients with low-risk disease can be spared and monitored with active surveillance.[51,52] Further surgical treatment for patients with high-risk disease is guided by the pathological results from the surgical staging. The reluctance to advocate automatic ilioinguinal lymphadenectomy in all patients with penile cancer stems from the substantial morbidity the procedure can produce. Postoperative complications have been reduced by improved preoperative and postoperative care and advances in surgical technique. The mortality from complete inguinal LND is rare and usually associated with septic complications.[53]

For men with evidence of palpable adenopathy upon clinical examination, baseline staging imaging using a computed tomography (CT), magnetic resonance imaging (MRI), or positron emission tomographic (PET)–CT to evaluate the extent of disease is considered standard per the European and American

guidelines. FNA for pathologic assessment can help with treatment planning because definitive surgical treatment is recommended for men with a positive FNA and no bulky, pelvic, or fixed lymphadenopathy upon imaging. In contrast, for men with low-risk disease (pTis, pTa, pT1a) with clinically suspicious adenopathy and a negative FNA result, we recommend confirmation with an excisional biopsy for definitive evaluation. For men with high-risk disease (≥T1b) with clinically suspicious adenopathy and a negative FNA result, confirmation with repeat excisional biopsy can be attempted but a superficial or modified inguinal LND with frozen section evaluation of the nodes is preferred to avoid delays. For patients with proven metastases via FNA or node biopsy, additional imaging studies, such as CT or MRI (that can show central necrosis or irregular nodal border)[44] or CT-PET scans, may be of value in predicting adverse nodal features, such as three or more positive nodes, extranodal extension, or pelvic metastases. Patients with these risk factors, those with a palpable lymph node (fixed or none fixed) larger than 4 cm inguinal, those with palpable fixed or bilateral metastatic LN that is 4 cm or smaller, and pelvic lymph node metastasis could benefit from multimodal therapy with neoadjuvant chemotherapy followed by surgical consolidation.

Computed Tomography Imaging

Patients with clinically palpable lymph nodes should undergo imaging to define the full extent of disease. MRI can be considered to evaluate tumor extent (invasion of the corpora or urethra) for patients with planned organ-sparing surgery as per the current EAU and NCCN guidelines.[54,55] Both CT and MRI scanning techniques depend primarily on lymph node enlargement for detection of metastases but are unable to define the internal architecture of normal-size nodes. Because CT and MRI have similar accuracy in detecting lymphadenopathy in other cancers, CT has often been the imaging modality chosen in penile cancer to examine the inguinal and pelvic areas as well as to rule out more distant metastases. CT scanning facilitates the examination of the inguinal region in obese patients and in those who have had prior inguinal surgery, for whom the physical examination may be unreliable. In addition, in patients with known inguinal metastases, CT-guided biopsy of enlarged pelvic nodes may provide important information for consideration of neoadjuvant chemotherapy. Otherwise, for patients with a normal inguinal examination, management recommendations should be based on the primary tumor risk factors with only intermediate- and high-risk patients requiring cross-sectional imaging.[54,55]

Positron Emission Tomography Imaging

The use of fluorodeoxyglucose (FDG) PET-CT in patients with PSCC with nonpalpable lymph nodes has been assessed by multiple studies, with the limitation of small sample size. Scher *et al*[56] examined 13 cN0 patients, and FDG PET-CT scans showed a sensitivity per lesion of 94% and 100% specificity. Leijte *et al*[57] published their effort in solely cN0 groin tumors, with 5 of 42 patients showing evidence of lymph node metastases, and PET-CT only identified 1, resulting in a sensitivity of only 20%, with 92% specificity. In 2012, a meta-analysis by Sadeghi *et al*[59] included seven studies, with the pooled sensitivity per groin for FDG PET-CT in cN0 patients reported as 56.5% (95% CI, 34.5%–76.8%). Based on this information, FDG PET-CT is not recommended to replace surgical staging for high-risk primary cancer with cN0 tumors, and surgical staging remains a necessity to identify small inguinal lymph node metastases.

TREATMENT

Local Control

Surgical amputation of the primary tumor remains the oncologic gold standard for rapid definitive treatment of the penile primary tumor; local recurrence rates range from 0% to 8%.[59] Amputation is often necessary for bulky stage T2 to T4 tumors, but it has been shown to decrease sexual quality of life.[60] It is generally accepted that patients with penile primary tumors exhibiting favorable histologic features (stages Tis, Ta, T1; grades 1 and 2 tumors) are at a lower risk for metastases. These patients are also best suited for organ-sparing or glans-sparing procedures, with the goal of preserving glans sensation where possible or at least to maximize penile shaft length. Such approaches include topical treatments (fluorouracil or imiquimod cream for Tis only), radiotherapy, Mohs surgery, limited excision strategies (eg, circumcision), and laser ablation.[61–65] MRI provides excellent soft tissue detail and can be a useful imaging strategy to assist in planning organ-sparing surgery.[66] Partial or total penectomy should be considered in patients exhibiting adverse features that defy adequate control by organ preservation strategies. These include tumors of size 4 cm or more, grade 3 lesions, and those invading deeply into the glans, urethra, or corpora cavernosa.

Therapeutic Lymph Node Dissection

The biology of penile cancer is such that it exhibits a prolonged locoregional phase before distant dissemination. Lymphadenectomy alone can be curative and should be incorporated into the treatment planning for

most patients. However, because of the morbidity of traditional lymphadenectomy, especially among those patients with clinically negative groins, contemporary controversial issues include the following: (1) the selection of patients for lymphadenectomy versus careful observation, (2) the types of procedures to correctly stage the inguinal region with low morbidity, and (3) multimodality strategies (eg, neoadjuvant chemotherapy, see further in the chapter) to improve survival among patients with bulky inguinal metastases.

The presence and the extent of metastasis to the inguinal region are the most important prognostic factors for survival in patients with SCC of the penis. The survival rates for therapeutic LND in patients with established regional lymph node metastases are variable, averaging about 60% (range, 0%–86%).[35,67] This variability in survival rates is directly attributable to the extent of nodal metastasis. Patients with pN1 or pN2 with a minimal number of lymph nodes involved have an average 5-year survival rate of 77% compared with only 25% when a greater degree of nodal involvement is present. In one study,[68] the 5-year survival rate of patients with extranodal involvement was only 6% (1 of 17 patients). The combined results of several small series suggest an average 5-year survival rate of 15% when pelvic lymph nodes are present. Taken together, these data suggest that the pathologic criteria that predict long-term survival (ie, 80% 5-year survival rate) after attempted curative surgical resection of inguinal metastases are (1) minimal nodal disease (up to two involved nodes in most series), (2) unilateral involvement, (3) no evidence of extranodal extension of cancer, and (4) absence of pelvic nodal metastases.

Chemotherapy for Stage IIIB/IV Penile Carcinoma

The first candidate drugs for the chemotherapeutic treatment of patients with stage IIIB/IV penile carcinoma included cisplatin, vincristine, methotrexate, fluorouracil, mitomycin, and bleomycin.[69] In a multicenter study conducted by the SWOG,[70] 26 patients with metastatic penile cancer received single-agent cisplatin at a dosage of 50 mg/m^2 on days 1 and 8 of each 28-day cycle. Only four patients (15%) experienced responses that persisted for 1 to 3 months.

The combination of bleomycin, methotrexate, and cisplatin (BMP) was studied in two phase II clinical trials, but the toxicity of the regimen was considerable, with multiple treatment-related deaths caused by bleomycin lung toxicity, other pulmonary causes, and infection.[71,72] The BMP regimen and bleomycin are no longer recommended for the treatment of patients with penile cancer because of the unacceptable toxicity.

Other cisplatin-based drug combinations demonstrated response rates of 8% to 50% (Table 46–3).[38,74–77] A regimen would be of interest if it has an overall response rate greater than 30% with acceptable toxicity. The study of irinotecan–cisplatin conducted by the European Organization for Research and Treatment of Cancer[74] was a prospective study with 26 evaluable patients but was interpreted as having a negative result by the authors because the response rate had an 80% confidence interval of 18.8% to 45.1%, extending well below 30%. In another study, paclitaxel, ifosfamide, and cisplatin (TIP) was given to patients with metastases limited to the inguinal and pelvic lymph nodes.[75] In this neoadjuvant study, patients with response or stable disease after four courses of TIP underwent surgery with curative intent. The response rate was 50%, and the safety profile of this regimen was a significant improvement over BMP, with no treatment-related deaths. In another study of taxane drugs for the treatment of metastatic penile cancer, docetaxel, 5-fluorouracil (5-FU), and cisplatin resulted in a response rate of 38.5%.[76] The response rate was not high enough to recommend this regimen in preference to 5-FU and cisplatin, and grade 3 and 4 toxicities were frequent.

5-FU and cisplatin were studied in a retrospective series of patients with metastatic penile cancer.[38] Partial responses had been seen in 8 of 25 evaluable patients (32%). Although there have been no randomized controlled trials to establish a single standard of chemotherapy treatment for metastatic penile cancer,

TABLE 46–3 Cisplatin-Based Chemotherapy Regimens Without Bleomycin

Reference	Regimen	Overall Response Rate (PR + CR) (%)	Median Overall Survival (Months)
Theodore et al[73] (2008)	Irinotecan Cisplatin	31	Not reported
Pagliaro et al[74] (2010)	Paclitaxel Ifosfamide Cisplatin	50[a]	17.1[a]
Di Lorenzo et al[38] (2012)	5-Fluorouracil Cisplatin	32	8
Nicholson et al[75] (2013)	Docetaxel Cisplatin 5-Fluorouracil	38.5	13.9
Houédé et al[76] (2015)	Gemcitabine Cisplatin	8	15

[a]Patients in this study had metastases confined to inguinal or pelvic lymph nodes (Tx N2–N3 M0) and underwent surgical consolidation when possible.
CR, complete response; PR, partial response.

either 5-FU plus cisplatin or paclitaxel, ifosfamide, and cisplatin have been endorsed by contemporary guidelines.[54,55]

Multimodality Therapy

Neoadjuvant Chemotherapy

As discussed in the section on therapeutic LND, the 5-year overall survival (OS) and disease-free survival (DFS) rates with surgery alone are as high as 80% for unilateral, superficial inguinal lymph node involvement with no more than two nodes (stage N1 or limited N2), only 10% to 20% for stages N2 and N3 (multiple, bilateral, or pelvic lymph node involved), and less than 10% in the presence of extranodal extension.[45,77] Nearly all recurrences are detected within 2 years of surgery, and an aggressive, multimodality approach to the treatment of high-risk patients could result in better OS.[37,74]

Neoadjuvant chemotherapy allows for timely delivery of systemic chemotherapy, results in potential volume reduction for enlarged lymphadenopathies, provides prognostic information, and facilitates subsequent surgical consolidation.[78,79] A group from the Netherlands reported on their retrospective analysis of 20 patients who had received preoperative chemotherapy to downstage unresectable disease.[80] Seventeen patients had bulky lymph node metastases (Tx, N3), and the other three had advanced primary tumors (T3–T4, N0–N1). The most commonly used regimens in the Dutch series, which spanned a 34-year period, were BMP (n = 10); bleomycin, vincristine, and methotrexate (n = 5); and single-agent bleomycin (n = 3). Severe toxicity occurred in four patients, including three treatment-related deaths. Twelve patients experienced an objective tumor response; nine of the 12 underwent surgery, and eight achieved long-term DFS. Two patients had no residual tumor in the surgical specimen. The finding of pathologic complete responses suggested that this could be used as a signal for efficacy, but the toxicity was deemed unacceptable with this specific chemotherapy regimen.

Neoadjuvant chemotherapy was next studied prospectively in a phase II clinical trial conducted at MD Anderson Cancer Center.[75] Thirty patients with clinical TX N2 to N3, M0 penile cancer received four courses of paclitaxel, ifosfamide, and cisplatin before a planned complete bilateral inguinal LND and uni- or bilateral pelvic LND. Fifteen patients (50%) experienced a partial or complete response to chemotherapy. Twenty-two patients (73%) were able to complete the neoadjuvant chemotherapy and surgery, of whom there were three patients (14%) with a pathologic complete response in the lymph nodes. Objective response to chemotherapy, absence of bilateral residual tumor, and absence of extranodal extension in residual tumor were associated with a higher rate of overall and progression-free survival (PFS) in a univariable analysis. The overall and PFS rates in N2 to N3 disease achieved with neoadjuvant paclitaxel, ifosfamide, and cisplatin are considered an improvement over the expected survival with surgery alone. Despite the absence of a randomized controlled trial, contemporary guidelines recommend neoadjuvant paclitaxel, ifosfamide, and cisplatin for patients presenting with bulky or high-risk regional lymph node metastases.[54,55]

Adjuvant Chemotherapy

Adjuvant chemotherapy has the advantage of allowing patient selection based on accurate pathologic staging. The development of neoadjuvant chemotherapy as standard treatment appears to be more achievable and has advantages of downstaging to facilitate surgery, better tolerance of chemotherapy in the preoperative setting, and earlier exposure of micrometastases to the chemotherapy agents. Tumor response can be detected in the neoadjuvant setting, but not in the adjuvant setting, and the histopathologic findings of postchemotherapy surgery provide an early indicator of the treatment effect and prognosis.[81] When patients have undergone surgery without neoadjuvant chemotherapy and are found to have multiple inguinal or any pelvic lymph nodes involved or extranodal extension, then a regimen such as paclitaxel, ifosfamide, and cisplatin can be administered as adjuvant therapy on the basis of extrapolation from the neoadjuvant data.[74]

Prospective data on adjuvant chemotherapy are not available, and only small retrospective studies have been reported. Recently, a large multicenter retrospective study assessed 141 patients with advanced pathological pelvic lymph node involvement and demonstrated a median OS improvement with the use of adjuvant chemotherapy.[82] This study showed a potential benefit of adjuvant chemotherapy use for patients with pelvic lymphadenopathy who did not receive neoadjuvant chemotherapy. This study has the inherent limitations of a retrospective study and incomplete information on the specific chemotherapy combinations used. Further prospective evaluation of adjuvant systemic chemotherapy in the management of locally advanced PSCC remains unavailable to define its specific role and benefit. The NCCN guidelines recommend using adjuvant chemotherapy if neoadjuvant chemotherapy was not given, with level 2A evidence, for patients with high pathological risk features (pathological N2, N3, or ECE).

Radiotherapy Combined with Surgery or Chemotherapy

Studies of radiotherapy in penile carcinoma have included penis-sparing treatment for small (T1–T2,

<4 cm) primary tumors, treatment of lymph node metastases, postoperative radiotherapy, and chemoradiotherapy. There are no published randomized trials of multimodality treatment with radiotherapy in penile cancer as there are in SCCs from other sites. For example, radiotherapy with surgical lymphadenectomy has been studied in women with cancer of the vulva, a disease site that has natural history and nodal drainage like those of the penis. Based on these studies, the standard of care for metastatic vulvar cancer is radiotherapy to the pelvis rather than pelvic LND.[83] The EAU penile cancer guideline group recently conducted a systematic review of the evidence and concluded that because of the heterogeneous and limited evidence showing clinical benefit, a routine recommendation of adjuvant radiotherapy is not yet warranted.[84] Pelvic LND remains the standard of care for penile cancer patients after definitive treatment of inguinal lymph node metastases.[39] Thus, a randomized trial in penile cancer would be informative concerning the optimal method for consolidation of pelvic lymph nodes.

International Randomized Trial

It has not been possible to conduct randomized controlled trials in penile cancer to answer basic questions. The International Penile Advanced Cancer Trial (InPACT) uses a Bayesian design for randomized treatment of patients with inguinal lymph node metastases from penile cancer. The trial has two independent randomizations, addressing key questions in the clinical pathway: (1) the role of neoadjuvant therapy prior to standard surgery, by randomizing to chemotherapy, chemoradiotherapy, or no neoadjuvant therapy, and (2), the role of prophylactic pelvic lymph node dissection after the standard surgery with therapeutic inguinal LND.[85] The primary outcome measure of the InPACT study is OS.[85]

CONCLUSION

The treatment of men with SCC of the penis has evolved considerably in recent years, along with our understanding of its molecular biology. Penis-sparing strategies for early-stage disease allow for better outcomes in terms of quality of life. Inguinal staging strategies to define microscopic inguinal metastases (including minimally invasive techniques) while decreasing morbidity continue to evolve. Neoadjuvant chemotherapy is now standard of care for patients presenting with bulky regional lymph nodes. An ambitious international randomized trial (InPACT) proposes to compare neoadjuvant and adjuvant as well as surgical and radiotherapeutic strategies in this clinical setting. Meanwhile, vaccination of both men and women against HPV offers to reduce the risk of cancer, particularly for uncircumcised men, who are already at increased risk. Viral antigens are a promising target for the immunotherapeutic treatment of patients with penile cancer and suggest a possible role in this disease for drugs that exert immune checkpoint blockade.[86]

MD ANDERSON PRACTICE TIPS

- We perform HPV/p16 testing among patients with penile cancer routinely because it can have prognostic value, information for counseling spouses and can provide further clinical trials options using HPV-directed novel therapies.
- We routinely perform penile-preserving strategies when appropriate to maximize penile length, function, and cosmetic appearance.
- We encourage patients with clinically evident lymph node metastases to enroll in the InPACT, a multicenter trial that aims to establish the standard of care for treatment of patients with penile cancer exhibiting regional metastases.
- We encourage genomic testing in patients with bulky advanced disease to identify potential therapy targets for enrollment of immune or targeted therapy trials.

47 Germ Cell Tumors

Joseph A. Moore
Shi-Ming Tu

KEY CONCEPTS

- Germ cell tumors (GCTs) are the most common new cancer diagnosis in young men and are divided into two types, seminoma and nonseminoma germ cell tumors (NSGCTs).
- In a young man without obvious testicular primary or unknown primary tumor, serum tumor markers, specifically human chorionic gonadotropinβ-, α-fetoprotein (AFP), and cytogenetic study, namely i(12p), have unique diagnostic and prognostic significance in GCTs.
- GCTs follow a distinct pattern of spread and metastasis—the right testicle drains to the interaortocaval lymph nodes, and the left testicle drains to the left paraaortic lymph nodes.
- Approximately half of testicular GCTs show histologic elements other than seminoma or produce serum elevation of AFP indicating nonseminoma. These cancers are collectively known as mixed NSGCTs, and they form a group of histologically and clinically diverse cancers.
- Optimal management of patients with high-risk or mixed NSGCTs requires a multidisciplinary approach, integrating chemotherapy and surgery, to achieve the highest cure rates.
- Patients who pose a unique diagnostic or therapeutic challenge should be considered for early referral to a large tertiary care center.

Testicular germ cell tumors (GCTs) account for the majority of testicular cancers and are highly curable. This chapter primarily discusses GCTs arising in the testicle, dividing this category into seminoma versus nonseminoma germ cell tumors (NSGCTs). In addition, the rare entity of extragonadal GCTs, which can arise in the mediastinum, retroperitoneum, or pineal body, is described.

OVERVIEW OF GERM CELL TUMORS

Epidemiology

The GCTs are the most common new cancer diagnosis in young men. Approximately 9600 new cases were expected to be diagnosed in 2020.[1] Highlighting the high curability of this cancer, GCTs only claimed approximately 440 lives in 2020 and carry a 5-year overall survival (OS) rate of approximately 95%.[1–3] The GCTs have a bimodal age distribution, with most men diagnosed between ages 15 and 25 years. There is a second peak of diagnosis around age 60 years, which largely represents seminoma histology and a lower mortality risk. Lifetime risk for the development of GCTs is approximately 0.5% or 1 in 200.[4]

Worldwide, GCTs are six times more common in developed countries, with the largest incidence reported in Denmark and Switzerland and the lowest in Japan, Finland, and Israel.[4] In the United States, the overall incidence of GCTs appears to be gradually increasing. The incidence has specifically increased among African Americans, with the greatest increase in seminoma histology. This does not appear to be related to screening or earlier diagnosis.[5] White men, although still representing the group most likely to be diagnosed, are more likely to be identified at an earlier stage than in the past.[6]

Risk Factors

Cryptorchidism is one of the few identifiable risk factors for the development of GCTs, representing at most about 10% of cases. When present, cryptorchidism imparts a relative risk between 3.5 and 17.1.[7] This increased risk includes the contralateral testicle, even if descended normally or via orchiopexy. It is unclear if

orchiopexy reduces the lifetime risk of GCTs, although data showing increased incidence even in the contralateral testicle support the theory that the etiology of GCTs lies in abnormal gonadal development rather than anatomic malposition.[8–10] Men with a prior history of GCTs also have an increased risk of GCTs in the contralateral testicle, suggesting a genetic predisposition, although men with a family history of GCTs account for only 1.5% of patients with new diagnosis.[11,12] A personal history of GCT carries an increased lifetime risk of secondary cancers, irrespective of histologic type.[13]

Tumor Biology

The most common genetic abnormality found in GCTs is an isochromosome of the short arm of chromosome 12, which has been identified in approximately 80% of GCTs and is pathognomonic.[14,15] This abnormality can be found in all histologic subtypes except spermatocytic seminoma.[16,17] Molecular characterization of 137 primary testicular GCTs demonstrated high aneuploidy, but somatic mutations are uncommon.[18] The most frequently mutated GCT gene is *KIT*, in which activating mutations are observed in 25% to 30% of seminomas, forming a distinct subtype of seminoma.[18–21] Significant differences in global DNA methylation and microRNA expression between GCT subtypes point to a likely role of epigenetic processes influencing final GCT histology.[18]

Germ cell neoplasia in situ (GCNIS), previously called intratubular germ cell neoplasia, has been identified as the precursor lesion in most GCTs. It is histologically described as atypical germ cells in the seminiferous tubules and is thought to arise from incompletely differentiated primordial germ cells. Such changes are found adjacent to most invasive GCTs, with the notable exception of spermatocytic seminoma.[22] The GCNIS cells express several proto-oncogenic proteins that play a role in tumorigenesis, including the receptor tyrosine kinase CD-117 or *c-kit*, a protein normally involved in germ cell migration and early differentiation.[23,24]

Histologic Classification

GCTs are divided into two types, seminoma and NSGCT, and each represents approximately 50% of all GCTs. Those that show exclusively seminoma histology constitute pure seminomas, and those containing any other histologic pattern are classified as NSGCTs, even if the dominant histologic pattern is seminoma. Thus, the term *seminoma* is used in two very different ways: as a histologic pattern and as a main subdivision of GCTs. NSGCTs can be divided into four main subtypes: embryonal carcinoma, yolk sac tumor, choriocarcinoma, and teratoma. The last can be further classified as mature, immature, or teratoma with malignant transformation. It is common to see more than one histologic subtype within a tumor, and these tumors are termed "mixed GCTs." The biology and clinical expression are dominated by the nonseminoma component, and thus the presence of any histologic component other than seminoma places the tumor in the category of NSGCT. Importantly, the clinical course can be largely inferred from the histology.

Clinical Presentation

Most patients with GCTs present with painless testicular swelling or a nodule. In some cases, testicular swelling can be accompanied by pain secondary to bleeding or infarction within the tumor. In the presence of pain or a history of injury, an appropriate differential diagnosis would include testicular torsion, epididymitis, orchitis, hydrocele, spermatocele, and hematoma. *It is extremely important that regardless of pain or other associated symptoms, all scrotal masses should be approached as if they were malignant*. In patients who present with gynecomastia, especially bilateral, GCTs should be considered.[25] Other symptoms can include fever, weight loss, lumbar back pain, cough, and hemoptysis (most often seen in patients presenting with high-volume disease).

Diagnosis

The importance of prompt diagnosis and treatment cannot be stressed enough because the extent of disease at presentation predicts overall prognosis. Awareness of GCT prevalence among young men is important for both general practitioners and the general public. Radiographic evaluation of a suspected primary should include high-resolution, transscrotal ultrasonography with color Doppler of both testicles, and any suspicious lesion should be definitively evaluated with radical orchiectomy.

Transscrotal biopsy is contraindicated in the diagnostic workup of a suspected testicular neoplasm because this procedure can disrupt regional lymphatics, potentially altering the otherwise-predictable nodal spread. Because the diagnosis of GCTs is rarely in question, the preferred diagnostic and therapeutic procedure for a testicular mass is radical inguinal orchiectomy. If a tissue diagnosis is believed to be necessary before orchiectomy, an open biopsy should be performed via an inguinal incision to allow for proper examination and tissue sampling with minimal risk of inguinal or scrotal contamination.

Serum Tumor Markers

Serum markers, specifically human chorionic gonadotropin (β-hCG), α-fetoprotein (AFP), and lactate dehydrogenase (LDH), have unique diagnostic and

prognostic significance in GCTs. These serum markers assist the clinician with diagnosis of GCTs, staging the patient and determining the optimal treatment based on risk stratification, assessing response to treatment, and monitoring surveillance.

Elevated in pregnancy, β-hCG is not normally detectable in males except in the setting of GCTs. It is the most commonly elevated tumor marker in testicular cancer. With a half-life of 18 to 36 hours, hCG can also be markedly elevated in gestational trophoblastic disease and occasionally in epithelial cancers.[26] It is composed of two subunits, α and β, which exist in multiple isoforms. The α subunit has sequence similarity to the α subunit of thyroid-stimulating hormone (TSH), follicle-stimulating hormone, and luteinizing hormone, which leads to "cross talk" between these hormones and hCG. For this reason, hCG assays measure the β subunit. This "cross talk" can be clinically significant in high-volume disease accompanied by high levels of hCG, where hCG causes hyperthyroidism by binding to the TSH receptor. *Extreme elevation of hCG in male patients should be considered pathognomonic for GCTs and, in selected cases of threatening disease, justifies initiation of therapy even before tissue confirmation.*

Normally produced by the fetal yolk sac, AFP also exists in multiple isoforms. It is elevated in GCT cells derived from the embryological yolk sac, including yolk sac tumor and embryonal carcinoma. AFP elevation is also found in other gastrointestinal (GI) malignancies, particularly hepatocellular carcinoma, as well as in conditions causing liver damage (cirrhosis, hepatitis, and so on). The serum half-life of AFP is approximately 5 to 7 days.[27] By definition, pure seminomas do not produce AFP, and in the setting of GCT, an elevated AFP implies a nonseminomatous histology.[28]

LDH is neither cancer specific nor germ cell specific. LDH concentrations are elevated in 40% to 60% of men with GCTs.[29] Of the LDH isoforms, LDH-1 is most specific for GCTs; however, there is no established routine use for the fractionation of LDH and precise measurement of LDH-1. Total LDH can be used to estimate the prognosis in advanced NSGCT at the time of diagnosis or to detect recurrent disease.[30]

Anatomic Progression

The GCTs follow a distinct pattern of spread and metastasis. The lymphatic drainage from the testicle reflects embryologic origin, and thus the right testicle drains to the interaortocaval lymph nodes, and the left testicle drains to the left paraaortic lymph nodes. These initial nodes of spread are termed the "landing zone." Epididymal lymphatics drain via the external iliac chain and scrotal lymphatics via the pelvic chain; therefore, locally advanced disease (involving the epididymis and scrotum) can present with involvement of these nodal basins. Distant metastasis involves the lungs principally followed by the liver, brain, and bones.

STAGING

Table 47–1 shows the American Joint Commission on Cancer (AJCC) TNM staging of testicular cancer.[31] This system uses primary tumor (T), lymph nodes (N), distant metastases (M), as well as elevated serum tumor markers (S) to categorize patients into prognostic stage groups I to III. It is important to note that for the purposes of staging, postorchiectomy serum tumor markers are used. In general, stage I disease is confined to the testis, stage II disease has nodal metastases confined to the retroperitoneum with markers in the good-prognosis range (S1), and stage III disease includes nodes that extend beyond the retroperitoneum, extranodal metastases, or elevation of tumor markers in the intermediate- or poor-prognosis range (S2–S3).

Fertility Considerations

The preservation of fertility is of particular importance to men with GCTs. Both the diagnosis and treatment of GCTs are associated with impaired fertility. It is recommended that if clinically feasible, the patient be counseled about and offered the opportunity to pursue sperm banking before starting chemotherapy. It is not recommended to delay chemotherapy in symptomatic poor-risk patients because poor physical condition often makes sperm donation difficult or even impossible.[32]

TESTICULAR SEMINOMA

Histology

Under microscopic visualization, classic seminoma has a "fried-egg" appearance, defined as a monotonous proliferation of large, rounded cells arranged in sheets or cords with large, centralized nuclei and nucleoli. These tumors can be difficult to distinguish from lymphoma if there is a background of lymphocytic infiltration. Further confirmation (ie, negativity for lymphocyte markers such as common leukocyte antigen) is often required. Although not specific, seminomas stain positive for placental alkaline phosphatase (PLAP) and are routinely negative for AFP and hCG. Figure 47–1 shows the histological appearance of classic seminoma.

On pathologic examination of the testis, seminoma tends to be a semisolid tumor that readily oozes onto the gross examination table. This

TABLE 47–1 Germ Cell Tumor: The American Joint Commission on Cancer Tumor, Node, Metastasis (TNM) Staging Classification of Testis Cancer

Pathological Primary Tumor (T)	
The extent of primary tumor is usually classified after radical orchiectomy, so a pathologic stage is assigned.	
pTX	Primary tumor cannot be assessed
pT0	No evidence of primary tumor (eg, histologic scar in testis)
pTis	Germ cell neoplasia in situ
pT1	Tumor limited to testis (including rete testis invasion) without lymphovascular invasion
pT2	Tumor limited to the testis (including rete testis invasion) with lymphovascular invasion or Tumor invading hilar soft tissue or epididymis or penetrating visceral mesothelial layer covering the external surface of the tunica albuginea with or without lymphovascular invasion
pT3	Tumor invades spermatic cord soft tissue with or without lymphovascular invasion
pT4	Tumor invades scrotum with or without lymphovascular invasion
Clinical Regional Lymph Nodes (cN)	
cNX	Regional lymph nodes cannot be assessed
cN0	No regional lymph node metastasis
cN1	Metastasis with a lymph node mass ≤2 cm in greatest dimension or multiple lymph nodes, with none >2 cm in greatest dimension
cN2	Metastasis with a lymph node mass >2 cm but not >5 cm in greatest dimension or multiple lymph nodes, with any one mass >2 cm but not >5 cm in greatest dimension
cN3	Metastasis with a lymph node mass >5 cm in greatest dimension
Pathological Regional Lymph Nodes (pN)	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass ≤2 cm in greatest dimension and ≤5 nodes positive, with none >2 cm in greatest dimension
pN2	Metastasis with a lymph node mass >2 cm but not >5 cm in greatest dimension; >5 nodes positive, with none >5 cm; or evidence of extranodal extension of tumor
pN3	Metastasis with a lymph node mass >5 cm in greatest dimension
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonretroperitoneal nodal or pulmonary metastasis
M1b	Nonpulmonary visceral metastases
Serum Tumor Markers (S)	
SX	Marker studies not available or not performed
S0	Marker study levels within normal limits
S1	LDH <1.5 × ULN and
	hCG <5000 mIU/mL and
	AFP <1000 ng/mL

makes the presence of malignant cells on the surface of the spermatic cord and at the margins of resection a ubiquitous finding. Thus, the clinician must be careful not to be unduly influenced by reports of "margin positivity" and "involvement of the spermatic cord" in the pathology report.[33] Figure 47–2 shows the typical gross appearance of seminoma.

Even in the presence of significant metastatic disease, it is not uncommon to find only a scar in the testicle. This phenomenon is known as "burned-out" seminoma and can also occur in NSGCT. The biological basis for this spontaneous regression of the primary is unknown. Seminomas are typically associated with significant lymphocytic infiltration, and metastatic deposits characteristically leave a dense desmoplastic residual mass after treatment, often making them difficult to resect.

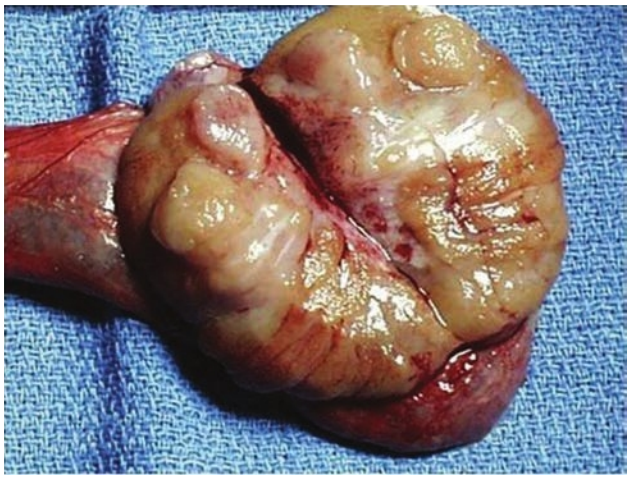

FIGURE 47–2 Gross appearance of seminoma.

Clinical Features

Pure seminoma is the most common GCT of the testicle, accounting for approximately 50% of GCTs. By definition, seminomas have no evidence of a nonseminoma component and do not produce AFP but may have modest elevation of β-hCG. Spermatocytic seminomas, a rare variant comprising only 10% of seminomas, are not associated with GCNIS. These tumors typically occur in men older than 50 years old, in stage I disease, and have a low metastatic rate. This subtype portends an excellent prognosis with resection alone (with or without radiotherapy).[34] Seminomas tend to spread via lymphatics initially, with late hematogenous spread, and are more likely to spread locally, as evidenced by positive margins and involvement of the spermatic cord on histology. The most common hematogenous spread is to the lungs, and metastatic seminomas rarely metastasize to the brain. Remarkably, bulky tumors rapidly respond, with dramatic loss of tumor bulk, but tumor lysis syndrome is never encountered.

Prognosis

The International Germ Cell Cancer Collaborative Group (IGCCCG) established a standard risk classification for both seminomas and NSGCTs (Table 47–2). Patients with metastatic seminoma are divided into either good- or intermediate-risk categories, with no definable "poor-risk" seminoma. The one characteristic that predicted worse outcome for seminoma was the presence of nonpulmonary visceral metastases (intermediate prognosis). The prechemotherapy tumor markers do not predict prognosis (unlike in NSGCTs, discussed further in the chapter). Ninety percent of patients with seminoma fall into the good-risk category, with a 5-year OS of 86%. Patients with seminoma in the intermediate-risk category have a 5-year OS of 72%.[2]

Management of Clinical Stage I Seminoma

Patients with clinical stage I seminoma, representing 70% of patients at diagnosis, have disease confined to the testicle with no evidence of nodal or distant metastasis. Most patients will be cured by radical orchiectomy alone, but approximately 20% recur without adjuvant

TABLE 47–2 International Germ Cell Cancer Collaborative Group Classification Prognostic Risk Stratification

Seminoma	Nonseminoma
Good Risk	
Any primary site	Testis or retroperitoneal primary
and	and
No nonpulmonary visceral metastases	No nonpulmonary visceral metastases
and	and
Normal AFP, any hCG, any LDH	AFP <1000 ng/mL
	hCG <5000 mIU/mL
	LDH <1.5 × ULN
82% 5-year PFS; 86% 5-year OS	89% 5-year PFS; 92% 5-year OS
Intermediate Risk	
Any primary site	Testis or retroperitoneal primary
and	and
Nonpulmonary visceral metastases	No nonpulmonary visceral metastases
and	and
Normal AFP, any hCG, any LDH	AFP 1000–10,000 ng/mL
	hCG 5000–50,000 mIU/mL
	LDH 1.5–10 × ULN
67% 5-year PFS; 72% 5-year OS	75% 5-year PFS; 80% 5-year OS
Poor Risk	
—	Mediastinal primary
	or
—	Nonpulmonary visceral metastases
	or
	AFP >10,000 ng/mL
—	hCG >50,000 mIU/mL
	LDH >10 × ULN
—	41% 5-year PFS; 48% 5-year OS

AFP, α-fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; OS, overall survival PFS, progression-free survival; ULN, upper limit of normal.

intervention. The disease-specific survival rate is nearly 100% with or without adjuvant treatment because patients who recur on surveillance are readily salvaged with standard treatment.

Active Surveillance

The benefits of active surveillance include avoidance of unnecessary treatment in patients who are likely to be already cured by orchiectomy. Mortensen et al[35] reported data on 1954 patients with clinical stage I seminoma managed with surveillance with a median follow-up time of 15 years. In total, 369 patients (19%) relapsed after a median 13.7 months. More than 70% of these patients relapsed during the first 2 years. In a pooled analysis of prognostic factors in 638 patients by Warde et al,[36] tumor size less than 4 cm maximum dimension and without invasion of rete testis had 5-year risk of relapse of only 12%. Patients with both risk factors had a risk of recurrence of 32%, but one of the two risk factors portends a 16% risk of relapse. Because of excellent outcomes of patients later treated for recurrent disease, active surveillance is considered a reasonable option for most patients, including those with both risk factors.

Radiotherapy

The recurrence rate after prophylactic radiotherapy for clinical stage I seminoma is about 4%, and most of those patients who recur after radiation survive with additional treatment (chemotherapy).[37] Treatment of paraaortic lymph nodes to a dose of 20 Gy was associated with excellent local control approaching 100%. A randomized trial of 20 Gy versus 30 Gy showed no difference in rate of recurrence.[38] Omission of ipsilateral iliac lymph nodes from the treatment field resulted in less toxicity (infertility, GI effects) and minimal loss of efficacy. Radiotherapy is contraindicated for patients with horseshoe kidney or inflammatory bowel disease.

Radiotherapy was once viewed favorably because it reduced the number of computed tomography (CT) scans that were necessary for follow-up, with a net reduction in the cost of treatment. There is, however, a risk of second malignant neoplasms related to treatment. Studies of testicular cancer survivors 25 or more years after treatment have revealed an increase in midline cancers, such as GI (colon, stomach, pancreas) and genitourinary (bladder, kidney) malignancies.[39,40] This added risk has brought about a reassessment of whether radiotherapy is warranted, especially considering that 80% of patients with clinical stage I seminoma will be treated unnecessarily, and that there is no survival benefit. At MD Anderson Cancer Center (MDACC), we no longer offer prophylactic radiation to men with stage I testicular seminoma.

Chemotherapy

A randomized controlled trial was conducted to compare a single infusion of carboplatin, with dose based on area under the curve of 7 versus radiotherapy for the adjuvant treatment of clinical stage I seminoma.[41] The median follow-up period was 6.5 years, and the relapse-free survival was similar in both treatment arms, 94.7% and 96.0%, respectively, showing noninferiority of the one cycle of single-agent carboplatin.[42] There are limited data comparing the long-term safety of carboplatin with that of radiotherapy, leading many practitioners to adopt surveillance as the preferred option. Figure 47–3 outlines an approach to therapy for stage I seminoma.

Management of Nonbulky, Good-Risk Seminoma (Stages IIA and IIB)

Patients with stage II seminoma are often divided into those with nonbulky versus bulky disease for treatment discussion. In general, nonbulky disease is defined as nodes less than 5 cm in cross-sectional dimension on CT or magnetic resonance imaging at MDACC. The primary mode of therapy for patients in this category is radiotherapy unless the patient has a contraindication or is unable to tolerate radiation treatment.

Radiotherapy

It is no longer recommended that patients with stages IIA and IIB seminoma receive high-dose radiation (30–35 Gy), mediastinal radiation, or left supraclavicular radiation. At MDACC, our current approach is to give 20 Gy to the paraaortic and ipsilateral iliac nodal fields with a 6-Gy boost to the paraaortic lymph nodes for patients with lymph nodes less than 3 cm.[43] For patients with lymph nodes greater than 3 cm but less than 5 cm, the MDACC approach is to give 20 Gy followed by a 10-Gy boost. Occasionally, radiographic evidence for residual disease is present postradiotherapy, but if the abnormality is less than 3 cm, observation is recommended.

Alternatives to Radiotherapy

A subset of patients exists who will not be able to receive radiation therapy for various reasons. These reasons may include patient refusal, inflammatory bowel disease, horseshoe or pelvic kidney, and history of abdominal surgery. In this setting, systemic chemotherapy could be offered. In a series published by Xiao et al,[44] patients with good-risk seminoma were included in the analysis and were treated with four cycles of etoposide and cisplatin (EP). Although this likely is overtreatment for stages IIA and IIB seminoma, it is a reasonable option for patients who

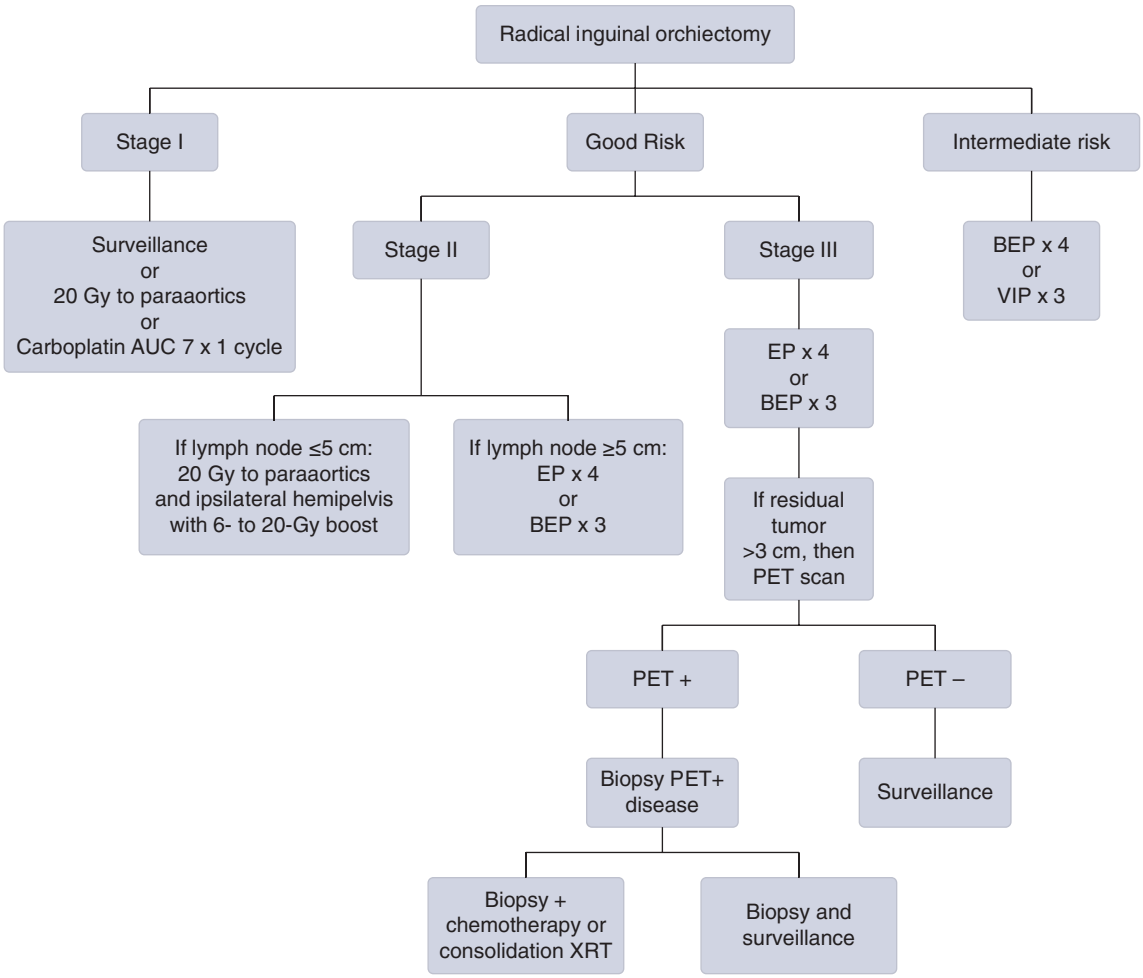

FIGURE 47–3 **Management of testicular cancer (seminoma). AUC, area under curve; BEP, bleomycin, etoposide, and cisplatin; EP, etoposide and cisplatin; PET, positron emission tomography; VIP, etoposide, ifosfamide, and cisplatin; XRT, radiation therapy.**

absolutely cannot receive radiation therapy. Alternatively, participation in a clinical trial investigating utility of laparoscopic retroperitoneal lymph node dissection as first-line treatment could be offered.

Management of Advanced, Good-Risk Seminoma (Stages IIC and III)

This treatment group includes patients with stage II with bulky lymphadenopathy (≥5 cm) and patients with stage III with good-risk disease. In this group of patients, the risk of recurrence remains high despite local therapy; therefore, the primary treatment recommendation is systemic chemotherapy.

Chemotherapy

The recommended systemic chemotherapy regimen for patients with good-risk advanced seminoma (stage IIC or III) is three cycles of bleomycin, etoposide, and cisplatin (BEP) or its equivalent. The evidence for use of three cycles of BEP versus four cycles was presented by de Wit et al.[45] These investigators showed that three cycles of BEP are equivalent to four cycles, with 2-year progression-free survival (PFS) of 90.4% and 89.4%, respectively.[45] Alternatively, patients who are unable or refuse to receive bleomycin or are older than 50 years can be successfully treated with four cycles of EP.

Residual Disease After Chemotherapy and the Role of Positron Emission Tomography

After completion of chemotherapy, restaging CT scans are performed. If a patient is found to have residual mass measuring 3 cm or less in size with normal tumor markers, active surveillance should be pursued. After chemotherapy, residual disease measuring greater than 3 cm can be further evaluated by positron emission tomography (PET) imaging. Evidence for the role of PET imaging in the setting of residual disease greater than 3 cm comes from the multicenter SEMPET study by De Santis et al.[46,47] In this evaluation of 56 patients with a median

follow-up time of 34 months, the positive predictive value of fluorodeoxyglucose (FDG) PET was 100%, with specificity and sensitivity of 100% and 80%, respectively, for the identification of residual disease in lesions larger than 3 cm. Since publication of the SEMPET study, there have been several conflicting studies with reported positive predictive value of PET ranging from 29% to 70%.[48–50]

Positron Emission Tomography–Negative Disease Postchemotherapy

If there is no evidence of avid uptake on PET after chemotherapy, the patient enters the active surveillance strategy. The negative predictive value of PET is greater than 90%.[47–49] If the patient is unable to have PET imaging, surgical biopsy can be considered for patients with residual disease measuring larger than 3 cm.

Positron Emission Tomography–Positive Disease Postchemotherapy

At MDACC, a positive PET scan result requires a confirmatory biopsy or resection of residual mass. If patient has a positive PET scan result in a location that is not amenable to biopsy, this is typically monitored at MDACC. If viable seminoma is confirmed with biopsy, several options can be considered. First, salvage radiation therapy to the residual mass can be offered, especially for smaller masses as seminomas may be more radiation sensitive than chemosensitive. Second, the patient can be offered salvage chemotherapy. Finally, the patient may undergo high-dose chemotherapy with autologous stem cell transplantation. See Figure 47–3 for the algorithm of our management strategy.

Management of Advanced, Intermediate-Risk Seminoma (Stage III)

Patients with stage III intermediate-risk seminoma have nonpulmonary visceral metastasis. The most common sites of disease are the liver and bone. These rare patients are offered systemic chemotherapy on presentation (see Fig. 47–3) with four cycles of BEP or four cycles of etoposide, ifosfamide, and cisplatin (VIP).

Salvage Therapy for Refractory or Recurrent Seminoma

The primary treatment for patients with recurrence after radiotherapy is salvage chemotherapy with treatment dictated by risk status. For patients with lung metastasis (good-risk category), the standard of care is administration of either three cycles of BEP or four cycles of EP. In patients with bone or liver metastasis (intermediate-risk category), salvage chemotherapy is pursued with four cycles of BEP or VIP.[51] Bleomycin should be avoided in men older than 50 years.

Clinical signs of chemotherapy-refractory disease should be approached with an aggressive change of strategy, including salvage chemotherapy and the option of high-dose chemotherapy with stem cell transplantation. These patients should be encouraged to enroll in a clinical trial if available, such as the ongoing TIGER trial, which randomizes patients to TIP or high-dose chemotherapy with autologous stem cell transplant.[52] Salvage TIP, Paclitaxel, Ifosfamide, Cisplatin is an option that can produce durable complete responses.[53] Usually reserved for BEP failures, the role of stem cell transplantation in refractory or recurrent advanced seminoma was addressed by Einhorn et al.[54] Nineteen percent of a series of 184 patients were patients with metastatic testicular seminoma. At a median follow-up period of 48 months, 26 of 35 patients with seminoma treated were in complete remission. Patients with relapsed refractory seminoma should be considered for referral to transplant centers if possible.

NONSEMINOMATOUS GERM CELL TUMORS

Histology

Embryonal Carcinoma

Embryonal carcinoma is the second most common pure presentation of GCT, accounting for approximately 2% of all testicular GCTs. It is a component of approximately 85% of all mixed GCTs.[55] It is rarely seen at the extremes of age, most commonly presenting in the 20- to 30-year age group, and presents with metastasis in one third of cases. Microscopically, embryonal carcinoma cells are the most undifferentiated of the

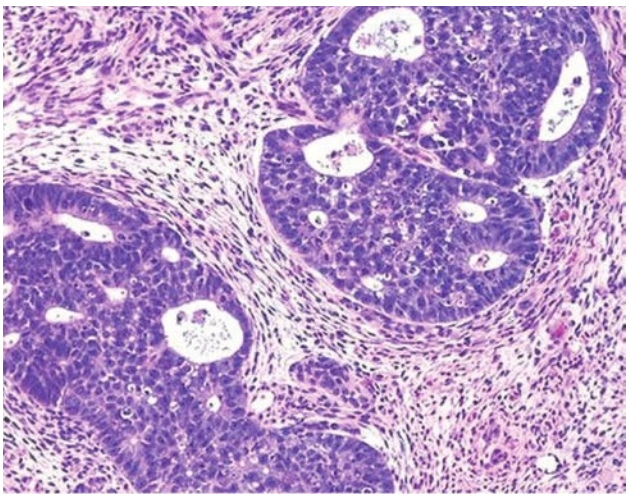

FIGURE 47–5 Histologic appearance of embryonal carcinoma.

Case 47–1: Seminoma Presenting with Renal Insufficiency

A 37-year-old man had a left inguinal orchiectomy for classic seminoma. Laboratory data at presentation to MDACC revealed serum creatinine of 1.8 mg/dL, calcium of 12.7 mg/dL, hemoglobin of 10.5 g/dL, human chorionic gonadotropin (hCG) of 113 mIU/mL, alkaline phosphatase of 194 IU/L, and lactate dehydrogenase (LDH) of 1773 IU/L (upper limit of normal, 618 IU/L). A computed tomography scan of the abdomen and pelvis revealed a large retroperitoneal mass with marked left hydronephrosis (Fig. 47–4A). The patient initially received one cycle of cyclophosphamide and carboplatin. Repeat laboratory data revealed serum creatinine of 1.1 mg/dL, calcium of 8.2 mg/dL, LDH of 483 IU/L, and undetectable hCG. He subsequently received three full cycles of etoposide and cisplatin (EP) with an excellent response. Repeat imaging shown in Figure 47–4B revealed marked improvement in the size of the mass (from 14 to 7 cm). Post-chemotherapy positron emission tomography imaging showed the residual mass to be metabolically inactive.

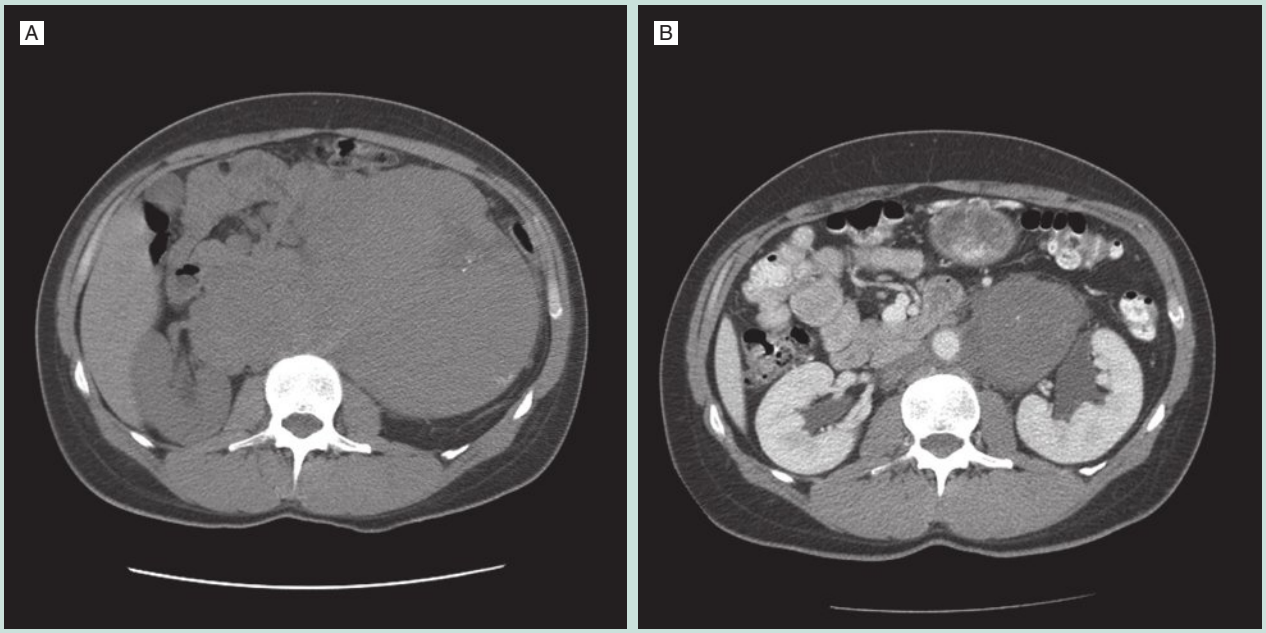

FIGURE 47–4 **A. Baseline imaging from the patient in Case 47–1 showing a large left retroperitoneal mass with left hydronephrosis. B. Repeat imaging from the patient in Case 47–1 showing marked improvement in mass after three cycles of chemotherapy.**

Comment: A patient with advanced seminoma presenting with hydronephrosis and renal insufficiency may receive induction chemotherapy with cyclophosphamide and carboplatin rather than placing nephrostomy tubes to allow administration of bleomycin, etoposide, and cisplatin (BEP) or EP in the first cycle. The patient can subsequently receive standard therapy after normalization of renal function.

GCT types and are characterized by pleomorphic cells with indistinct borders and scant cytoplasm, giving the appearance of overlapping nuclei. Tumor cells can be seen in sheets or arranged as papillary or tubular structures with a high mitotic rate. There is a propensity for vascular invasion. Phenotypic characterization can reveal positivity for cytokeratin, CD30, PLAP, OCT3/4, SOX2, AFP, and hCG. Modest elevations of both AFP and hCG are typical, but importantly, pure embryonal cancers can be marker negative in the serum. Figure 47–5 shows the typical histologic appearance of embryonal carcinoma.

Yolk Sac Tumors (or Endodermal Sinus Tumors)

Pure yolk sac tumors are extremely rare in adult patients but account for the majority of childhood GCTs. In adults, yolk sac elements are commonly seen as a component of mixed NSGCTs. Microscopically, yolk sac tumors are the most variable of GCTs and can manifest as macrocystic, papillary, solid, or a glandular and alveolar pattern with perivascular arrangements of epithelial cells known as glomeruloid or Schiller-Duval bodies. Very high serum AFP levels generally reflect the presence of a yolk sac component,

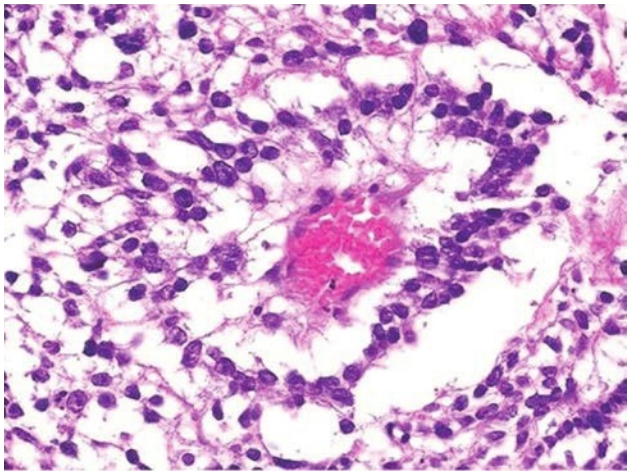

FIGURE 47–6 Histologic appearance of yolk sac tumor.

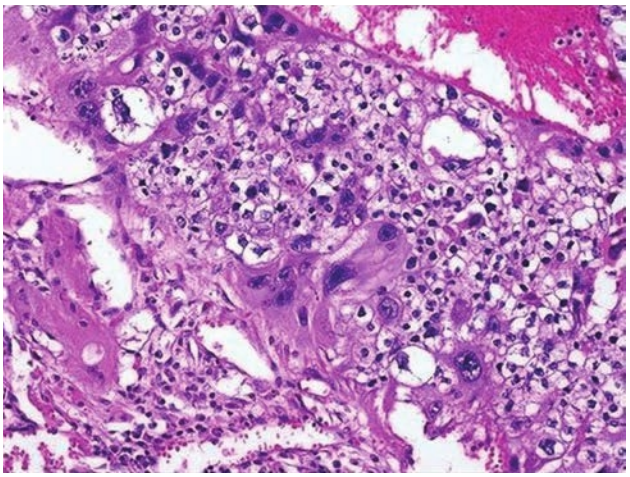

FIGURE 47–7 Histologic appearance of choriocarcinoma.

and serum levels of AFP immediately before the start of chemotherapy are important prognostically in the classification of good- (AFP <1000 ng/mL), intermediate- (1000-10,000 ng/mL), and poor-risk (>10,000 ng/mL) metastatic NSGCTs. Figure 47–6 shows the typical histologic appearance of a yolk sac tumor.

Choriocarcinoma

Also rare in the pure form in the adult population, choriocarcinoma frequently presents as a component of mixed NSGCTs. Choriocarcinomas comprise both syncytiotrophoblasts and cytotrophoblasts, typically arranged in sheets or nests. They are characterized by areas of hemorrhage and necrosis. Choriocarcinomas generally make copious amounts of hCG, and the level of this marker is also an indication of prognosis in metastatic NSGCTs. Levels of hCG greater than 50,000 mIU/mL are a marker of poor-prognosis NSGCT and are typical of metastatic choriocarcinoma. Half of choriocarcinomas are PLAP positive. Choriocarcinoma elements tend to dominate the clinical course and frequently metastasize to the brain. Symptoms of hyperthyroidism are common, owing to stimulation of the TSH receptor by hCG, and treatment such as a β-blocker is indicated while chemotherapy is initiated. Figure 47–7 shows the typical histologic appearance of choriocarcinoma.

Teratoma

Teratomas possess somatic cells from at least two germ cell layers (ectoderm, endoderm, and mesoderm). Variable degrees of differentiation allow for the subclassification of mature and immature forms. A mature teratoma consists of terminally differentiated tissues and can form cystic structures. Although histologically bland, this low-grade malignancy can grow to a threatening dimension and become unresectable. Only about 2% to 3% of all GCTs show mature teratoma as the only histologic component, but teratoma is commonly present as an element of a mixed GCT. A man presenting with teratoma as the only histologic pattern should be presumed to have a mixed GCT and be treated as such. An immature teratoma is less differentiated, although this distinction has no known clinical significance.

One of the unfortunate manifestations is somatic transformation or the development of somatic (non-GCT) malignancy within a teratoma. Sometimes known as "teratoma with malignant transformation," this entity typically displays the biology of whatever histology develops and can range from leukemias to sarcomas to carcinomas. In general, transformation to somatic malignancy carries a poor prognosis, and the best prevention is to surgically remove all residual teratoma whenever possible.[56] Figures 47–8 and 47–9 represent the typical histological and gross appearance of teratoma, respectively.

Clinical Features

As described previously, approximately half of testicular GCTs show histologic elements other than seminoma or produce serum elevation of AFP indicating nonseminoma. These cancers are collectively known as mixed GCTs or NSGCTs, and they form a group of histologically and clinically diverse cancers.[57] The NSGCTs are more likely than seminomas to spread hematogenously with increased risk of distant metastasis. Because of the unique and heterogeneous nature of NSGCTs, several clinical presentations warrant further discussion because of their significance to patient care and prognosis.

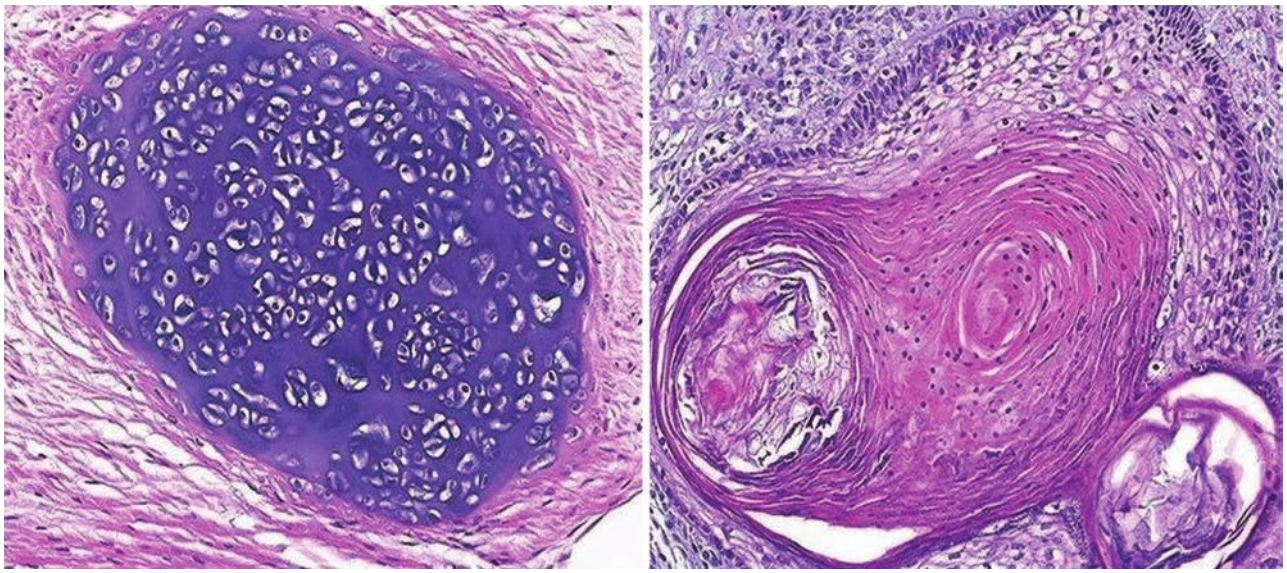

FIGURE 47–8 Histologic appearance of teratoma.

Growing Teratoma Syndrome

Residual teratoma is a low-grade, slow-growing malignancy that can be fatal by inexorable growth. This can take 10 or even 20 years to become threatening and thus can be missed without dedicated lifelong follow-up of patients with NSGCTs. Serum tumor markers are often normal in these patients. One of the most remarkable and clinically important features of teratomas is that they are often "pushing" and rarely invasive. Thus, at surgery, even very large masses are sometimes removed far more easily than would be expected on the basis of the preoperative imaging. It is important to consult a center where sufficient surgical experience is available before concluding that a residual teratoma is "unresectable."[58,59]

FIGURE 47–9 Gross appearance of teratoma.

Choriocarcinoma Syndrome

As the name implies, choriocarcinoma syndrome is seen in the setting of high-volume NSGCT that shows predominantly choriocarcinoma histology and is associated with very high (in some cases >1 million mIU/mL) levels of β-hCG. This syndrome is characterized by prominent constitutional symptoms that represent the effects of both a bulky cancer and secondary hyperthyroidism caused by cross-reaction of hCG with TSH receptors. Typically, patients are rapidly losing weight, tachycardic, anxious, and diaphoretic and have tender gynecomastia from secondary hyperprolactinemia. In addition, most patients have high-volume lung metastases with impending respiratory compromise from the burden of pulmonary metastasis. Hemorrhage can occur at any metastatic site. This is a medical emergency, and treatment should not be delayed for histologic confirmation because this is a pathognomonic constellation in a young man. Metastatic choriocarcinoma has a propensity for brain metastasis, although this is not always apparent on baseline imaging. At MDACC, low-dose induction chemotherapy is given first as fatal bleeding has been described with full-dose chemotherapy. In addition, several institutions have proposed using induction bleomycin, vincristine, and cisplatin (BOP) at low doses, which does not seem to compromise survival outcomes.[60,61] However, there are limited data on how to optimally administer induction chemotherapy.[62]

Prognosis

As described for seminoma, the IGCCCG developed a prognostic staging system for NSGCTs, with

extrapulmonary visceral metastasis found as a major factor in prognosis. Unlike seminoma, prechemotherapy tumor markers were identified as significant in the prognosis of these patients.[2] The prognostic categories are outlined in Table 47–2. In general, patients with mediastinal primary, nonpulmonary visceral metastasis and "poor-risk markers" as defined in the table are considered to have a poor prognosis and have a 5-year OS of 48% with standard treatment. Patients with testis or retroperitoneal primary and no extrapulmonary visceral metastasis are placed in the good-prognosis category based on tumor marker levels as described in the table. Patients with a good prognosis have a 5-year OS of 92%. All others are placed in the intermediate-risk group and have a 5-year OS of 80%.[2] Van Dijk et al[3] updated the 5-year OS data for NSGCTs in a pooled meta-analysis. The authors reported a 5-year OS of 94% for good prognosis, 83% for intermediate prognosis, and 71% for poor prognosis. This illustrates the improving survival rates in the high-risk group.

Management of Clinical Stage I Nonseminomatous Germ Cell Tumors

In general, individuals with clinical stage I NSGCT include patients with normal markers postorchiectomy and no evidence of disease outside the resected testis, epididymis, or cord. As with seminoma, radical inguinal orchiectomy is the initial therapy for early-stage NSGCT. Appropriate surgery will cure approximately 70% of patients in clinical stage I. The two identified risk factors in these patients include percentage of embryonal carcinoma histology and presence of lymphovascular invasion (LVI), with LVI the most predictive.[63] Patients are considered low risk for recurrence postorchiectomy if there is less than 50% embryonal component in the tumor and no evidence of LVI. The role of percentage of embryonal component is debatable because it is often seen together with LVI. In fact, European guidelines use only absence of LVI for determination of "low risk" for recommendation of observation.[64] Patients with either of these risk factors seem to have approximately 40% to 50% risk of recurrence.[65–67]

Observation

Observation is a reasonable strategy for the reliable low-risk patient, which in practice can be those with absence of LVI. The active surveillance schedule as outlined by the National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology recommends that patients should have a physical examination and tumor marker measurements every 2 months during the first year, every 3 months during the second year, and every 4 to 6 months during the third year. Chest radiography is recommended at 4 and 12 months and then annually. Abdominal and pelvic CT is recommended approximately every 4 to 6 months during the first year, every 6 months during the second year, and annually for year 3.[68]

Observation is also acceptable for high-risk patients. The NCCN guidelines recommend more frequent imaging, with chest radiography every 2 months in the first year, every 3 months in the second year, and every 4 to 6 months in the third year. Also recommended are abdominal and pelvic CT every 4 months in the first year, every 4 to 6 months in the second year, and every 6 months in the third year.

Retroperitoneal Lymph Node Dissection

Retroperitoneal lymph node dissection (RPLND) is a surgical removal of the "landing zone" lymph nodes and is an accurate staging strategy. However, its role in primary prevention of recurrence in patients with stage I NSGCT is controversial. RPLND may be a reasonable option for patients with a teratoma-predominant tumor who are not comfortable with active surveillance and decline chemotherapy. Morbidity of RPLND includes sympathetic nerve damage that may lead to failure of ejaculation and infertility; however, use of a modified surgical template is a nerve-sparing approach that can preserve the sympathetic nerves and may facilitate anterograde ejaculation in 90% or more patients. RPLND (especially laparoscopic) should only be performed in high-volume centers to minimize morbidity. Stephenson et al[69] reported that RPLND in patients with clinical stage I yielded a 4-year progression-free probability of 96% and is an option for therapy in this patient population. Higher failure rates have been reported for patients with high-risk clinical stage I NSGCT. Patients who do not undergo prophylactic RPLND must undergo periodic CT scanning of the abdomen to rule out growing teratoma in the retroperitoneum.

Chemotherapy

Adjuvant chemotherapy for clinical stage I NSGCT consists of one or two cycles of BEP. In a randomized controlled trial, Albers et al,[70] in the German Testicular Cancer Study Group, compared RPLND with one cycle of BEP in 382 patients with a median follow-up period of 4.7 years. The 2-year recurrence-free survival rates were 99.46% in the chemotherapy group and 91.87% in the RPLND group, suggesting an advantage of one cycle of BEP chemotherapy. Tandstad et al,[71] in the Swedish and Norwegian Testicular Cancer Project (SWENOTECA) study, reported that one cycle of BEP reduced the risk of recurrence by 90% in patients with or without LVI. In practice, adjuvant chemotherapy should only be offered to patients with either LVI, embryonal carcinoma-predominant tumor, or both.

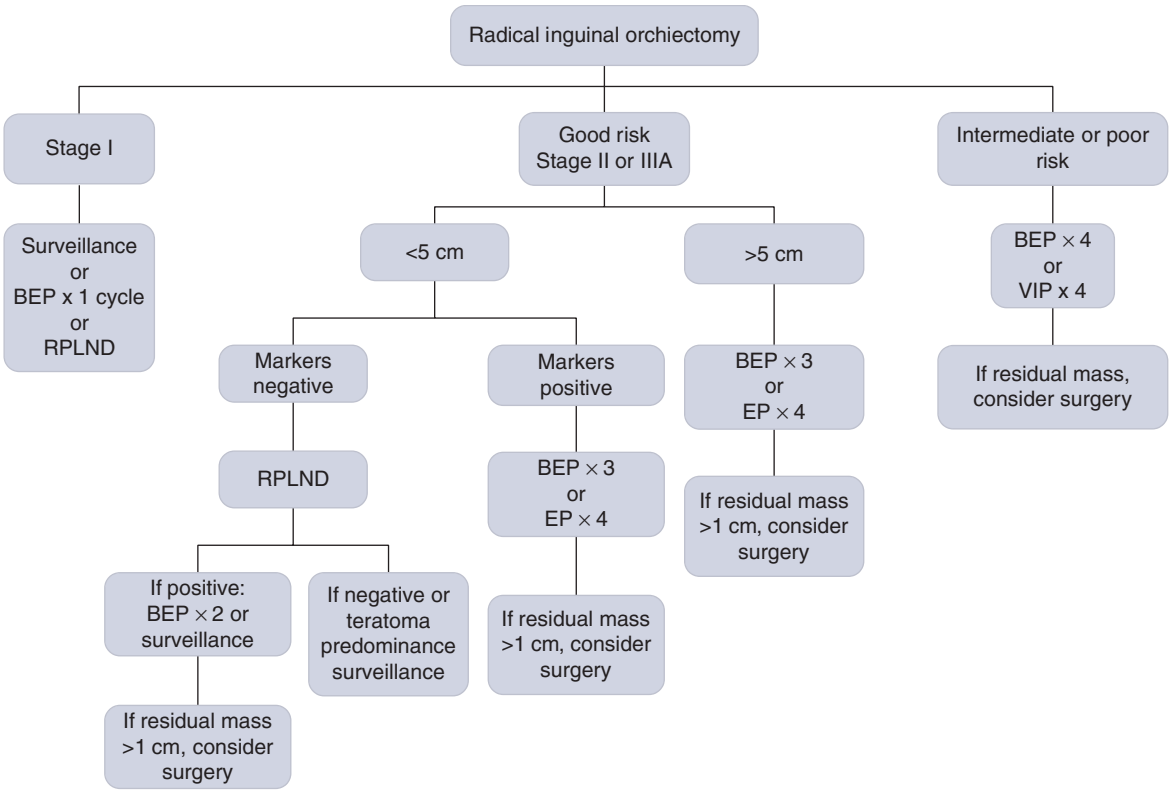

FIGURE 47–10 **Management of testicular cancer (nonseminoma). BEP, bleomycin, etoposide, and cisplatin; EP, etoposide and cisplatin; RPLND, retroperitoneal lymph node dissection; VIP, etoposide, ifosfamide, and cisplatin.**

Our algorithm for management of nonseminoma testicular cancer is shown in Figure 47–10.

Management of Clinical Stage IS Nonseminoma Germ Cell Tumors

Controversy exists regarding the optimal management strategy for clinical stage IS NSGCTs, which are stage I NSGCTs with persistent elevation of serum tumor markers after orchiectomy despite negative radiographic evidence of metastases. Current NCCN guidelines recommend treating these tumors like stage II and III tumors with immediate adjuvant chemotherapy with three cycles of BEP or four cycles of EP. These recommendations are based on small observational reports, and thus this practice remains controversial.[72–74] In a recent evaluation of stage IS patients with NSGCT in the National Cancer Database (NCDB) between 2004 and 2012, approximately 47% of the 781 patients received adjuvant therapy, and the remaining patients were placed on observation.[75] Of the patients who received adjuvant therapy, 80% were treated with chemotherapy, and 20% were treated with RPLND. The authors concluded there was no statistical difference in 5-year OS between the adjuvant therapy and observation cohorts, likely reflecting the high salvage rates with cisplatin-based chemotherapy in those patients initially observed. It is important to note that these data are retrospective and should be interpreted cautiously. At MDACC, patients with clinical stage IS are treated with adjuvant chemotherapy typically with three cycles of BEP, though this likely represents overtreatment.

Management of Good-Risk Clinical Stages IIA and IIB Nonseminoma Germ Cell Tumors

Patients with tumor marker-negative stages IIA or IIB NSGCTs present a unique clinical situation. Treatment options include primary RPLND or chemotherapy consisting of BEP for three cycles or EP for four cycles. At our institution, primary RPLND is favored for stage IIA patients. Patients with pathologic N1 (pN1) disease (see Table 47–1) have a relapse rate of 10% to 20%, and thus surveillance is generally favored if the patient is reliable.[76] The relapse rate for patients with pathologic N2 (pN2) disease is much higher; therefore, adjuvant chemotherapy with two cycles of EP is recommended. Inclusion of bleomycin in this setting is not necessary.[77] In addition, patients with exclusively teratoma

involvement in lymph nodes are observed given their observed resistance to chemotherapy. Patients with elevated serum tumor markers or retroperitoneal mass larger than 2 cm are typically treated with primary chemotherapy with BEP for three cycles or EP for four cycles. If residual mass greater than 1 cm is detected on follow-up staging, surgical resection is recommended.

Management of Good-Risk Stages IIC and III Nonseminoma Germ Cell Tumors

Patients with bulky retroperitoneal disease of greater than 5 cm or pulmonary metastasis with relatively low serum markers constitute those with advanced disease but still with a favorable prognosis. These patients may have either stage IIC or IIIA disease according to the AJCC criteria and are considered together in this discussion. The primary mode of treatment in this patient population is systemic chemotherapy. This may be administered before or after radical orchiectomy as long as surgical resection of the primary is performed after completion of therapy. Again, three cycles of BEP chemotherapy are considered standard of care, and four cycles of EP are considered a reasonable alternative for patients with a contraindication to receive bleomycin. Resection of residual disease present on restaging should be performed.

Pathology of the resected tumor after salvage chemotherapy is different from after primary chemotherapy. After primary chemotherapy, viable GCT, fibrosis, and teratoma are found in approximately 20%, 40%, and 40% of pathological specimens, respectively, compared with 50%, 10%, and 40% after salvage chemotherapy, respectively.[78,79] Patients with greater than 10% viable GCT in the residual pathology specimen after primary chemotherapy should receive an additional two cycles of platinum-based chemotherapy (see Fig. 47–10) based on NCCN recommendations.[68] However, it is unclear whether additional chemotherapy provides a survival advantage, and some experts may opt for surveillance, especially if microscopic disease was present.[80,81]

Management of Intermediate- and Poor-Risk Advanced-Stage IIIB and IIIC Nonseminoma Germ Cell Tumors

Patients with advanced NSGCTs who present with intermediate- or poor-risk features are managed with systemic chemotherapy consisting of four cycles of BEP or VIP. In selected cases, the treatment may be started based on clinical diagnosis before radical orchiectomy. We consider VIP for patients who are not candidates for bleomycin, such as those with underlying lung disease. Patients with persistent elevation of tumor markers after four courses of first-line chemotherapy in most cases should go on to receive salvage chemotherapy or high-dose chemotherapy with autologous stem cell transplantation.

Personalized Strategy Based on Tumor Marker Decline

Failure of either AFP or hCG to normalize is a well-recognized feature of chemotherapy resistance.[82] The rate of tumor marker decline has also been studied as a predictor of poor outcome. For patients presenting with stage IIIC NSGCT, it is possible to identify a subgroup of about 25% who, based on favorable marker decline, will do comparatively well and a larger group of about 75% whose outcome with standard therapy is poor.[83] This observation led to a phase III clinical trial in which patients with stage IIIC NSGCT received BEP in the first cycle, and at completion of the first cycle, those with normalization or favorable decline in both tumor markers remained on BEP (four courses total), and the rest were randomized (1:1) to BEP or an intensified regimen. Final results of this study confirmed superior PFS and OS in the group with favorable decline compared with unfavorable decline (treated with BEP) and demonstrated a statistically significant improvement in 3-year PFS for patients randomized to intensified treatment versus BEP.[84] However, intensified regimens have not shown improvement in OS and thus are not considered standard of care.

Management of Recurrent and Refractory Nonseminoma Germ Cell Tumors

Several chemotherapy regimens with clinical activity in the salvage setting have been reported, and these include VIP, TIP, VeIP (vinblastine, ifosfamide, and cisplatin), or gemcitabine–oxaliplatin. In general, many patients respond, and some are even cured with salvage chemotherapy and surgical consolidation, especially those with a small or moderate volume of disease. There is clinical equipoise regarding high-dose chemotherapy with autologous stem cell transplant versus conventional-dose chemotherapy in the salvage setting.[85–88] If possible, relapsed or refractory patients should be enrolled in the ongoing phase III TIGER trial, which randomizes patients to TIP or high-dose chemotherapy with autologous stem cell transplant.[52]

High-Dose Chemotherapy

High-dose induction chemotherapy with autologous peripheral-blood stem cell transplantation has been

studied in first recurrence and later recurrence of GCT.[54] Einhorn et al[89] retrospectively reviewed 365 patients (285 patients with advanced NSGCT) with a median follow-up period of 3.3 years. Patients with advanced NSGCT treated with high-dose chemotherapy and subsequent autologous stem cell transplantation had 2-year PFS rate of 52%. The authors advocated the use of this aggressive treatment as second-line therapy, suggesting that it is more advantageous than when it is used in the third-line setting. Based on this study and despite the absence of a randomized trial, patients with recurrent or refractory advanced-stage NSGCT may be considered for this aggressive, yet effective, treatment strategy.

Special Considerations

Pitfalls in Tumor Marker Elevation

Mild elevation of β-hCG (usually <20 mIU/mL) may occur secondary to hypogonadism or marijuana use and therefore should not always be attributed to residual or recurrent tumor. It is also possible to have β-hCG entrapped or sequestered in necrotic tumor after chemotherapy.[90] Modest elevation of AFP may be present with residual teratoma and normalizes after surgical resection, but it may also be constitutionally elevated or indicate the presence of liver disease. In addition, elevated tumor markers may indicate unidentified central nervous system disease or residual primary testicular tumor (sanctuary sites).

Role of Desperation Surgery

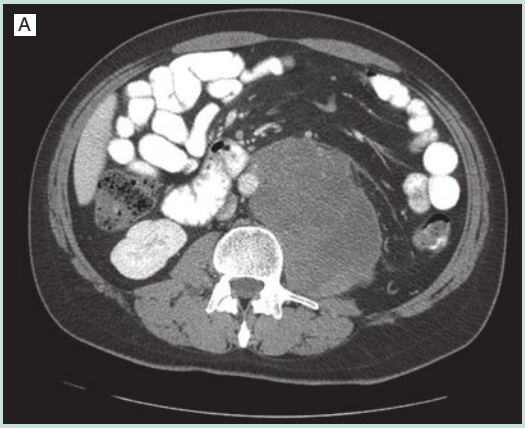
Some patients with NSGCTs have rising tumor markers despite optimal systemic therapy. In these instances, "desperation surgery" to resect all visible disease may be the only option. It is estimated that up to 20% of patients who fit these criteria can be cured with surgical resection. Patients with isolated retroperitoneal lymph node disease, those with AFP-only elevation, and those who undergo a complete resection of residual disease have the most favorable outcomes.[91,92] Referral to a center with high surgical expertise in this setting is recommended because potentially large en bloc resections may be required to achieve the desired outcome of complete resection.

Treatment of Late Relapse

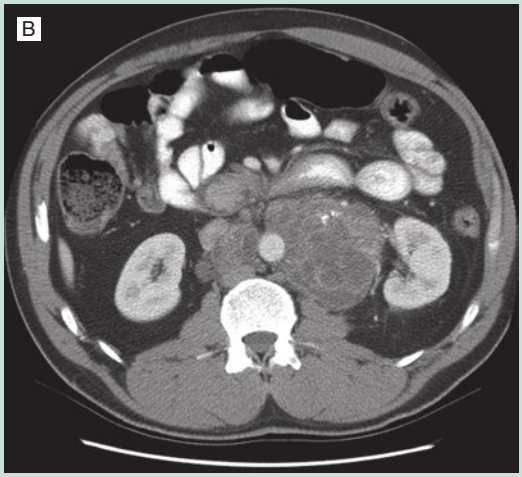
Late relapse is defined as disease recurrence after 24 months from chemotherapy treatment. Teratoma and embryonal carcinoma are the most common histologies in this setting, with pure teratoma conferring a better prognosis. Surgery is the preferred initial treatment in these cases if the tumor is anatomically resectable.

Case 47–2: The Challenge of Managing Intercurrent Illness

A 35-year-old man who was a heavy smoker and marijuana user underwent a left orchiectomy for a 3.5-cm mixed nonseminoma germ cell tumors (NSGCT) and presented 2 months later to MDACC with left groin pain and left thigh numbness. Tumor markers were α-fetoprotein (AFP), 6575; human chorionic gonadotropin, 1059; and lactate dehydrogenase, 2441. Computed tomography scans revealed bilateral lung nodules, a large (14.7-cm) retroperitoneal mass, left hydronephrosis, and multiple other enlarged abdominal and pelvic lymph nodes. During the first bleomycin, etoposide, and cisplatin (BEP) chemotherapy cycle, he had an inferior myocardial infarction (MI) secondary to an occluding atherosclerotic plaque in the right coronary artery. After coronary stenting and optimal medical therapy, the patient was able to complete four cycles of BEP on schedule and at full dose, without delay or significant complications, except for moderate peripheral neuropathy. His tumor markers declined as follows:



- s/p cycle 1 AFP = 3,853 ng/mL, hCG = 34.7 mIU/mL
- s/p cycle 2 AFP = 542 ng/mL, hCG = 5.2 mIU/mL
- s/p cycle 3 AFP = 88.1 ng/mL, hCG = 4.6 mIU/mL
- s/p cycle 4 AFP = 42 ng/mL, hCG = 4.7 mIU/mL



The patient received intramuscular testosterone injection for a low serum testosterone level, and 3 weeks later, serum hCG was less than 1.0 mIU/mL. Six months after his MI, the patient had resection of the large left retroperitoneal mass, left kidney, left adrenal gland, segmental resection of the left psoas muscle, as well as retroperitoneal lymph node dissection . Pathology of the specimen revealed 98% necrosis and only two microscopic foci of residual viable yolk sac tumor in transition to adenocarcinoma. The patient has been recurrence free for 3 years.

Comments: This case illustrates three points. The first is the importance of pursuing chemotherapy while managing an intercurrent illness. The second point is to remember that there are causes of elevated tumor markers other than tumor. The third point is that we do not treat foci of malignant transformation of teratoma.

Case 47–3: Desperation Surgery

A 46-year-old man presented with back pain and was found to have an 11-cm retroperitoneal mass, biopsy of which revealed high-grade germ cell tumor (GCT) (Fig. 47–11A). He underwent a left radical orchiectomy for a 2.8-cm mixed GCT (99% seminoma, 1% teratoma). Postoperatively, serum α-fetoprotein (AFP) was greater than 10,000 ng/mL. He received six cycles of etoposide and cisplatin (EP) followed by one cycle of vinblastine, ifosfamide, cisplatin (VeIP) but never achieved tumor marker normalization (Fig. 47–11B). At presentation to MDACC, his serum AFP was 604 ng/mL. The patient received multiple additional cycles of rotating salvage chemotherapy, including actinomycin-D, cyclophosphamide, and etoposide (ACE); TIP, Paclitaxel, Ifosfamide, Cisplatin, vincristine, methotrexate, and bleomycin (POMB); doxorubicin, paclitaxel, and gemcitabine (ATG); and cisplatin, cyclophosphamide, and doxorubicin (CisCA) (Fig. 47–11C). The patient developed renal insufficiency, recalcitrant anemia, and grade 3 peripheral neuropathy and had transient normalization of serum tumor markers while awaiting surgical resection. At the time of surgery, serum AFP was 46.9 ng/mL. The patient underwent retroperitoneal lymph node dissection with excision of retroperitoneal masses, left radical nephrectomy, and excision of retrocrural lymph node masses. Pathology demonstrated metastatic mixed GCT, including areas of embryonal carcinoma (EST), mature teratoma, and focal areas suspicious for embryonal carcinoma and choriocarcinoma. He remains disease free past 5 years from the time of his salvage surgery.

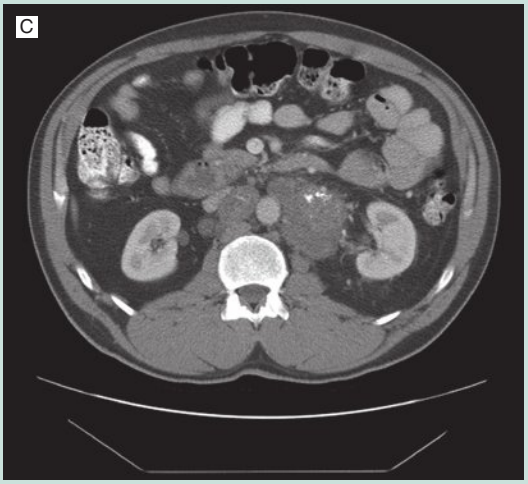


FIGURE 47–11 A. Baseline imaging of the patient described in Case 47–4 with a large retroperitoneal mass. B. Repeat imaging of the patient in Case 47–4 after six cycles of etoposide and cisplatin. C. Imaging of the patient from Case 47–4 showing residual disease despite multiple lines of salvage chemotherapy before desperation surgery.

Comments: Four cycles of bleomycin, etoposide, and cisplatin (BEP) and not EP is the standard for patients with intermediate- and poor-risk nonseminoma germ cell tumor. In rare cases, when the tumor markers do not normalize, even after exhausting all chemotherapeutic options, patients may be salvaged surgically. Patients who have primarily AFP elevation and EST or teratoma benefit the most from such an approach.

Late Complications of Therapy

Although rare, specific complications are associated with treatment of GCTs that are especially important in this patient population because curability may lead to a normal life expectancy. Secondary leukemias occur in fewer than 0.5% of patients and are associated with use of etoposide. Bleomycin toxicity can appear early and is most associated with dose greater than 200 IU. Patients may also have increased risk of vascular side effects, including Raynaud syndrome and hypertension. Up to 20% of patients may develop metabolic syndrome.[93] Additional complications include renal insufficiency, chemotherapy-induced peripheral neurotoxicity, sensorineural hearing loss, chronic electrolyte abnormalities, hypogonadism, and neuropsychiatric abnormalities.[94]

EXTRAGONADAL GERM CELL TUMORS

Extragonadal GCTs (EGCTs) are classified as such if there is no evidence of a primary tumor in the testis or ovary. Typically arising in the midline, the most common sites for EGCTs are the anterior mediastinum, pineal, and suprasellar regions. Mediastinal EGCTs appear as large anterior masses on radiographs. Mediastinal seminomas constitute approximately one third of mediastinal GCTs.[95] Patients with pure seminoma arising in the mediastinum have similar prognosis as patients with testicular seminomas and are treated with four cycles of EP at our institution, provided they do not have extrapulmonary visceral metastasis.

Case 47–4: Germ Cell Tumors with Occult Primary

A 29-year-old man presented with weight loss and left supraclavicular lymphadenopathy (Fig. 47–12A) but had negative testicular examination and ultrasound results. Imaging studies confirmed a 5-cm left supraclavicular lymph node and showed a small left pleural effusion. A biopsy of the supraclavicular lymph node demonstrated poorly differentiated adenocarcinoma. Embryonal carcinoma could not be excluded. Immunostains for placental alkaline phosphatase and Ki-1 were positive but were negative for α-fetoprotein and inconclusive for human chorionic gonadotropin. Laboratory evaluation revealed azoospermia but normal serum chemistries and tumor markers. The patient was treated with three cycles of bleomycin, etoposide, and cisplatin (BEP) and achieved a complete remission; he is now disease free for 5 years without surgical consolidation (Fig. 47–12B).

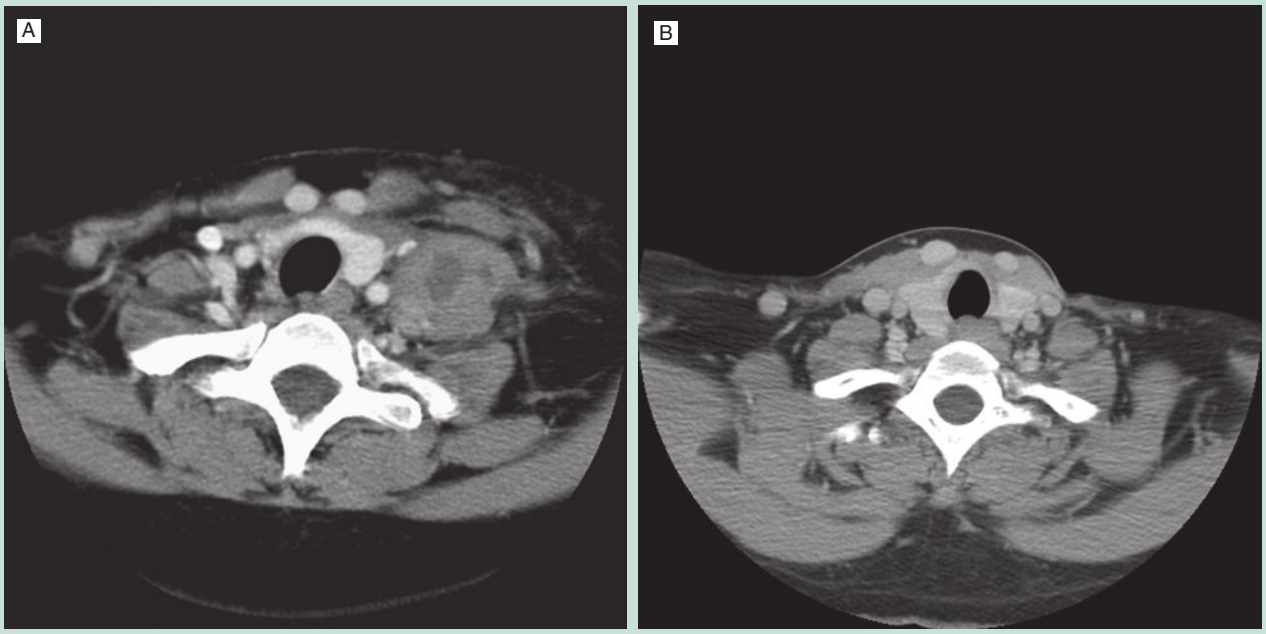

FIGURE 47–12 A. Baseline imaging of the patient described in Case 47–5 showing bulky left supraclavicular adenopathy. B. Imaging after three cycles of chemotherapy.

Comments: The case of unknown primary carcinoma in a young man, even if tumor marker results are negative, should raise the diagnosis of germ cell tumor and should be treated as such. Surgical consolidation is not always necessary when a clinical complete response is achieved with chemotherapy.

Extragonadal NSGCTs represent a distinct subset of GCTs and carry a poor prognosis with 5-year OS rates of about 40% to 50%.[2,96–99] The most common origin is the mediastinum, but they can also arise in the retroperitoneum or pineal region. Rare cases involve the vagina, prostate, liver, and orbit. Extragonadal NSGCTs are characterized by prominence of yolk sac tumor and teratoma histology compared with primary testicular GCTs.[100] Initial diagnosis may be aided by elevations of AFP or hCG. Klinefelter syndrome is associated with increased risk of primary mediastinal NSGCTs.[101] Additional associations include acute megakaryoblastic and myelogenous leukemia, myelodysplastic syndrome, and malignant histiocytosis. Some of these cases represent malignant transformation of immature teratoma elements.

The aggressive nature of mediastinal NSGCTs is coupled with the surgical difficulty of resection of residual disease after therapy. Early diagnosis and aggressive resection of mediastinal NSGCTs may improve the outcome. At our institution, the treatment strategy for patients with this rare entity includes presurgical chemotherapy to optimum response and then consolidation surgery. Four cycles of VIP, rather than four cycles of BEP, are preferred at MDACC because these patients typically undergo thoracic surgery and may require prolonged exposure to high partial pressures of oxygen during surgery, which can provoke bleomycin-related pneumonitis.[102]

CONCLUSION

The GCTs represent the paradigm of curable solid tumors. Optimal management of patients with GCTs requires a multidisciplinary approach, integrating chemotherapy and surgery, to achieve the highest cure rates. Patients who pose a unique diagnostic or therapeutic challenge should be considered for early referral to a large tertiary care center.

MD ANDERSON PRACTICE TIPS

- All scrotal masses should be approached as if they are malignant. Appropriate workup includes transscrotal ultrasonography with color Doppler of both testicles, and any suspicious lesion should be definitively evaluated with radical orchiectomy.
- Extreme elevation of hCG in men should be considered pathognomonic for GCTs and, in selected cases of threatening disease, justifies initiation of therapy even before tissue confirmation.
- Beware of common pitfalls in serum tumor marker elevation, including hypogonadism, marijuana use, or hepatitis.
- Clinical signs of chemotherapy-refractory disease should be approached with an aggressive change of strategy, including salvage chemotherapy and the option of high-dose chemotherapy with stem cell transplantation. These patients should be encouraged to enroll in a clinical trial if available, such as the ongoing TIGER trial, which randomizes patients to TIP or high-dose chemotherapy with autologous stem cell transplant.
- RPLND (especially laparoscopic) should only be performed in high-volume centers to minimize morbidity.
- The treatment strategy for extragonadal NSGCTs typically includes presurgical chemotherapy to optimum response and then consolidation surgery. Special attention should be paid to patients with growing teratoma syndrome, as well as those with indolent or chemotherapy-resistant tumors who may benefit from early surgical intervention.

KEY CONCEPTS

- Brain tumors are a heterogeneous group of lesions divided into two main categories: (1) primary brain and spinal tumors arising from the cells of the central nervous system (CNS) and (2) brain metastases from systemic cancer, which are significantly more common. Neurologic deficits are determined by the location and extent of CNS involvement, as opposed to histology. Brain tumors of all kinds can predispose to seizure and high intracranial pressure.
- The most common systemic malignancy that gives arise to brain metastases is lung cancer followed by breast cancer, melanoma, renal cancer, and colorectal cancer. Of these solid tumors, melanoma is known to have the highest tropism to colonize the brain. Tumors classically associated with hemorrhagic brain metastases include melanoma, renal cell carcinoma, thyroid carcinoma, and choriocarcinoma.
- Gliomas are the most frequently occurring primary brain tumors and include astrocytomas (including glioblastoma), oligodendrogliomas, and ependymomas. Primary brain glial tumors are graded according to the most malignant portion of the tumor. Grade is inversely correlated with prognosis. Increasingly, molecular features are being used to define and classify glial tumors because these features yield additional insight about the anticipated behavior of the tumor and response to therapy.
- Mutation of isocitrate dehydrogenase (IDH) is thought to represent an early step in gliomagenesis and is nearly ubiquitous in low-grade gliomas. It therefore distinguishes secondary glioblastoma that has evolved from a low-grade tumor from primary glioblastoma that arises de novo. IDH mutation has been established as a positive prognostic factor in glioblastoma (GBM). The most common IDH mutation is R132H, which can be detected by immunohistochemistry, though other noncanonical mutations in IDH1 and IDH2 can be identified through next-generation sequencing. IDH inhibition is under investigation as a possible therapeutic strategy.
- Hypermethylation of the promotor region of the O6-methylguanine-DNA methyltransferase (MGMT) gene is another prognostic alteration in glioblastoma. Promotor methylation decreases MGMT transcription, thereby also decreasing production of a DNA repair enzyme that reverses damage induced by alkylating chemotherapy.
- The development of brain metastases and leptomeningeal carcinomatosis is predicated on complex interactions between tumor cells and the adjacent microenvironment, sometimes referred to as the "seed and soil" hypothesis. Emerging therapeutic options for brain metastases include molecularly targeted therapies and immunotherapy used either in addition to or in lieu of conventional treatment depending on the clinical scenario.
- Patients with brain tumors experience unique physical and cognitive symptoms that can have a significant impact on functional status and quality of life such as weakness, aphasia, memory impairment, hemispatial neglect, vision changes, dysphagia, mood dysregulation, and personality change. Care should be taken to identify and manage such symptoms in addition to treating the underlying disease process.

OVERVIEW

Brain tumors are a heterogeneous group of lesions that range from benign, slow-growing tumors found only incidentally on autopsy to malignant, rapidly growing tumors that cause death within months. The most common intracranial tumors are brain metastases from systemic cancer, estimated at 200,000 new cases per year in the United States, based on a 10% to 15% incidence.[1] In comparison, the incidence of primary

brain and spinal cord tumors for 2020 was estimated at 23,890 new cases (https://www.cancer.org/cancer/brain-spinal-cord-tumors-adults/about/key-statistics.html).

Because of their histologic heterogeneity, as well as the unique microenvironment within the blood–brain barrier (BBB), management of patients with brain tumors is complex and benefits from a multidisciplinary team using an individualized approach. Accurate characterization of the tumor pathology can have a significant impact on treatment selection, often necessitating confirmation at a specialized cancer center. Optimal outcomes involve the coordination of neurosurgery, radiation oncology, and neuro-oncology specialists.

Despite advances in neurosurgical techniques, radiation therapy, and chemotherapy, the prognosis for patients with high-grade gliomas such as glioblastoma, the most common form of glioma, remains dismal. Large clinical trials have reported a median survival of only 14 to 16 months with a 26% to 33% 2-year survival rate.[2,3] A review of eight consecutive phase II chemotherapy trials for recurrent glioblastoma demonstrated only a 6% response rate (complete response [CR] and partial response [PR]), with a 6-month progression-free survival (PFS) rate of 15% and a 1-year survival rate of 21%.[4] It is therefore important to consider patients with brain tumors—specifically, those with high-grade gliomas—for entry into clinical trials, which exist for all stages of disease from initial diagnosis to salvage therapy at relapse. This chapter provides basic principles that can be used for diagnosing and treating patients with brain tumors along with an introduction to the molecular mechanisms underlying gliomagenesis.

CLASSIFICATION

Brain tumors are either primary tumors that arise de novo or secondary metastases, the latter of which is far more common. Most commonly, brain metastases result from lung cancer followed by breast, melanoma, renal, and colorectal cancers. Most patients with brain metastases die from progression of their systemic cancer, but because of improvements in systemic therapy, brain metastases are now seen more frequently and with increasing morbidity and mortality. Advances in treating brain metastasis with surgery and radiotherapy (RT) have improved overall survival (OS) when systemic disease is controlled.

Primary brain tumors are classified by the World Health Organization (WHO) grading system (Table 48–1), which is based on the pattern of cell differentiation in the tumor, molecular characteristics (eg, isocitrate dehydrogenase [IDH] or 1p19q status), and histologic features associated with biological aggressiveness (ie, mitotic figures, necrosis, and vascular proliferation). Tumor grade is inversely correlated with prognosis, with grade I the least aggressive and grade IV the most. The most common primary brain tumors are meningiomas, gliomas, nerve sheath tumors, and pituitary tumors'.[5]

Molecular features are an increasingly significant factor in the WHO classification system because we have learned that some of these may better distinguish between distinct entities than histologic characterization alone. The Consortium to Inform Molecular and Practical Approaches to CNS Tumor Taxonomy (cIMPACT-NOW) was founded in 2016 and has sought to elucidate the im pact that such features have on tumor behavior and response to treatment. The upcoming WHO 2020-2021 classification is expected to incorporate several interim recommendations from the cIMPACT-NOW working groups that pertain to classification of IDH-mutant astrocytoma, identification of IDH wild-type astrocytomas with molecular features of glioblastoma, and definition of other types of glioma. These updates are further discussed in later sections.

EPIDEMIOLOGY

Brain Metastases

Brain metastases occur far more commonly than primary brain tumors. Nearly any type of primary cancer can metastasize to the brain, including hematologic malignancies. Most commonly, brain metastases originate from lung cancer, which represents the second most common systemic cancer in men and women.[6] The next most common pathology to metastasize to the brain is breast cancer followed by melanoma, renal cancer, and colorectal cancer.[7] Among solid tumors, melanoma has the highest propensity to metastasize to the brain. Based on autopsy findings, 40% to 60% of patients with melanoma develop brain metastases.[8]

Most brain metastases, particularly melanoma, present with multiple lesions, although when renal cancer metastasizes to the brain, it often results in a single lesion. Approximately 10% of metastatic lesions present as an intraparenchymal hemorrhage. Hemorrhagic metastases are most commonly seen in patients with melanoma, renal cell carcinoma, thyroid carcinoma, and choriocarcinoma. The pattern of distribution of metastases in the brain varies depending on the primary cancer. For example, posterior fossa metastases primarily originate from abdominal or pelvic primaries.

The incidence of brain metastases appears to be rising, which may be a consequence of increasingly sensitive imaging modalities such as magnetic resonance imaging (MRI), increased frequency of surveillance,

TABLE 48–1 Major Entities in the 2016 World Health Organization Classification of Tumors of the Central Nervous System

Diffuse Astrocytic and Oligodendroglial Tumors	
Diffuse astrocytoma (IDH-mutant, IDH wild-type, NOS)	Diffuse midline glioma, H3K27M-mutant
Anaplastic astrocytoma (IDH-mutant, IDH wild-type, NOS)	Oligodendroglioma (IDH-mutant and 1p/19q codeleted, NOS)
Glioblastoma (IDH-mutant, IDH wild-type, NOS)	Anaplastic oligodendroglioma (IDH-mutant and 1p/19q codeleted
Ependymal Tumors	
Subependymoma	Anaplastic ependymoma
Myxopapillary ependymoma	
Ependymoma (papillary, clear cell, tanycytic)	
Ependymoma, RELA fusion positive	
Neuronal and Mixed Neuronal-Glial Tumors	
Dysembryoplastic neuroepithelial tumor	Rosette-forming glioneuronal tumor
Gangliocytoma	Diffuse leptomeningeal glioneuronal tumor
Ganglioglioma	Central neurocytoma
Embryonal Tumors	
Medulloblastomas (can be genetically or histologically defined)	Embryonal tumor with multilayered rosettes (C19MC-altered, NOS)
CNS neuroblastoma	Atypical teratoid/rhabdoid tumor
Other Astrocytic Tumors	
Pilocytic astrocytoma	Pleomorphic xanthoastrocytoma
Subependymal giant cell astrocytoma	Anaplastic pleomorphic xanthoastrocytoma
Choroid Plexus Tumors	
Choroid plexus papilloma	
Choroid plexus carcinoma	
Tumors of the Pineal Region	
Pineocytoma	Pineoblastoma
Pineal parenchymal tumor of intermediate differentiation	Papillary tumor of the pineal region

CNS, central nervous system; IDH, isocitrate dehydrogenase; NOS, not otherwise specified.

and the improving survival of patients with metastatic disease. The development of brain metastases usually occurs in the context of systemic relapse, although relapses can be isolated to the central nervous system (CNS). The impermeability of the BBB, which often limits chemotherapy penetration into the CNS, may be the culprit in circumstances of isolated CNS relapse.

Primary Brain Tumors

Of the primary brain tumors, meningiomas arising from the arachnoid cap cells of the meninges represent the most common histologic entity, comprising 38% of all tumors and 53% of nonmalignant tumors.[5] The second most common group is glioma, which describes tumors arising from the glial support cells of the CNS and includes astrocytomas, oligodendrogliomas, and ependymomas. Combined, gliomas account for approximately 25% of all primary brain tumors and more than 80% of all malignant CNS tumors. As previously noted, glioblastoma is the most aggressive type of glioma and, representing 57% of this group, is also the most common. It is also the most common malignant primary brain tumor. The most recent data from the Central Brain Tumor Registry of the United States reported an incidence of all primary benign and malignant CNS tumors of 23.41 cases per 100,000 between 2012 and 2016.[5]

The incidence of primary brain tumors differs by age. Glioblastomas typically peak in incidence between ages 65 and 74 years, anaplastic gliomas peak between ages 45 and 54 years, and low-grade gliomas are most typically seen between ages 20 and 34 years.[5] In addition to the disparities of age, gender differences are seen in the incidence of primary brain tumors. Overall,

41.9% of all tumors diagnosed between 2012 and 2016 occurred in males (169,868 tumors) and 58.1% in females (235,872 tumors), and specific tumor types are noted to be more common in certain genders; for example, glioblastoma is more common in males and meningioma more common in females, potentially related to estrogen exposure.[5]

Primary CNS lymphoma (PCNSL), concordant with AIDS, has decreased since its peak in the early 1990s, when it reached 10.2 per 1 million person-years. By 1998, the incidence decreased to 5.1 per 1 million person-years, which was attributed to the treatment of human immunodeficiency virus (HIV) with highly active antiretroviral therapy in men younger than the age of 60 years.[9] An increased incidence in PCNSL is seen not only in HIV/AIDS but also in iatrogenic immunosuppression, such as organ transplant, autoimmune disease, and cancer. The rate for persons older than 60 years of age, however, has remained stable since 1994, at approximately 16 per 1 million person-years.[9]

Risk Assessment and Reduction

Although many factors have been considered as putatively involved in gliomagenesis, moderate- to high-dose ionizing radiation is the strongest established causative agent underlying the development of brain tumors, as was seen notably in atomic bomb survivors. Children are particularly radiosensitive, and it has been demonstrated that children given prophylactic cranial irradiation for acute lymphoblastic leukemia have an increased risk for both gliomas and meningiomas.[10] Increased risk of brain tumors has been seen after therapeutic irradiation for pituitary tumors as well. Even low doses of radiation previously used to treat scalp ringworm increased the risk of developing nerve sheath tumors, meningiomas, and gliomas.[11] Fortunately, diagnostic radiation does not appear to be strongly associated with the development of gliomas.[12] Although one recent review found an excess relative risk (1.29) of developing a brain tumor in children exposed to one or more head computed tomography (CT) scans, this association does not necessarily imply causation.[13] Judicious use of ionizing diagnostic radiation is nevertheless recommended in patients with underlying susceptibility to develop brain tumors, such as those with Li-Fraumeni syndrome.

Although a link between brain tumors and chemical exposure has been suggested, no specific agent has been identified with a link to brain tumors that can be validated with an exposure-disease correlation. No consistent link has been proven to underlie for the occurrence of cancer in agricultural workers. Positive correlations have been drawn between the occurrence of brain tumors and occupations involving exposure to synthetic rubber, vinyl chloride, and petroleum refining.[14] Whereas smoking is implicated in an increased risk for many cancers, it is not associated with an increased risk of brain tumors. Exposure to cured foods and nitrites has also been studied, with mixed results.[15] No correlation between alcohol intake or cosmetic use and brain tumors has been found.[16] There has been concern, particularly in the popular press, about the relationship between exposure to cell phones and the risk for brain tumors. Thus far, several case-control studies and a cohort study have failed to establish such a link.

Other than the increased incidence of PCNSL in patients with HIV infection, associations between viral exposures and brain tumors have not been consistent. Human cytomegalovirus (CMV) has recently garnered increasing attention in regard to its role in gliomagenesis. There is sufficient evidence that CMV sequences and viral gene expression exist in most gliomas and that CMV could modulate the malignant phenotype in glioblastoma, but a specific role of CMV in glioma development has yet to be defined.[17]

A protective effect of allergies (asthma, eczema, and hay fever) was noted in a meta-analysis of more than 3000 patients, with a relative risk of glioma incidence of 0.61,[18] supporting a role for immune modulation in brain tumor genesis. A retrospective case-control series demonstrated a decreased incidence of glioma in patients who reported histories of chickenpox, shingles, herpes simplex virus, and Epstein-Barr virus,[19] and as a surrogate for exposure to infections in early life, birth order was correlated with increased risk for the development of glioma in adulthood.[20]

Genetic Predisposition

Relatively few brain tumors are attributable to heredity; studies have cited from 1% to 5%.[21] Brain tumors can arise as a component of familial tumor syndromes, such as neurofibromatosis type 1 (NF1), neurofibromatosis type 2 (NF2), Li-Fraumeni syndrome, and others.

NF1 is caused by a mutation of the *NF-1* gene on chromosome 17q11.2 that encodes the tumor suppressor protein neurofibromin that normally downregulates the RAS-MAPK (mitogen-activated protein kinase) pathway. Patients with NF1 are at increased risk for the development of gliomas originating predominantly in the optic pathway and brainstem. These neoplasms are typically pilocytic astrocytomas with a tendency toward a more indolent course compared with their sporadic counterparts. Optic gliomas are present in approximately 20% of patients with NF1 and cause symptoms in approximately one third of patients.[22] In addition to gliomas, NF1 is also associated with peripheral neurofibromas, café-au-lait macules, iris hamartomas, and other malignancies,

including leukemia and pheochromocytoma. Cancer is the second leading cause of death in patients with NF1.

NF2 is marked by a mutation of the *NF-2* gene on chromosome 22q12 that encodes the protein merlin. NF2 is associated with bilateral vestibular schwannomas, meningiomas, and gliomas, including an increased risk for ependymomas, particularly of the spinal cord at the cervicomedullary junction. Meningiomas occur in approximately 80% of patients with NF2 and are largely low grade with benign behavior.[23]

Several other notable genetic syndromes confer an increased risk of developing brain tumors. Li-Fraumeni syndrome results from an autosomal dominant mutation of the *p53* tumor suppressor gene, located on chromosome 17p. This *p53* mutation results in many types of malignancies, including glioma and medulloblastoma, as well as sarcoma, breast cancer, leukemia, and adrenocortical cancer. Gorlin syndrome results from mutations in tumor suppressor gene *PTCH1* on chromosome 9 and is associated with increased risks of meningioma and medulloblastoma. Turcot syndrome is an autosomal dominant disease characterized by multiple polyps of the gastrointestinal tract as well as brain tumors. Two separate mutations have been identified in Turcot syndrome. One involves the adenomatous polyposis coli gene, which is associated with medulloblastoma, and mutation of the *hMLH1* DNA mismatch repair gene is associated with glioblastoma.

BIOLOGY AND MOLECULAR GENETICS

The understanding of cancer relies on uncovering the underlying molecular biologic mechanisms and signaling pathways that drive tumorigenesis. Delineating such mechanisms is complicated by the tremendous degree of intertumoral and intratumoral heterogeneity. Newer drugs target specific extracellular receptors or block intracellular signal transduction systems.

Glial Tumors

Pathway Alterations

Malignant glial tumors often exhibit significant histologic heterogeneity, which is reflected at the molecular level. Large-scale profiling efforts have accelerated our understanding of gliomas. The landscape of somatic genomic alterations has been comprehensively characterized by The Cancer Genome Atlas (TCGA). In the 2013 TCGA publication, alterations in three core overlapping pathways were described: receptor tyrosine kinase–RAS–phosphatidylinositol 3 kinase (RTK-RAS-PI3K [phosphoinositide 3-kinase]) signaling (altered in 90% of glioblastomas), p53 signaling (altered in 86% of glioblastomas), and retinoblastoma (*RB*) signaling (altered in 79% of glioblastomas). The alterations affecting the p53 pathway (*MDM2, MDM4,* and *TP53*), the Rb pathway (*CDK4, CKD6, CCND2, CDKN2A/B,* and *RB1*), and the PI3K pathway (*PIK3CA, PIK3R1, PTEN, EGFR, PDGFRA*, and *NF1*) were found to be mutually exclusive.[24] Of the 251 glioblastomas analyzed, at least one RTK was found altered: *EGFR* (57.4%), *PDGFRA* (13.1%), *MET* (1.6%), and *FGFR2/3* (3.2%). Mutations of PI3K were found in 25.1% of glioblastomas and were found to be mutually exclusive for *PTEN* mutations and deletions. The p53 pathway was found to be altered in 85.3% of tumors through mutations and deletion of *TP53* (27.9%), amplification of *MDM1/2/4* (15.1%), or deletion of *CDKN2A* (57.8%).[24] TCGA analysis also identified mutations in genes for which targeted therapies have been developed, including *BRAF*[25] and *FGFR1/FGFR2/FGFR3*.[26]

The epidermal growth factor (EGF) pathway was found to be altered in 57.4% of glioblastoma (GBMs) in the most recent TCGA data. An alternate mutation in the external domain generates a truncated receptor, the EGFRvIII mutant, which is constitutively activated in gliomas.[27] Growth factors such as EGF and platelet-derived growth factor (PDGF) activate multiple signal transduction pathways that lead to cell survival and proliferation. The *EGFR* can activate the PI3K pathway, which is also frequently mutated in glioma. When the PI3K pathway is activated, the activation of *AKT* (protein kinase B) is triggered, in turn activating multiple prosurvival pathways, such as nuclear factor κB (NF-κB), forkhead, and glycolysis. The activation of the PI3K pathway has been associated with the reduced survival of patients with glioma.[28] Growth factors can also stimulate the *ras* pathway, which initiates a signal cascade through *Raf-MEK-Erk* and promotes cell survival and tumorigenesis.[29] PTEN (phosphatase and tensin homolog) has phosphatase activity that inhibits the PI3K pathway. The deletion of *MMAC/PTEN* leads to *AKT* pathway activation. The activation of *p53* can result in either apoptosis or cell cycle arrest and initiation of DNA repair mechanisms. The abrogation of *p53* activity would be expected to increase proliferation and mutations, leading to genetic instability, the prodrome of tumorigenesis.

Cell cycle regulation is a key target of carcinogenesis. Cell cycle checkpoints are affected by multiple proteins, acting either as accelerators or inhibitors of cell regulation. Important molecules in this process include *p53, p21,* and *MDM*. Another cell cycle regulation pathway important for glial tumors involves the *RB* gene. When the *RB* gene is phosphorylated, the E2F transcription factor is released and activates cellular proliferation. The regulation of *RB* activity is complex and involves multiple cyclins (cyclin D), cyclin-dependent kinases (CDK4/6), and CDK inhibitors (p16), whose activities are under investigation.[30]

Gliomagenesis

The majority of glioblastomas (~90%) are primary, characterized by rapid development in the absence of any clinical or histologic evidence of a lower-grade lesion, in contrast to secondary glioblastomas, which are IDH mutated and progress from a low-grade astrocytoma or anaplastic astrocytoma. Primary and secondary glioblastomas arise from distinctly different genetic pathways. Primary glioblastomas are postulated to develop quickly from glial progenitor cells over a period of a few months, potentially acquiring mutations in *EGFR, TP53*, or *PTEN*. In contrast, secondary glioblastomas are believed to arise from a stepwise accumulation of mutations.

IDH mutations are believed to be a very early event in gliomagenesis that persist during progression to secondary glioblastomas. The *IDH1/2* mutations likely occur before the acquisition of a *TP53* mutation, a driving force toward astrocytic differentiation, and before the acquisition of 1p/19q loss which believed to be the driving force toward oligodendroglial differentiation. Codeletion of 1p/19q has been classified as the genetic signature of oligodendrogliomas. Recent exomic sequencing has revealed that mutations in the *CIC* gene at 19q13.2 and *FUBP1* gene at 1p are also frequently observed in oligodendrogliomas. In addition to the acquisition of *TP53* mutations, *ATRX* mutations are often noted in WHO grade II and III astrocytomas and secondary glioblastomas.[31]

Predictive and Prognostic Factors

In glioma, allelic losses of chromosomes 1p and 19q (1p19q loss) emerged as markers of chemotherapeutic response and longer survival,[31] qualifying 1p19q loss as a prognostic factor. Studies have also confirmed that 1p/19q LOH is also predictive of response to chemotherapy. In independent seminal studies by the European Organization for Research and Treatment of Cancer (EORTC) and Radiation Therapy Oncology Group (RTOG), patients with anaplastic oligodendrogliomas harboring 1p/19q LOH did significantly better when treated with a combination of radiation and chemotherapy compared with treatment with radiation alone. Tumors without 1p/19q LOH did not incur a survival benefit.[32–34] 1p19q loss was subsequently determined to be a defining characteristic of oligodendroglioma histology, allowing for elimination of the previous diagnostic entity "mixed oligoastrocytoma."

O6-methylguanine-DNAmethyltransferase(MGMT) is a DNA repair protein that reverses DNA damage induced by alkylating agents such as temozolomide and has been implicated as a major mechanism of resistance to alkylating agents. Hypermethylation of the promoter region of the *MGMT* gene, which inactivates *MGMT* gene transcription, has been associated with response to alkylating agents and increased survival in patients with glioma.[35]

IDH mutations were first reported in 2008[36] and quickly became a seminal discovery. The *IDH* mutations now definitively distinguish primary from secondary glioblastomas and have been established as a positive prognostic factor with an increase in OS noted in patients harboring an *IDH* mutation over those with wild-type *IDH*.[37] In low-grade glioma, anaplastic glioma, and glioblastoma, *IDH*-mutation status appears to be the most important prognostic factor.[36,38] In a study of 382 patients with high-grade gliomas, *IDH1* mutation was found to be of greater prognostic relevance than histologic diagnosis according to the 2007 WHO classification system. The sequence of more favorable to poorer outcome was[1] anaplastic astrocytoma with *IDH1* mutation,[2] glioblastoma with *IDH1* mutation,[3] anaplastic astrocytoma without *IDH1* mutation, and[4] glioblastoma without *IDH1* mutation.[38]

Given the information from recent studies, a logical flow to identification of diffuse gliomas has been established in the WHO 2016 classification. After a diffusely infiltrative glioma has been identified on histopathology, testing for IDH1 and IDH2 is undertaken by either immunohistochemistry or next-generation sequencing.

If an IDH mutation is identified, then evaluation for combined loss of chromosome arms 1p and 19q through balanced translocation may be required in tumors that are suspicious for oligodendroglioma. If needed, it is done via fluorescence in situ hybridization. This is done in this sequence as 1p19q loss is essentially only found in IDH-mutated tumors. Loss of 1p19q defines oligodendroglioma (and anaplastic oligodendroglioma), whereas intact 1p19q defines IDH-mutant astrocytomas (including diffuse astrocytoma, anaplastic astrocytoma, and glioblastoma, though the latter may be renamed to IDH-mutated astrocytoma, grade IV, to better distinguish it from IDH wild-type glioblastoma). It has also been noted that CDKN2A and CKDN2B loss is associated with poor prognosis in IDH-mutant astrocytoma, and this feature may be incorporated into subsequent classification schema.[39]

If 1p and 19q are intact or there is only loss of one arm, additional tests may help to clarify. ATRX mutation (or "loss" of normal expression) and TP53 mutation characterize astrocytoma, whereas as previously noted CIC, TERT promoter, and FUBP1 mutations are typically found in oligodendroglioma. CIC mutations are associated with worse OS. It is important to note that TERT promoter mutations are common in both oligodendroglioma and glioblastoma; therefore, first classifying by IDH and 1p19q status is essential. TERT promoter mutations are also prognostically significant, and detection of these mutations was found to be

associated with better prognosis in oligodendroglioma and oligoastrocytoma in historical studies of glioma.

In IDH wild-type glioma, several molecular features have been identified that confer a worse prognosis. A recent publication by the cIMPACT-NOW working group recommends that IDH wild-type glioma with EGFR amplification, or combined gain of chromosome 7 and loss of chromosome 10, or TERT promoter mutation should be classified as "diffuse astrocytic glioma, IDH-wildtype, with molecular features of glioblastoma, WHO grade IV." This means that even histologically "lower-grade" tumors are expected to behave more similar to glioblastoma than other grade II or grade III entities.[40]

Meningiomas

Germline mutations of the NF2 gene result in neurofibromatosis type 2, as described earlier, though somatic mutations are also frequently noted, and disruption is seen in approximately half of meningiomas.[41,42] Merlin, as noted, functions as a tumor suppressor and is a member of a family of cytoskeleton-associated proteins linked to RTK activity and ECM interactions.[43]

In one study, whole-genome or whole-exome sequencing was performed on 17 sporadic meningiomas. The majority of meningiomas harbored simple genomes, with fewer mutations, rearrangements, and copy number alterations than observed in other adult tumors. Focal *NF2* inactivation was confirmed in 43% of tumors.

A subset of meningiomas lacking *NF2* alterations exhibited recurrent oncogenic mutations in *AKT1* and *SMO* with immunohistochemical (IHC) evidence of activation of their pathways. Mutations involving *SMO* were observed in 3 of 17 tumors, and *AKT*1 mutations were noted in 5 of 17 samples. Interestingly, these mutations were seen in the more therapeutically challenging tumors involving the skull base and were of higher grade.[44] Hyperactive Hedgehog signaling has been linked to many other cancers and is under active investigation in meningiomas highlighting SMO as a potential therapeutic target.[45] Inhibitors of PI3K/AKT/mTOR (mammalian target of rapamycin) are also under active investigation for meningiomas harboring *AKT1* mutations.

Of note, other inherited syndromes are associated with meningioma to be aware of, including schwannomatosis (mutation in SMARCB), Gorlin syndrome (PTCH1), and Coffin-Siris syndrome (SMARCE1).

Brain Metastases

The development of brain metastases is an intricate sequential process. In addition to proliferating, tumor cells must migrate and enter the systemic circulation, survive, travel, or transport through the blood to the brain; adhere to and extravasate through the endothelium, invade the brain parenchyma; and proliferate, which requires the recruitment of a secondary blood supply. Failure at any of these steps will halt the metastatic process. Each of these steps requires complex interactions between the tumor cell and its changing microenvironment.

An understanding of the biological processes of brain metastases and the role of the BBB provides potential targets for intervention to improve treatment. There are multiple complex regulators of cell adhesion, including molecules such as integrins, cadherins, selectins, and heparin sulfate proteoglycans.[46] In addition, integrins can recruit intracellular signaling molecules such as focal adhesion kinase and src, which can lead to a cascade of cellular signaling that affects cell cycle control and proliferation. Integrins also play a part in regulating angiogenesis and tumor invasion. Other molecules that mediate invasion include the MMP family, serine proteases, and heparinase.[47]

Tumor cells must generate their own blood supply if they are to grow successfully and remain viable. Important activators of angiogenesis include vascular endothelial growth factor (VEGF), angiopoietin, hypoxia-inducible transcription factor, cyclooxygenase 2, PDGF, integrins, matrix metalloproteinases, and others. Important inhibitors of angiogenesis include angiostatin, endostatin, tissue inhibitors of matrix metalloproteinases (TIMPs), interferons, and platelet factor 4.[48] Upregulation of activators or downregulation of inhibitors favors angiogenesis. As tumors grow, they begin to produce increasing numbers of angiogenic molecules that can participate in metastasis.[48] Because a multitude of pathways are involved in tumor growth and invasion, it is likely that if one pathway is inhibited, cells may escape through alternate pathways.

Effective drug delivery through the BBB to tumor cells is a significant obstacle to chemotherapy, both for brain metastases and primary brain tumors. The P-glycoprotein family of transporters actively exports drugs such as anthracyclines, vinca alkaloids, taxanes, and etoposide.[49] The BBB can be breached by circulating cancer cells, which migrate across the BBB without degrading its permeability and proliferate. When the tumor reaches a size that requires recruitment of new vessels, the BBB is disrupted, which allows imaging of brain tumors with contrast agents. In experimental models, whereas brain metastases smaller than 0.25 mm in diameter are associated with an intact BBB, larger tumors demonstrate BBB permeability.[50] Despite the presence of the BBB, studies of drug levels in brain tumors from systemic delivery have demonstrated pharmacologically relevant concentrations of drugs such as etoposide, cisplatin, cytarabine, and

methotrexate. Measurements of drug levels in cerebrospinal fluid (CSF) are not accurate indicators of tissue drug levels and vary widely depending on the agent.[51] Finding novel ways to circumvent the issues presented by the BBB is an area of active research. Current strategies under development include the use of focused ultrasound to open the BBB, the use of immunotherapy (checkpoint inhibitors, for example, are not required to enter the CNS to exert their effects on the immune system), and the increasing use of BBB-penetrant small-molecule drugs such as alectinib, which can have both systemic and CNS effects. These approaches are discussed in further detail later in this chapter.

Similarly, the development of leptomeningeal disease depends on tumor cells adapting to the harsh, relatively oxygen and micronutrient-poor environment in the CSF. Tumor cells are thought to enter the leptomeningeal space through hematogenous dissemination, direct invasion from a tumor adjacent to the cranial or peripheral nerves, or venous spread.

CLINICAL PRESENTATION, DIAGNOSIS, AND PATHOLOGY

Clinical Presentation

Brain tumors are usually diagnosed after presentation with symptoms such as seizure, headache, or focal neurologic deficits. We commonly see high-grade, malignant tumors presenting with headache, which reflects elevated intracranial pressure, and focal neurologic signs, such as weakness or aphasia. Low-grade glial tumors often come to attention with seizure, possibly caused by *IDH* mutation, resulting in accumulation of 2-hydroxyglutarate, which mimics an excitatory neurotransmitter. Other slow-growing tumors, such as meningioma, may be clinically silent and incidentally detected during imaging for an unrelated problem.

Diagnosis

Universally, the first step in diagnosis is imaging. We use contrast-enhanced MRI, the diagnostic standard, for brain tumor imaging. In addition to its superior sensitivity compared with CT, MRI provides more detailed anatomic as well as physiologic information that can contribute to a differential diagnosis. Although contrast-enhanced CT can detect high-grade lesions that cause BBB breakdown, low-grade lesions may be detectable only on MRI using sequences sensitive for edema, ischemia, and tissue changes. Even in the case of known systemic primary cancer, contrast-enhanced CT may miss small foci of metastatic disease that are visible on MRI (Figs. 48–1 to 48–8). In special cases, advanced brain tumor imaging techniques such as MR spectroscopy, positron emission tomography (PET), or perfusion may be indicated, which is discussed further later.

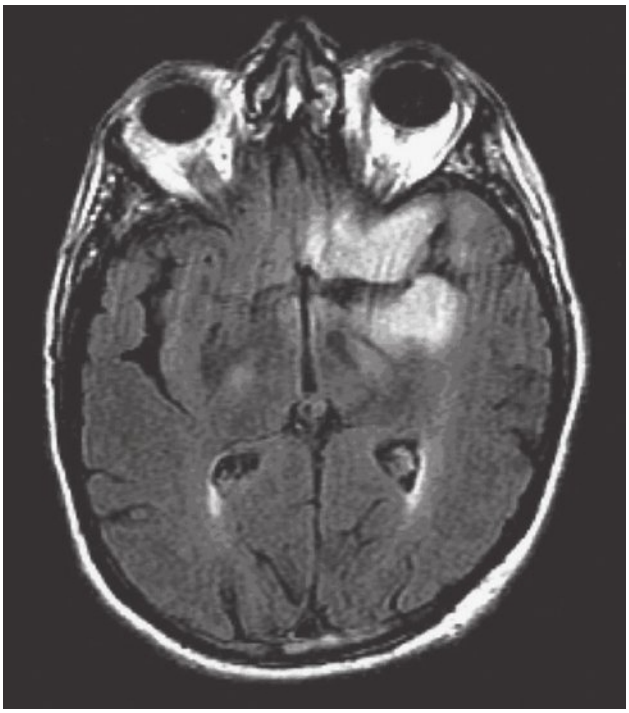

FIGURE 48–1 Low-grade glioma.

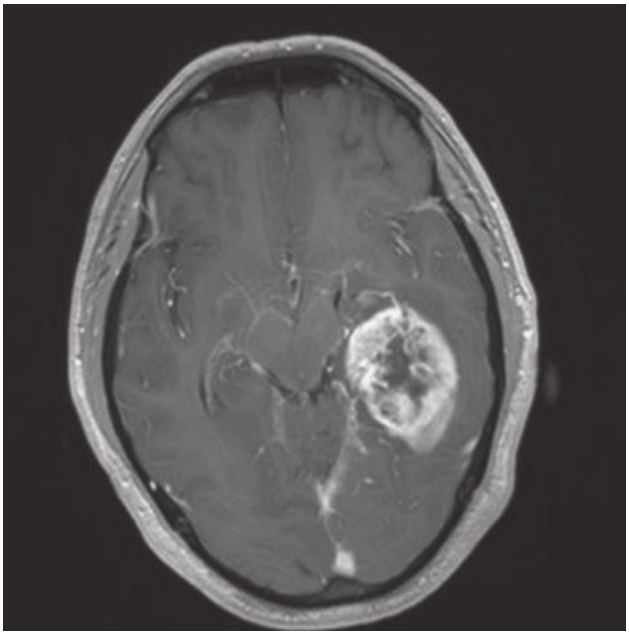

FIGURE 48–2 Glioblastoma.

Noncancerous brain lesions that may be mistaken for malignancy on imaging include infection, demyelinating disease, vascular malformations, and stroke. A particular variant of demyelinating disease (tumefactive

multiple sclerosis) with large focal tumorlike lesions is known to resemble a malignant brain tumor. Unfortunately, some of these lesions have been irradiated, under the presumptive diagnosis of glioblastoma, which only increases the severity of the demyelination. Conversely, patients with primary brain tumors are sometimes initially diagnosed with stroke or demyelinating disease. Further complicating the picture are patients who have brain tumors in addition to stroke, which is far more prevalent with increasing age. Patients with systemic cancer, often in remission,

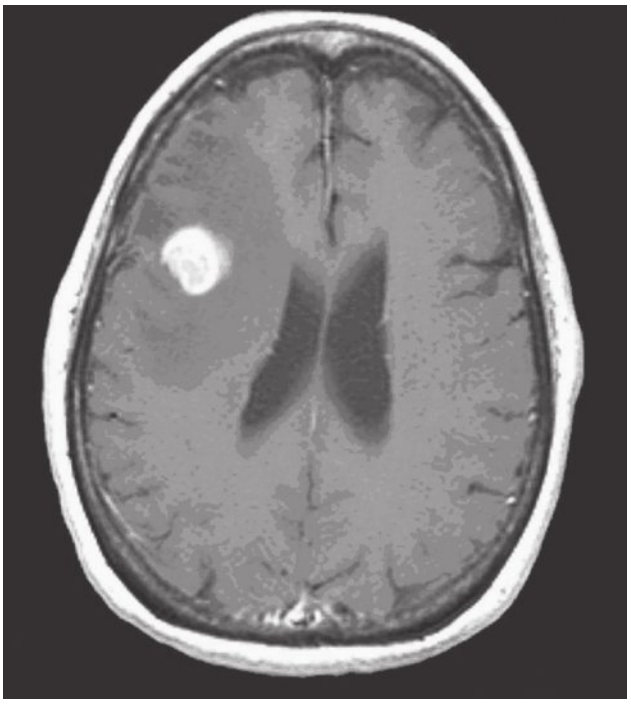

FIGURE 48–7 Single brain metastasis, lung adenocarcinoma.

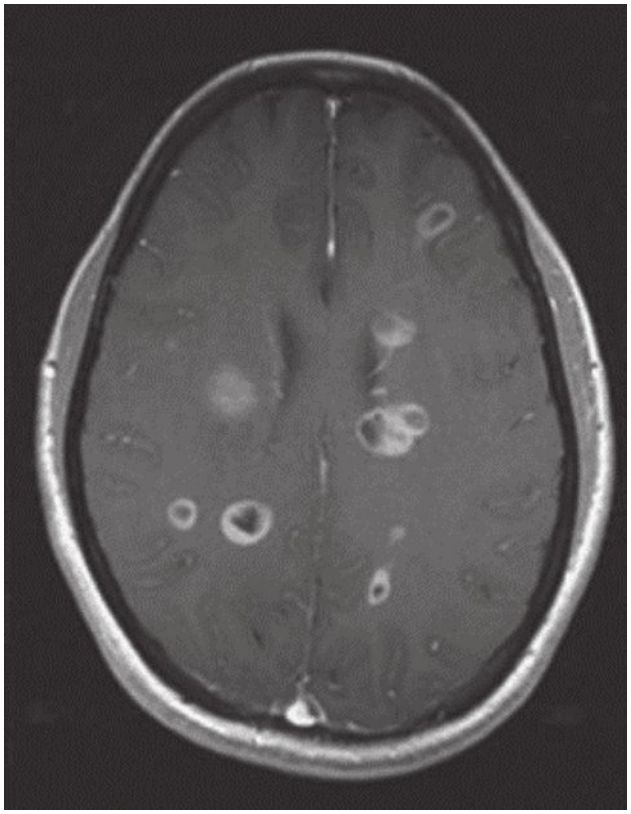

FIGURE 48–8 Multiple brain metastases, breast.

or in stable condition, can present with brain lesions that are suspected to be brain metastases but turn out to be a primary brain tumor. These types of cases often benefit from an interpretation by a specialized neuroradiologist who has been provided with a relevant patient history. A history of immunosuppression and multiple subcortical enhancing lesions may prompt the suspicion of a PCNSL or infection with toxoplasmosis. Further testing with brain thallium single-photon emission computed tomography (SPECT) scanning or fluorodeoxyglucose (FDG) imaging may serve to distinguish between the two possibilities.

Several classic radiographic appearances of brain tumors suggest malignancy. An irregular enhancing lesion with extensive edema following white matter pathways suggests a malignant glioma. Non–contrast-enhancing lesions with increased diffuse signals on FLAIR (fluid-attenuated inversion recovery) imaging suggest a low-grade astrocytoma. Recently, an imaging characteristic called "T2–FLAIR mismatch"—wherein a lesion is hyperintense on T2-weighted imaging but predominantly hypointense with a small hyperintense rim on FLAIR—has been shown to be a highly specific finding in IDH-mutant, 1p19q intact tumors.[52] As a general rule for glial tumors, the presence of contrast enhancement suggests a high-grade malignancy. The WHO grade IV tumors nearly always enhance, as opposed to grade II tumors, which are typically nonenhancing. Two notable exceptions include pilocytic astrocytoma (WHO grade I) and pleomorphic xanthoastrocytoma (WHO grade II), which typically have an enhancing nodule and associated cyst. Meningiomas are typically homogeneously enhancing dural-based lesions associated with calcification. The appearance of multiple enhancing subcortical lesions with homogeneous enhancement suggests PCNSL. However, the same lesions, if associated with a known primary malignancy, may indicate brain metastases.

The brain tumor imaging characteristics seen on MRI are helpful in making a diagnosis. However, confirmation of the diagnosis with pathology is necessary in nearly all cases. It should be noted that testing of the CSF for tumor markers, cytology, and cell-free DNA is an emerging modality for diagnostic pathology of brain tumors. One recent report showed that tumor-derived DNA was detected in CSF in 49.4% of patients with infiltrative glioma, particularly in patients with significant disease burden, and correlated well with certain early, foundational mutations (eg, IDH) in the primary tumor.[53] The significance of other mutations in the CSF is less clear. At this point, CSF sampling does not obviate the need for surgical biopsy or resection of a parenchymal lesion in most situations.

The discovery of a brain lesion should therefore trigger prompt referral to a neurosurgeon. A referral to a specialized neuropathologist may be necessary for

diagnosis of uncommon or rare tumors and in cases when there is only limited biopsy tissue available. Biopsies must be of adequate quality and be representative of the overall tumor to allow accurate diagnosis. Our institution insists on reviewing patient diagnostic slides before rendering a treatment recommendation, and it is not uncommon for our neuropathologists to disagree with the diagnosis provided by the referring physician. One study found diagnostic discrepancy in up to 42% of cases reviewed by neuropathologists at our institution, with 8.8% of disagreements being categorized as "serious" such that they would impact treatment.[54] Primary brain glial tumors are graded according to the most malignant portion of the tumor. A brain lesion that is predominantly grade III astrocytoma but has a few regions that meet the criteria for grade IV astrocytoma (glioblastoma) should be graded as a glioblastoma. The tumor grade may be underestimated if the most malignant portion of the tumor is not sampled. Typically, the most malignant region corresponds to an area of contrast enhancement. If a patient is suspected of having PCNSL, the use of corticosteroids should be avoided. Primary CNS lymphoma can be sensitive to steroids that are lymphocytolytic, and the preoperative use of even small doses of corticosteroids can lead to a nondiagnostic biopsy. These patients usually require repeat biopsy after steroid discontinuation. Patients may present with deep central lesions involving the brainstem or thalamus. These cases may require referral to a specialized neurosurgical center to evaluate whether open biopsy, resection, or stereotactic-guided biopsy is appropriate. In these cases, close coordination with a department of neuropathology is critical in obtaining adequate tissue for diagnosis.

Pathology

Diffuse astrocytomas are characterized by well-differentiated astrocytes—fibrillary, gemistocytic, or rarely protoplasmic—with mildly increased cellularity. The cellular morphology of the tumor cells may differ within the same tumor sample and show great variability between tumors. Necrosis and microvascular proliferation are absent. Rare mitotic figures may occur, and nuclear atypia may be present but not sufficiently to characterize the tumor as an anaplastic astrocytoma. The typical MIB-1 labeling index is less than 4% (Figs. 48–9 and 48–10).

Oligodendrogliomas are characterized by moderately cellular tumor cells with rounded, homogeneous nuclei, giving a "fried egg" artifactual appearance that is referred to as "classical oligodendroglioma" As noted earlier, after several studies including an RTOG trial found that 80% of tumors with classical oligodendroglial morphology were associated with 1p/19q deletion compared with only 13% of 1p and 19q deletions seen in nonclassical oligodendrogliomas; 1p19q codeletion is now a defining feature of oligodendroglioma. Microcalcifications, microcyst formation, extracellular mucin deposition, and a dense network of branching capillaries are other oligodendroglial features. Nuclear atypia may be seen, but significant mitotic activity or microvascular proliferation is suggestive of an anaplastic tumor. The MIB-1 index is typically less than 5% (Figs. 48–11 and 48–12).

Anaplastic oligodendrogliomas are characterized by oligodendroglial cells, with signs of increased cellularity, nuclear atypia, and mitotic activity. Cellular pleomorphism may be present, with formation of multinucleated giant cells or spindle cells. Gliofibrillary

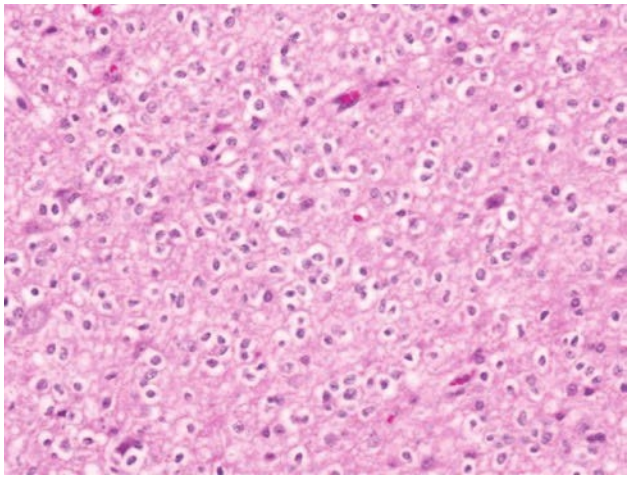

FIGURE 48–11 Oligodendroglioma, World Health Organization grade II (×200).

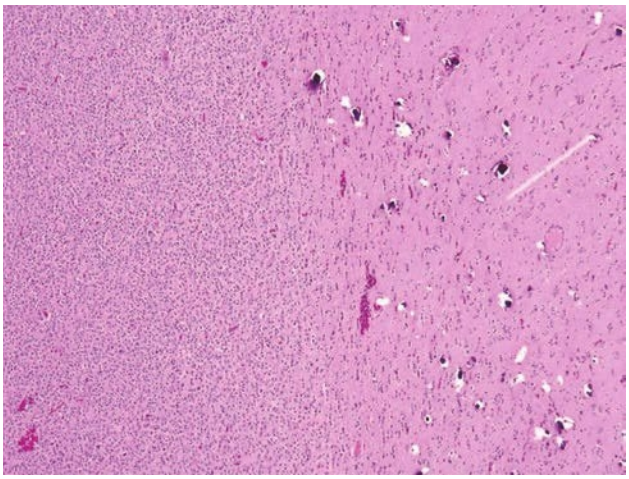

FIGURE 48–13 Anaplastic oligodendroglioma, World Health Organization grade III (×40).

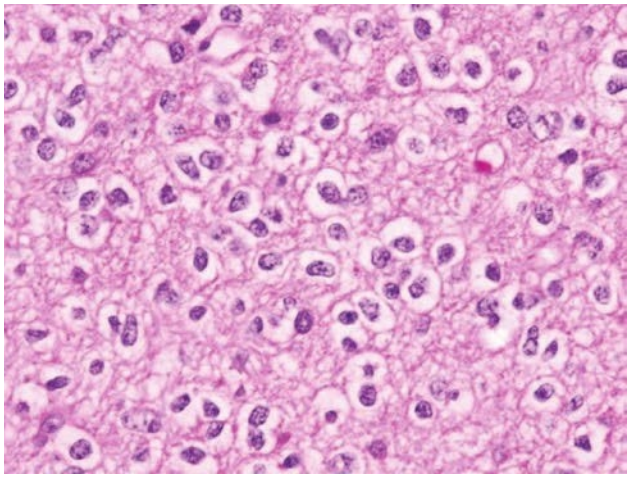

FIGURE 48–12 Oligodendroglioma, World Health Organization grade II (×400).

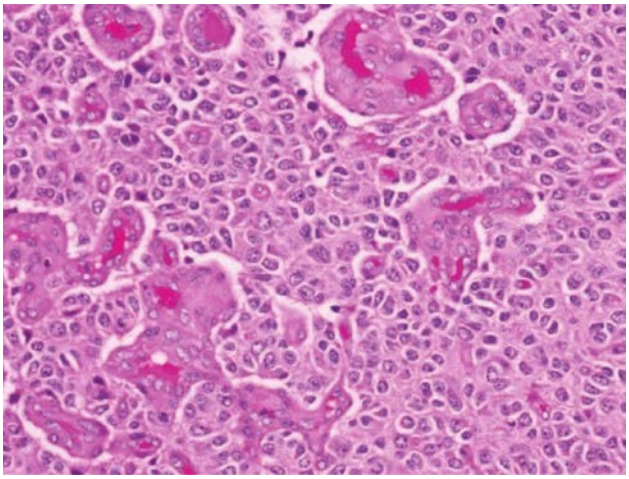

FIGURE 48–14 Anaplastic oligodendroglioma, World Health Organization grade III (×200).

oligodendrocytes and minigemistocytes are common. Although microvascular proliferation and necrosis may be present, their presence does not change the diagnosis to glioblastoma. There is currently no designation for a WHO grade IV oligodendroglioma. The MIB-1 ratio is usually greater than 5% (Figs. 48–13 to 48–15.)

Anaplastic astrocytoma is characterized by diffusely infiltrating astrocytes with increased cellularity, nuclear atypia, and mitotic activity. They are more cellular than low-grade astrocytomas, and the nuclear atypia include formation of nuclear inclusions, multinucleated cells, and abnormal mitoses. Microvascular proliferation is absent; if present, it would upgrade the tumor to glioblastoma. The typical MIB-1 labeling index ranges from 5% to 10% and can occasionally overlap with index values for low-grade astrocytoma and glioblastoma (Figs. 48–16 and 48–17).

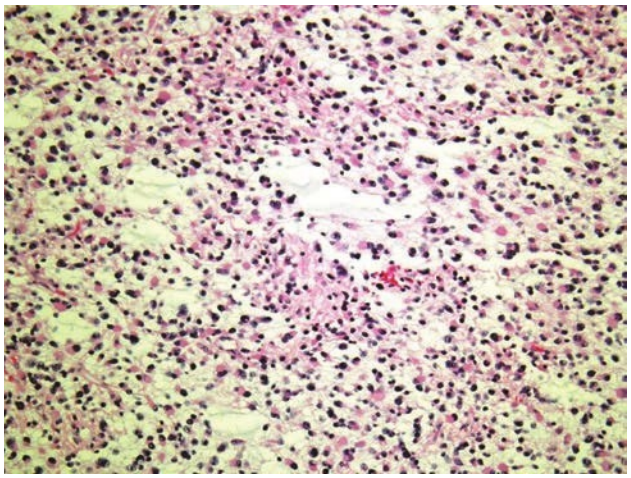

FIGURE 48–16 Anaplastic astrocytoma, World Health Organization grade III (×100).

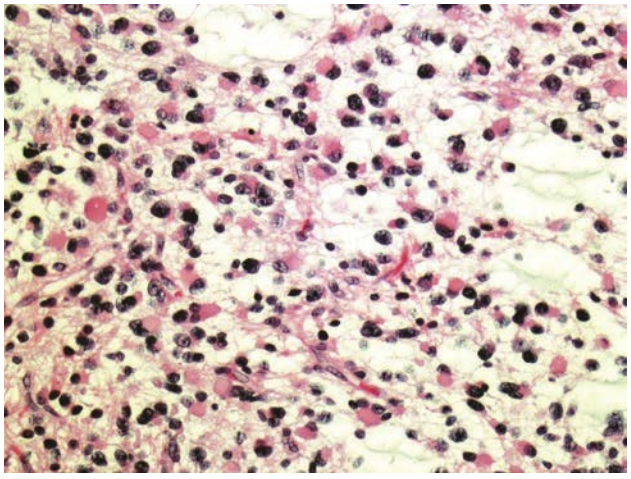

FIGURE 48–17 Anaplastic astrocytoma, World Health Organization grade III (×200).

Glioblastoma and glioblastoma multiforme are synonymous; "multiforme" was dropped from the name in the 2007 WHO classification book, although glioblastoma is still commonly referred to as GBM or glioblastoma multiforme. Glioblastoma is an anaplastic cellular tumor with marked nuclear atypia and mitotic activity, often with marked regional heterogeneity and cellular polymorphism. The presence of either microvascular proliferation or necrosis differentiate this lesion from anaplastic astrocytoma. Other features associated with glioblastoma include formation of epithelial "adenoid" structures, multinucleated giant cells, granular cells, lipidized cells, perivascular lymphocytes, and metaplasia. Glioblastoma is associated with a high proliferative rate, and MIB-1 labeling typically ranges from 15% to 20% (Figs. 48–18 to 48–20).

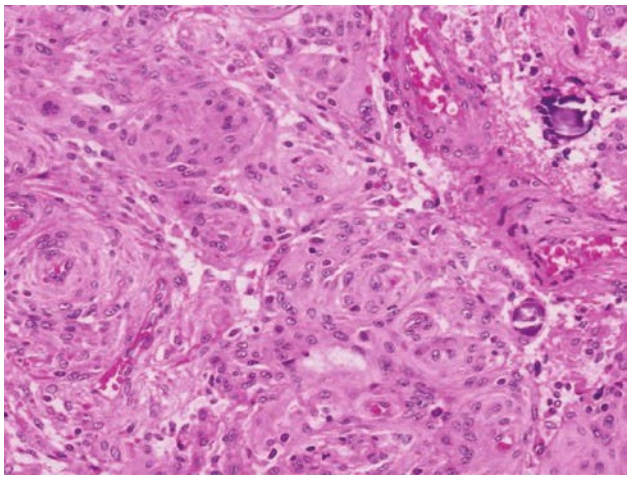

FIGURE 48–21 Meningioma (×100).

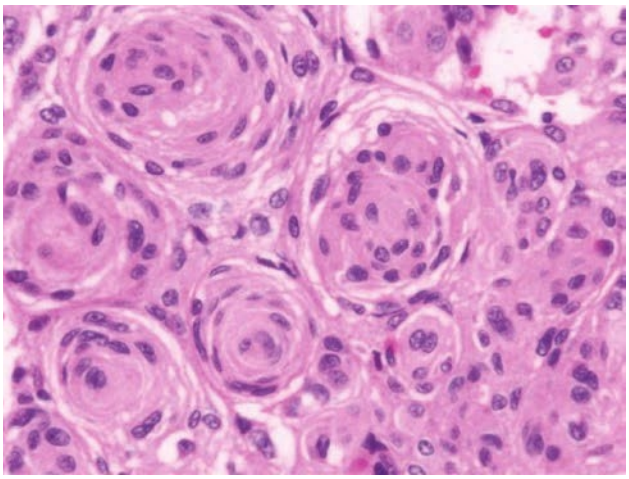

FIGURE 48–22 Meningioma (×200).

As noted in the earlier discussion of molecular genetics, molecular profiling is becoming an increasingly important tool in classification of different tumors. At our institution, molecular classification of diffuse gliomas has become standard. IDH and 1p/19q status are now routinely reported as part of an integrated diagnosis in addition to other pathologic features, including morphologic characteristics such as oligodendroglial or astrocytic phenotype, the results of other relevant IHC stains or diagnostic molecular tests (eg, p53, ATRX, *EGFR* amplification, proliferation indices), and the method of molecular feature determination (eg, fluorescence in situ hybridization, IHC, comparative genomic hybridization).55 This comprehensive format helps inform clinical decision making and patient counseling.

Meningiomas can have a wide range of appearances and are subtyped according to their appearance. Most meningiomas are grade I. The transitional variant has numerous concentric "onion bulb" structures. The psammomatous variant has calcified psammoma bodies. Pleomorphic nuclei and occasional mitoses are allowed, although four or more mitoses per 10 high-power field (hpf) would qualify in diagnosing atypical meningioma, grade II. Increased cellularity, high nuclear-to-cytoplasmic ratio, prominent nucleoli, and foci of necrosis also upgrade these to a grade II. Anaplastic meningiomas, grade III, have more than 20 mitoses per 10 hpf or obviously malignant cytology resembling carcinoma, melanoma, or high-grade sarcoma56 (Figs. 48–21 and 48–22).

TREATMENT AND PROGNOSIS

Low-Grade Glioma

Diffuse astrocytomas are infiltrative low-grade brain tumors. Patients commonly present with new-onset seizures. Their peak incidence is in the third decade of life followed by the second decade. Overall, these low-grade tumors represent 4% of glial tumors.[5] Variation in length of survival depends on patient age, performance status at diagnosis, and total versus partial tumor (as visualized on MRI) resection.[57,58]

Oligodendrogliomas are diffusely infiltrative, well-differentiated tumors composed of oligodendrocytes. These tumors comprise 3% to 4% of all primary brain tumors and approximately 7% of glial tumors, with an incidence of 0.3 per 100,000 per year. The peak incidence is from the ages of 30 to 50 years. Tumors with oligodendroglial differentiation behave more indolently than astrocytomas. The oligodendrogliomas appear to be more sensitive to both chemotherapy and radiation therapy than astrocytomas, and the benefit from these therapies is more pronounced and durable.

Clinical Management

When a diagnosis of low-grade glioma is suspected, we recommend proceeding with a biopsy or resection to differentiate between a low-grade glioma and a nonenhancing anaplastic glioma (Tables 48–2 and 48–3). As previously noted, histologic grade does not convey the full story. Within the category of a grade II infiltrating glioma, for example, it is important to distinguish

TABLE 48–4 Management of Low-Grade Gliomas

Confirmation of diagnosis with biopsy or resection is preferred, although observation is acceptable with close follow-up.
Maximal safe resection should be considered.
Observation for low-risk patients is reasonable.
For high-risk patients (age older than 40 or subtotal resection), consider radiation therapy followed by chemotherapy.
Radiation therapy (focal brain irradiation) is the current standard of treatment.
Formal serial neuropsychologic testing is helpful in assessing cognitive function.
Consider use of psychostimulants to improve cognitive function and quality of life.
Consider biopsy or resection of progressive tumor to confirm diagnosis and consider the same salvage regimens as for malignant glioma.

IDH-mutant from IDH wild-type disease because the latter represents a more aggressive entity. It is also important to distinguish an oligodendroglioma from an astrocytoma if the histologic features are unclear because these entities are also treated differently.

If gross total resection or a major resection is possible without significant morbidity, neuro-oncologists generally recommend a complete resection, which may decrease the risk of malignant transformation from residual tumor cells. In multiple retrospective series, total resection of nonenhancing tumor improves survival.[57] A volumetric analysis of the preoperative tumor, in addition to analysis of postoperative residual tumor, showed a correlation with time to recurrence and the likelihood of malignant transformation.[59] There are several low-grade tumors—such as pilocytic astrocytoma, ependymoma and subependymoma, pleomorphic xanthoastrocytoma, ganglioglioma, and dysembryoplastic neuroepithelial tumor—that may be definitively treated by complete surgical resection alone. These patients may benefit from treatment at a specialized neurosurgical center that treats a large volume of patients with brain tumors (Table 48–4).

If a complete resection is not recommended, therapeutic options range from observation to treatment with focal brain irradiation, chemotherapy, or both. Older studies of low-grade astrocytomas suggested that radiation improved survival. The 5-year survival rates ranged from 49% to 68% for irradiated tumors compared with 32% for nonirradiated tumors.[60] The EORTC 22845 trial randomized patients to either up-front RT (54 Gy in 6 weeks) or delayed radiation therapy at progression. The PFS was 5.3 years in the early radiation group and 3.4 years in the control group. OS, however, was 7.4 years in the up-front radiation group versus 7.2 years in the control group.[2] No data were collected on quality of life. These data suggest that it is acceptable to delay radiation therapy until there are signs of tumor progression, especially for asymptomatic patients and patients who have had a complete tumor resection.

Patients with low-grade glioma should be carefully assessed to determine whether their symptoms are caused by the tumor. Formal neuropsychological testing may reveal cognitive deficits that are not apparent in the simple mental status screening used for dementia. In addition, these tests can be repeated to detect subtle cognitive decline, which may lead to a decision to alter a prescribed therapy. Patients who are symptomatic from their tumor from seizures, who have altered mental status because of tumor bulk or location, or who have other focal neurologic signs would be expected to improve with treatment of the tumor.

The etiology of cognitive decline in patients with a primary brain tumor is multifactorial. The causes include direct tumor effects from invasion and destruction as well as side effects from radiation therapy, chemotherapy, and anticonvulsants.[61] We have found the use of psychostimulants such as methylphenidate to be helpful in improving cognitive function, mood, and fatigue.[62] Other supportive care considerations are discussed in a later section.

Although there are concerns about the long-term effects of brain irradiation, radiation therapy is the standard of care.[61] The dose of RT currently used by the RTOG for low-grade glioma is 54 Gy to localized treatment fields as defined by the tumor appearance on T2-weighted MRI and including a 2-cm margin. A European trial involving 379 patients with low-grade glioma did not demonstrate a benefit for higher radiation dose when comparing 45 Gy with 59.4 Gy.[63] A second prospective study that randomized 203 patients with low-grade glioma to radiation therapy with either 50.4 or 64.8 Gy found a slightly lower survival (64% vs 72% at 5 years) and higher incidence of radiation

necrosis in the group receiving the higher dose of 64.8 Gy.[64] Current National Comprehensive Cancer Network guidelines recommend that patients with grade II gliomas be treated with 45 to 54 Gy in 1.8- to 2.0-Gy fractions but with the caveat that patients with IDH wild-type gliomas—which, as previously noted, will soon be reclassified to reflect their more aggressive behavior—may be treated with higher doses.[65]

Chemotherapy is also used in low-grade glioma. A small study of patients with incompletely resected tumors randomized to RT alone or RT with CCNU (lomustine) demonstrated a median survival time of 4.5 years with no difference between the two treatment arms.[66] An RTOG trial (RTOG 98-02) randomized patients with low-grade glioma and a high risk of recurrence (age 40 years or older or subtotal resection or biopsy) to either radiation therapy alone or radiation therapy followed by six cycles of procarbazine, CCNU, and vincristine (PCV). The early results of this trial were first presented at the American Society of Clinical Oncology (ASCO) meeting in 2014. The combination of PCV and radiation therapy prolonged both OS and PFS compared with radiation therapy alone in patients with high-risk grade 2 glioma, defined as patients with less than a subtotal resection and age older than 40 years.[67] Subsequent analysis published in the *New England Journal of Medicine* confirmed that addition of PCV to radiation doubled the median survival period from 7.8 years to 13.3 years and increased the 10-year survival rate by from 40% to 60%.[68] This benefit was initially predominantly seen in IDH-mutant, 1p19q-co-deleted tumors, though recently published genomic analysis confirms that there is also a benefit in 1p19q-intact tumors (ie, IDH-mutant astrocytoma).[69] The standard of care for low-grade gliomas that are not thought appropriate for observation is therefore radiation followed by adjuvant chemotherapy. For high-risk low-grade astrocytomas (IDH-mutant, 1p19q-intact), the adjuvant chemotherapy of choice in clinical practice is temozolomide. For high-risk low-grade oligodendrogliomas (IDH-mutant, 1p19q-co-deleted), the PCV regimen is preferred.

The utility of chemotherapy as an initial treatment for patients with low-grade gliomas without high-risk features is unproven. It has been postulated that perhaps in some low-risk patients, chemotherapy might delay the need for radiation therapy (which, although it can prolong PFS, can have long-term cognitive sequelae).[70] Several limited studies have demonstrated an encouraging radiographic response by low-grade gliomas (primarily oligodendrogliomas but also astrocytomas) after treatment with temozolomide or PCV.[34,71,72] Another strategy to mitigate the long-term risk of cognitive effects is the emerging use of proton radiation. In contrast to conventional photon-based radiation, the mass of protons limits their ability to penetrate normal tissue surrounding the tumor and allows for better dose conformity. Evidence suggests that patients with low-grade glioma treated with proton radiation have largely stable cognitive function on limited longitudinal follow-up.[73]

Malignant Gliomas

Anaplastic Oligodendroglioma

Anaplastic oligodendrogliomas make up between 20% and 50% of all oligodendroglial tumors and approximately 5% of anaplastic tumors. The peak incidence is between ages 40 and 50 years. The clinical presentation of these tumors is similar to that of other anaplastic tumors, with focal neurologic signs, seizures, or symptoms of increased intracranial pressure. These lesions, which are usually contrast enhancing, can show calcification on CT scans as well as cystic structures, necrosis, and hemorrhage.

The initial standard therapy for patients with anaplastic oligodendroglioma is surgery, with the goal of gross total resection. In RTOG 94-02, random assignment of 291 eligible patients with anaplastic oligodendroglioma (an important caveat is to note that the historical entity of "mixed oligoastrocytoma" was also included, and therefore some tumors were actually molecular astrocytomas) was made for the patients to receive PCV plus RT versus RT alone. There was no difference in median survival by treatment between the 148 patients randomized to PCV plus RT and the 143 patients randomized to RT.[74] However, the significance of codeletion of 1p/19q was supported by the results of EORTC 26951 with increased survival of both anaplastic oligodendroglioma and anaplastic oligoastrocytoma with 1p/19q codeletion noted regardless of the treatment given: radiation alone versus radiation with chemotherapy.[75] The prognostic significance of 1p/19q was validated in the long-term results of RTOG 9402. Patients with co-deleted tumors treated with both PCV and RT had a median survival period of 15 years, double that of patients who received radiation alone (median OS, 7.5 years). Neither timing (before, during, or after radiation treatment) nor dose intensity of PCV was found to be significant. No difference in median survival by treatment arm was appreciated in patients with non–co-deleted tumors.[74]

Although PCV is the most studied regimen in oligodendroglioma, in clinical practice, temozolomide is sometimes used instead because of its more tolerable toxicity profile. A discussion of the evidence for temozolomide use in anaplastic 1p19q-intact glioma follows in the next section. Despite initially high response rates, these tumors usually recur. The median survival period for anaplastic oligodendroglioma treated with surgery, irradiation, and chemotherapy ranges from

TABLE 48–5 Management of High-Grade Gliomas

Consider clinical trials at all stages: up front, adjuvant, and at relapse (especially at first or second recurrence).
Multidisciplinary approach is necessary for optimal outcome:
Neurosurgery
Neuro-oncology
Radiation therapy
Psychiatry
Neuropsychology
Rehabilitation
Social work
Maximal, safe resection
Concurrent chemoradiotherapy with temozolomide for glioblastoma.
Adjuvant chemotherapy for glioblastoma (temozolomide)
For 1p/19q co-deleted anaplastic oligodendroglioma, PCV or temozolomide after radiation therapy or vice versa
For 1p/19q intact anaplastic glioma, temozolomide after radiation therapy (radiation with or without concurrent temozolomide)
Avoid use of anticonvulsants that induce cytochrome P-450 3A4 metabolism when possible.
Progressive disease
Consider clinical trials.
Consider surgical resection at relapse (especially to rule out radiation necrosis).
Salvage chemotherapy agents include single-agent and combination regimens incorporating temozolomide, nitrosoureas, irinotecan, and platinum agents.
Consider re-irradiation.

CCNU, and vincristine; PCV, procarbazine.

TABLE 48–6 Chemotherapy Regimens for Gliomas

NEWLY DIAGNOSED GLIOMAS
Temozolomide
Newly diagnosed glioblastoma:
75 mg/m^2/day by mouth days 1–42 during radiotherapy followed by 150–200 mg/m^2/day[a] by mouth days 1–5 of a 28-day cycle
PCV[b]
Newly diagnosed oligodendroglioma and anaplastic oligodendroglioma:
Procarbazine 60–75 mg/m^2/day by mouth days 8–21 of a 42-day cycle
and
Lomustine 110–130 mg/m^2/day by mouth day 1 of a 42-day cycle
and
Vincristine 1.4 mg/m^2/day IV days 8 and 29 (maximum dose, 2 mg) of a 42-day cycle
RECURRENT GLIOMAS
Temozolomide
150–200 mg/m^2/day[a] by mouth days 1–5 of a 28-day cycle
Lomustine monotherapy
90–110 mg/m^2 by mouth day 1 of a 42-day cycle
Carboplatin monotherapy
AUC 4–5 IV day 1 of a 28-day cycle
Bevacizumab monotherapy or in combination with chemotherapy
10 mg/kg/dose IV days 1 and 15 of a 28-day cycle *or* days 1, 15, and 29 of a 42-day cycle
Bevacizumab and lomustine
Bevacizumab 10 mg/kg/dose IV days 1, 15, and 29 of a 42-day cycle
and
Lomustine 90 mg/m^2 by mouth day 1 of a 42-day cycle
Bevacizumab and carboplatin
Bevacizumab 10 mg/kg/dose IV days 1 and 15 of a 28-day cycle
and
Carboplatin AUC 4–5 IV on day 1 of a 28-day cycle

[a]Begin at 150 mg/m^2/day for cycle 1; increase to 200 mg/m^2/day for cycle 2 if no myelosuppression.
[b]Dose adjusted based on timing of radiotherapy.
AUC, area under the curve; IV, intravenous.

3 to 5 years, although some patients survive past 10 years.[5] Patients with recurrent disease are often treated with salvage regimens similar to those used for patients with anaplastic astrocytoma and glioblastoma (Tables 48–5 and 48–6).

Anaplastic Astrocytoma

Anaplastic astrocytomas are diffusely infiltrating with nuclear atypia and anaplasia as well as marked proliferation, features that distinguish them from low-grade astrocytomas. A lack of vascular proliferation or necrosis distinguishes these tumors histologically from glioblastoma. The highest incidence of anaplastic astrocytoma is in the fourth decade of life followed by the third decade, with nearly equal incidence rates in the second, fifth, and sixth decades. These tumors account for 7.5% of all glial tumors.[5] Some patients may have a history of prior low-grade astrocytoma. Brain imaging shows diffuse hypointense tumor on CT scans and T1-weighted MRI. There is usually more mass effect and edema compared with low-grade astrocytomas, and contrast enhancement is typical. Because these tumors can occasionally be nonenhancing, neuroimaging alone is not sufficient to distinguish these lesions from low-grade astrocytomas. The median survival for patients with anaplastic astrocytoma ranges from 5 to 7 years.

Optimal initial management begins with surgery with the goal of maximal, safe resection, both to provide adequate tissue for accurate analysis of pathology

and to improve survival. After surgery, limited-field radiation therapy to a target dose of 60 Gy is commonly recommended. The target radiation field typically includes the contrast-enhancing region of the tumor as well as the surrounding edema or nonenhancing tumor plus a 2-cm margin. The size of this field is often reduced after a 46-Gy dose has been applied to the contrast-enhancing lesion alone plus a 2-cm margin. Clinical trials using alternate radiation schemes of hyperfractionation or accelerated fractionation have not demonstrated an increased survival benefit over conventional fractionated conformal radiation therapy.[76] Adjuvant chemotherapy following radiation therapy increases time to progression and survival. A phase III study (CATNON) with a factorial design was done to evaluate the efficacy of concurrent and adjuvant temozolomide in patients with anaplastic 1p19q-intact glioma.[77] Recent results revealed that adjuvant temozolomide increased OS in IDH-mutant but not IDH wild-type tumors. Concurrent temozolomide during radiation did not demonstrably increase OS, but there was a trend to benefit in IDH-mutant tumors. Therefore, in anaplastic astrocytoma temozolomide is favored, though combination therapy composed of PCV has been used in the past as well (see Table 48–6) temozolomide.[78]

Patients with recurrent anaplastic astrocytoma should be considered for clinical trials. Surgical resection should also be considered to provide a palliative benefit, relieve mass effect, allow dose reduction of steroids, and confirm histology. The recurrent tumor may actually have progressed to glioblastoma from anaplastic astrocytoma, and such patients are often eligible for a wider array of clinical trials than are available for recurrent anaplastic astrocytoma. Trials have used temozolomide in combination with agents such as interferon-α (IFN-α), *cis*-retinoic acid, metalloproteinase inhibitors, carmustine, irinotecan, and thalidomide.[79–81] Other agents that have been used for recurrent anaplastic astrocytoma include tamoxifen, carboplatin, etoposide, irinotecan, and combination chemotherapy. To date, no single trial has proven to be superior. Reirradiation can be considered for patients who are more than 2 years beyond their original radiation treatment and for patients whose site of recurrent disease lies outside the initial radiation treatment field.

Glioblastoma

Glioblastoma is the most common and most malignant glial tumor of the brain. It comprises 50% of all glial tumors, with an incidence of approximately two to three per 100,000 per year.[5] Glioblastomas are characterized by poorly differentiated astrocytes with cellular polymorphism, nuclear atypia, microvascular proliferation, and necrosis. The peak incidence is in the fifth decade of life followed by the sixth and fourth decades. Glioblastoma is rare in children and young adults.[5] Clinically, these tumors often present with signs of increased intracranial pressure, such as headache. They can also present with seizures or focal neurologic symptoms such as hemiparesis and aphasia, often with a short history of symptoms.

Imaging with CT or MRI usually reveals a contrast-enhancing lesion with irregular borders, frequently with a necrotic center. Vasogenic edema and nonenhancing tumor often surround the area of contrast enhancement and are best seen on T2-weighted or FLAIR imaging on MRI. Glioblastomas commonly spread through white matter tracts across the corpus callosum, internal capsule, and optic radiations. Multifocal lesions are seen. If these multiple lesions truly arise independently as opposed to spreading diffusely through tracts that are not visualized by imaging or pathology, they may have a polyclonal origin.

Glioblastomas are highly lethal. Despite extensive clinical research, survival has not changed greatly during the last 20 years. Prognostic factors include age and Karnofsky performance status (KPS). Surgical resection has shown some benefit, especially gross total resection, described when 90% or more of the enhancing tumor is removed.[82]

The addition of chemotherapy to radiation emerged as the standard of care for glioblastoma based on the seminal large prospective, randomized, phase III trial from the EORTC. This trial randomized 573 patients to receive either standard RT (60 Gy in 30 daily fractions) or concurrent temozolomide (75 mg/m^2/day) with RT followed by adjuvant temozolomide for 6 months (150 to 200 mg/m^2/day for 5 days every 28 days). The group receiving concurrent and adjuvant temozolomide had a significant improvement in PFS (median, 7.2 months vs 5.0 months), survival (median, 14.6 months vs 12 months), and 2-year survival rate (median, 26% vs 8%). Both groups had similar age, KPS, and surgical resection rates.

Our center strongly recommends patient participation in clinical trials, which enroll patients in either the newly diagnosed or recurrent setting. Patients are eligible for entry into a clinical trial for recurrent disease if it has been more than 12 weeks since completion of concurrent chemoradiation to avoid enrolling patients with pseudoprogression (radiographic change that can mimic tumor progression but is actually caused by radiation-induced changes) or if the patient has clear evidence of progression outside the prior radiation treatment field. For patients new to our institution after surgery at an outside hospital, we always consider if a patient is a candidate for a more optimized up-front resection. It is not unusual for our patients to have repeat resection of tumor after biopsy or subtotal

resection at an outside institution. After resection, we treat patients with concurrent temozolomide (75 mg/m^2/day throughout radiation therapy) and standard conformal radiation therapy (59.4 Gy in 1.8-Gy fractions). After radiation therapy, we use adjuvant temozolomide, which is the only Food and Drug Administration (FDA)–approved treatment specifically for patients with newly diagnosed glioblastoma. Although the EORTC study only used adjuvant temozolomide for 6 months, we typically continue treatment for at least 1 year, given the lethal natural history of this disease.

Dose-dense scheduling of temozolomide was evaluated in a large randomized, phase III trial based on the premise that prolonged exposure to temozolomide would result in prolonged depletion of MGMT, possibly translating into an improved survival in patients with newly diagnosed glioblastoma. Standard adjuvant temozolomide (days 1–5 every 28 days) was compared with a dose-dense schedule (days 1–21 every 28 days). No statistically significant difference in either median OS or median PFS was observed between the two treatment arms. Treatment toxicity was higher with the dose-dense schedule.[3] Toxicity can include nausea, vomiting, fatigue, and myelosuppression.

The only other treatment modality specifically approved for newly diagnosed glioblastoma is tumor-treating fields (TTFs). This approval was based on a study in which patients were randomized after concurrent radiation to either adjuvant temozolomide alone or adjuvant temozolomide with TTFs.[83] The patients who were treated with TTFs in addition to temozolomide had survival time of 20.9 months versus 16.0 months for patients treated with temozolomide alone. The survival of the control group was notably worse than for historical cohorts. Also, there was no placebo arm with a sham device, and there is therefore some possibility that patients did better due to other factors such as an increase in supportive care. Theoretically, TTFs exert an electrical field on the charged DNA and mitotic spindles of dividing tumor cells.

Patients with glioblastoma and progressive disease are offered salvage therapy if their KPS is adequate. We consider options including resection of tumor, laser interstitial thermal therapy (LITT), chemotherapy, and repeat radiation therapy. Some novel neurosurgical clinical trials have offered local therapy with gene therapy using *p53*, although this was limited by lack of dispersion of the therapy into surrounding tissues.[84] An interleukin-13–conjugated *Pseudomonas* exotoxin has been studied using convection-enhanced delivery to lead to higher tissue concentration with larger volumes of distribution in phase I.[85,86] Another ongoing trial uses a conditionally replication-competent adenovirus (Delta-24-RGD) injected into the resection cavity for recurrent malignant gliomas.

Laser interstitial therapy is another emerging modality in the treatment of patients with primary brain tumors.[87] A laser catheter is inserted into the tumor and heated to kill tumor cells. It is used at our institution as a salvage therapy in recurrent unresectable glioblastoma and is under investigation in the treatment of patients with brain metastases and radiation necrosis as well. Re-resection of progressive disease can be considered with or without concomitant LITT.

One advantage of re-resection of progressive disease is to confirm pathology and specifically to determine whether the progressive enhancement on MRI represents tumor or radiation necrosis. MRI dynamic contrast and MR spectroscopy imaging, FDG-PET scanning, and brain SPECT thallium imaging sometimes help to distinguish between these two possibilities. However, all of these modalities have limited sensitivity and specificity, and sometimes the pathology reveals both treatment-related necrosis and foci of active tumor. Patients with pathology-confirmed radiation necrosis are often treated with steroids. More recently, bevacizumab, a monoclonal antibody targeted against VEGF, has been used to treat radiation necrosis.[88]

Chemotherapy for recurrent disease typically produces response rates less than 10% and a 6-month PFS of 15%.[4] Response rates that include stable disease and complete or PRs are 40% at best, but as the 6-month PFS value indicates, these responses are not durable. It is hypothesized that the multiple mutations and alterations in glioblastoma and the heterogeneity of the tumor cell population may partially explain the striking resistance of these tumors to therapy. Younger patients respond best to chemotherapy, although responses to alkylating agents can be seen in patients older than 60 years of age. Long-term survivors of glioblastoma (>5 years) have typically had gross total resection, radiation therapy to a dose of 60 Gy, and chemotherapy, generally with temozolomide or a nitrosourea or other alkylating agent.

Salvage agents used for malignant glioma are identical to those used for recurrent anaplastic astrocytoma (see Table 48–6). Rechallenging with continuous dose-intense temozolomide 50 mg/m^2/day is a valuable therapeutic option as evidenced by the RESCUE study. The overall 6-month PFS for recurrent progressive glioblastoma was 23.9%[89] in contrast to 15% based on a pooled analysis of eight consecutive phase II trials of cytostatic and cytotoxic agents. In this study, the greatest therapeutic benefit was observed in patients with progressive disease during the first six cycles of conventional adjuvant temozolomide therapy (150–200 mg/m^2 × 5 days every 28 days) or after a treatment-free interval.[4]

Bevacizumab has been approved by the FDA for progressive disease after prior therapy based on two trials.

One study showed a 6-month PFS of 42% and OS of 8.7 months in patients receiving bevacizumab alone.[90] Another study showed a response rate of 19.6% with a median duration of 3.9 months. The 6-month PFS was 29%, and the 6-month survival rate was 57%. In addition, 50% of patients experienced decreased cerebral edema, 58% were able to decrease corticosteroid dependency, and 52% had improvement in neurologic symptoms.[91]

Bevacizumab was subsequently evaluated in phase III clinical trials for newly diagnosed glioblastoma. Unfortunately, no effect was seen on overall patient survival. Two recent large randomized, phase III trials, AVAglio and RTOG 0825, demonstrated that the addition of bevacizumab to up-front treatment with radiation and temozolomide conferred no benefit in terms of OS. PFS was prolonged in both studies by approximately 3 to 4 months, reaching statistical significance in the AVAglio study but not in the RTOG 0825 study based on predefined criteria.[92,93]

Other active agents include CCNU (lomustine), irinotecan, and carboplatin, which have been investigated both as single agents in the salvage setting and in combination with bevacizumab in patients with bevacizumab-naïve recurrent glioblastoma.[94] Lomustine, also referred to as CCNU, is a nitrosourea BBB-penetrant alkylating agent increasingly used in recurrent glioblastoma. Clinical trials have increasingly used lomustine as a control arm in comparison with other novel therapies providing relevant clinical efficacy data in a phase 3 setting. Although its utility is largely extrapolated from the significant role it plays in PCV combination chemotherapy, as well as several older studies of the related compound BCNU in glioblastoma, it is nevertheless a standard of care chemotherapy regimen in recurrent GBM. Potential toxicities include thrombocytopenia, liver failure, and a cumulative risk of pulmonary fibrosis. Pulmonary function tests are recommended intermittently for patients on CCNU chemotherapy.

The optimal schedule and combination of bevacizumab with alternative drugs has not been identified. Agents targeting angiogenesis have also been studied, although the use of IFN, thalidomide, EGF-RTK antagonists, and integrin receptor antagonists is not standard. Many of these targeted therapies demonstrated only limited activity as single agents, and efforts are underway to combine them with cytotoxic therapy.[95] Other cellular pathways being investigated with small-molecule inhibitors include the *ras* pathway with farnesyl-transferase inhibitors and the PI3Kinase pathway with *mTOR* inhibitors. Other novel approaches to malignant brain tumor therapy include use of oncolytic adenovirus, vaccine and dendritic cell immunotherapy, and histone deacetylase inhibitors. An important reaction has been discovered from the interaction between anticonvulsants that induce the hepatic cytochrome P450 3A4 enzyme and other chemotherapy agents also metabolized by this same enzyme. Pharmacokinetic studies of patients with malignant glioma on single-agent irinotecan and sirolimus found significantly lower levels of active drug in patients on enzyme-inducing anticonvulsant drugs.[96] We recommend that patients on chemotherapy avoid the use of anticonvulsants that induce the expression of the P450 3A4 enzyme whenever possible.

Given the success of immunotherapy in other malignancies there has been much interest in using similar strategies in primary brain tumors, specifically glioblastoma. There may be utility in using checkpoint-blockade immunotherapy in patients with hypermutated glioblastoma secondary to disorders such as constitutional mismatch repair deficiency.[97] In other situations, the "cold" immune microenvironment of brain tumors may limit the efficacy of checkpoint-blockade and chimeric antigen-receptor T-cells, although further studies are needed.

Meningioma

Meningiomas comprise 38% of primary brain tumors, with a rate of 5.35 per 100,000 person-years. The incidence of meningioma increases with age; the median age at diagnosis is 64 years.[5] The tumor is often discovered incidentally without any symptoms. The main treatment is surgical resection, with the goal of complete resection when possible, accounting for relative risks and benefits depending on the patient's age and condition.[98] Options for residual tumor include observation and radiation therapy, which can incorporate stereotactic delivery to minimize effects to local tissue.[99]

Chemotherapy for meningioma has been used for patients who have progressive disease after resection and RT; it is sometimes used in an adjuvant setting after RT when pathology indicates malignant meningioma. Response rates have been disappointing in small case series. Agents that have been used include hydroxyurea,[100] IFN-α,[101] and liposomal doxorubicin.[102] Results using temozolomide have been discouraging, with no responders.[103] Because there are no established treatments after surgery and radiation have been exhausted and response to chemotherapy has been disappointing, the use of molecularly targeted therapy is being explored in aggressive meningioma. Frequently, EGF, PDGF, and VEGF receptors are overexpressed in meningiomas. Clinical trials using small-molecule signal transduction inhibitors such as erlotinib, gefitinib, and imatinib are being explored.[104,105] In a recent phase II trial, sunitinib, a small-molecule tyrosine kinase inhibitor that targets VEGF and PDGF receptors, was found to have activity in patients with recurrent atypical or

malignant meningiomas and warrants investigation in a randomized trial.[106]

Primary Central Nervous System Lymphoma

In contrast to most other brain tumors, chemotherapy is the initial treatment of choice for patients with CNS lymphoma given it is often deep and multifocal. The traditional view has been that gross total resection conferred no survival benefit over biopsy, but this view has been challenged recently. In a phase III trial of 526 patients, PFS was found to be significantly shorter in patients who were biopsied compared with patients who had undergone subtotal or gross total resections, with no difference in outcome attributable to KPS or age, suggesting that surgical resection could be considered for otherwise healthy patients with single lesions for which resection is deemed safe.[107]

Methotrexate-based, multiagent chemotherapy has been viewed as the treatment of choice in PCNSL. The incorporation of high-dose methotrexate (>1 g/m^2) has resulted in a significantly greater response and improved survival compared with previous regimens using a CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisolone) regimen before whole-brain radiation therapy (WBRT). A report by DeAngelis et al,[108] incorporating methotrexate (1 g/m^2), followed by WBRT and two cycles of high-dose cytarabine (ara-C) (3 g/m^2), demonstrated a median survival of 42.5 months. This strategy is the basis for current CNS lymphoma protocols that have increased the dose of methotrexate and incorporated agents that more easily cross the BBB, such as procarbazine. A follow-up clinical trial incorporating methotrexate at 3.5 g/m^2 with procarbazine and vincristine, followed by WBRT and cytarabine demonstrated a median survival of 60 months.[109] The improvement in patient survival has also brought to attention significant rates of cognitive decline and radiation-induced dementia, especially in patients older than 60 years.[110]

Current approaches to therapy of CNS lymphoma are investigating whether radiation therapy can be avoided or delayed to reduce cognitive decline and dementia without adversely affecting survival. Preliminary results from a trial using single-agent methotrexate at 8 g/m^2 every 2 weeks demonstrated a PFS of 12.8 months. Median survival had not been reached at more than 22.8 months.[111] Many clinicians at our center are cautiously delaying radiation therapy until relapse and continuing to use high-dose–based methotrexate regimens such as R-MVP (rituximab, methotrexate, vincristine, procarbazine).

Patients with recurrent disease may respond again to methotrexate. Other regimens used include PCV,[112] high-dose cytarabine,[113] temozolomide,[114] rituximab,[115] and the combination of temozolomide and rituximab.[116]

After induction chemotherapy, if patients achieve CR, either WBRT or high-dose chemotherapy with autologous stem cell transplant may be effective as consolidation.[117]

Brain Metastasis

The treatment of brain metastasis involves optimal interactions between oncology, neurosurgery, and radiation therapy. Depending on the setting of relapse, patient survival may depend more on local tumor control in the brain or on systemic control for progressive metastasis. Advances in local brain tumor control with surgery and radiosurgery will not improve patient survival if the patient ultimately succumbs to progressive systemic disease or continues to develop new brain metastases. The median survival of patients with brain metastases is 3 to 6 months.[118]

The options for therapy include surgical resection, WBRT, stereotactic radiosurgery (SRS), and systemic chemotherapy. Surgical resection is the treatment option considered primarily in patients with single large tumors. Resection of brain metastases has emerged as a standard treatment option for patients with surgically accessible single lesions, good performance status, and controlled or absent extracranial disease. SRS uses multiple convergent beams to deliver a single high dose of radiation to a discrete target volume and is usually reserved for lesions whose maximum diameter is 3 cm or less. The ability to treat locations that were otherwise considered surgically inaccessible is a distinct advantage of SRS. WBRT via 30 to 40 Gy (in daily fractions of 2 to 3 Gy) is the standard therapy for brain metastasis, with an established body of literature supporting its use for multiple metastases. This therapy has the ability to eradicate micrometastatic disease to delay recurrence[118,119] and is often used in conjunction with surgical resection or radiosurgery. It is well tolerated and can be effective for radiosensitive tumors such as metastases from small cell lung cancer or germ cell tumors. The greatest concern about WBRT has been the risk of neurocognitive effects, which can range from mild impairment to dementia.

We frequently treat patients at our institution with surgery if the lesions are greater than 3 cm and the patients are symptomatic. If the patient's medical condition makes a surgical procedure risky, the patient may receive WBRT. Patients who have lesions smaller than 3 cm can receive radiosurgery if they are asymptomatic or if the lesion is in a deep region not amenable to resection.

Classically, chemosensitive types of brain metastases include breast cancer, small cell lung cancer, and germ cell tumors. The primary consideration in

choosing a given regimen chemotherapy regimen is to use agents with known activity in a given tumor type.

Many clinical trials of investigational agents for solid tumors explicitly exclude patients with brain metastases. Compounding this omission is their common inclusion in studies of a heterogeneous group of patients with mixed tumor types and differing prior exposures to chemotherapy. Patients might also be expected to be more resistant to treatment with chemotherapeutic agents if they had failed RT. If chemotherapy is given during and after RT, it may be difficult to separate the efficacy due to RT versus chemotherapy. These factors make it difficult to compare treatment regimens and interpret studies.[120]

Newer drugs have been developed targeting specific intracellular transduction mechanisms or extracellular receptors. Owing to their specificity, they often lack the side effects commonly associated with standard cytotoxic chemotherapy. If the therapeutic target is crucial for the cancer cell's continued viability, the drug can be especially effective. The identification of *BRAF* mutations in 50% to 60% of advanced melanomas resulted in the development of potent and selective inhibitors. Vemurafenib and dabrafenib are FDA approved for the treatment of advanced melanoma and have transformed melanoma therapy, with high response rates seen in patients even with advanced, symptomatic, metastatic disease.[121]

Recently, a number of small-molecule BBB-penetrant chemotherapies have been found to control both systemic and CNS disease. Several are pertinent to make mention of, based on recent data. Osimertinib is a third-generation EGFR inhibitor used to treat non–small cell lung cancer (NSCLC) that has also been shown to have activity against brain metastases, in one case report inducing complete remission.[122] The BLOOM study further demonstrated that osimertinib at a dose of 160 mg/day was efficacious in treating leptomeningeal disease, with a median OS of 11.0 months representing a significant improvement from the historically dismal prognosis of this manifestation of cancer.[123] Alectinib, as noted earlier in this chapter, is an ALK inhibitor that has been found to have significant CNS activity relative to previous generation ALK inhibitors such as crizotinib and now is commonly used as a first-line agent in patients who have brain metastases from NSCLC at diagnosis.[124] Last, tucatinib is an agent that selectively targets HER2 in breast cancer and has been shown to improve survival in patients with brain metastases when added to trastuzumab and capecitabine.[125] Other similar agents are under development and may further revolutionize the treatment of patients with brain metastases.

The use of chemotherapy for patients with brain metastases is faced with great challenges. The most important imperative is to discover new agents that can overcome tumor resistance to standard chemotherapy, whether through selection by prior pretreatment or inherent chemoresistance of tumor cell clones that metastasize from a primary site. Improvement in patient survival result in a multimodality approach to the treatment of the patient with brain metastases.

Seizure Control

The management of seizures in patients with brain tumors is important to improve patient functioning and quality of life. Typically, antiepileptics are not given until the patient has had a seizure, though many neurosurgeons may temporarily prophylax patients perioperatively. A decline in seizure control may indicate tumor progression or worsening edema. It may also indicate a systemic infection or a drug interaction leading to decreased anticonvulsant drug effectiveness. In the case of tumor progression, a reduction in the amount of brain edema with high-potency corticosteroids (dexamethasone) may be sufficient to prevent further seizures. A second anticonvulsant is often necessary. Dexamethasone is a hepatic cytochrome P450 3A4–inducing agent and often causes a reduction in serum levels of antiepileptic medications such as phenytoin and carbamazepine (also enzyme inducers) when the dose is increased. Similarly, patients can become symptomatic with toxic levels of anticonvulsants in the midst of a dexamethasone taper. It is important to follow serum anticonvulsant levels when using agents metabolized by the cytochrome P450 system. Anticonvulsants that are highly protein bound can demonstrate significant changes in levels of circulating free drug without significantly changing the total serum level. It is useful to check serum-free phenytoin or valproic acid levels when patients taking these agents have seizures or show signs of toxicity.

Despite the numerous choices of anticonvulsants, it can be difficult to control seizures. Of the newer generation of anticonvulsants, we have had success using levetiracetam and lacosamide, which are easily titrated without significant drug interactions. Phenobarbital and clonazepam can be useful in resistant cases of seizures. Short-term use of lorazepam can help bridge changes in anticonvulsant regimens.

Quality-of-Life Considerations

It is critical to provide effective supportive care to patients with brain tumors to improve their functional status and quality of life for themselves and their caregivers. This care is typically labor intensive and often beyond the means of patients and their families to provide. We involve social work and case management early in the

treatment of patients. They can provide interventions that may prevent a later breakdown in care.

The incidence of depression is high among this population and should be treated early. The causes of depression are typically multifactorial and may include direct effects of the tumor, side effects of chemotherapy and radiation therapy, and side effects of steroids in addition to issues associated with a loss of independence and a diagnosis of cancer. We suggest referral to psychiatry to optimally address these issues. A related concern is the impact of fatigue and somnolence, common side effects of brain radiation. We advocate the use of psychostimulants such as methylphenidate to treat both fatigue and cognitive side effects.[58] Although there are theoretical concerns that the use of stimulants may exacerbate seizures, we have not observed this in practice.

Patients often require high doses of steroids to manage edema and experience both acute and chronic toxicities from their administration. Acutely, the steroids may induce hyperglycemia requiring an insulin sliding scale. Patients often become agitated and irritable, have extreme mood swings, and even become psychotic when taking steroids. Low-dose neuroleptics can be effective in treating these side effects. Clinicians should aim to taper steroid use to the lowest doses necessary. Patients typically tolerate initial steroid weaning but often experience fatigue or worsening of neurologic function as dexamethasone doses are reduced to below 4 mg/day. This can be ameliorated with an extremely slow steroid taper and only lowering doses every 1 to 2 weeks by decrements of 1 mg or even 0.5 mg. Psychostimulants can help treat the inevitable fatigue experienced with the steroid taper. There is no effective treatment for steroid myopathy other than tapering off steroids and initiating physical therapy and rehabilitation as early as possible.

MD ANDERSON PRACTICE TIPS

- All patients with brain tumors are best treated with a collaborative multidisciplinary approach involving medical and neuro-oncologists, radiation oncologists, and neurosurgeons. The neuropathological and molecular differences between different brain tumors can be subtle and have significant ramifications for treatment planning. Therefore, review by an experienced neuropathologist to render an accurate diagnosis is critical.
- There is some equipoise regarding the optimal treatment of low-grade glioma, given their overall favorable natural history. At our institution, maximal safe surgical resection is followed by sequential radiation and chemotherapy in high-risk patients. In patients who are thought to be low risk, a period of close surveillance may be reasonable. For astrocytomas, temozolomide is typically selected as adjuvant therapy. For oligodendrogliomas, the strongest evidence supports use of PCV, though temozolomide is considered reasonable.
- In glioblastoma, IDH mutation and MGMT methylation status should be checked due to their prognostic significance. Standard of care for glioblastoma includes maximal safe surgical resection followed by concurrent radiation (59.4 Gy in 1.8-Gy fractions) with temozolomide (75 mg/m^2/day throughout radiation therapy). Although studies have used adjuvant temozolomide for 6 months after completion of radiation, we typically continue treatment for 1 year, or 12 cycles, given the lethal natural history of glioblastoma. However, the patient should be closely monitored because of the increased risk of myelosuppression with cumulative exposure to alkylating agents.
- The options for treating brain metastases include surgical resection, WBRT, SRS, and systemic chemotherapy. Surgical resection is considered primarily in patients with few, surgically accessible single lesions; good performance status; and controlled or absent extracranial disease.
- Leptomeningeal disease commonly presents insidiously with cranial nerve deficits, symptoms of raised intracranial pressure, radiculopathy, saddle anesthesia, and bowel or bladder habit changes. Diagnostic evaluation includes an MRI of the entire neuroaxis (brain and spine) with and without gadolinium contrast followed by up to three lumbar punctures for examination of CSF parameters, including protein, glucose, cell count, and cytology. Treatment typically includes radiation to symptomatic areas and, if possible, optimizing systemic chemotherapy to CNS penetrant agents. Intrathecal chemotherapy via Ommaya reservoir can be considered in selected patients with good performance status.

KEY CONCEPTS

- Mutations in the RAS-RAF-MAPK signaling pathway are detected in most cutaneous melanomas, most commonly affecting *BRAF, NRAS,* and *Nf1*. The prevalence and pattern of mutations differs between cutaneous melanomas and noncutaneous (ie, mucosal, uveal) melanomas.
- Surgery is the mainstay of initial treatment for patients with primary cutaneous melanoma without clinical evidence of regional nodal or distant metastatic disease. Sentinel lymph node biopsy should be considered in patients with a significant risk of regional metastasis. For patients with sentinel lymph node involvement, it is no longer standard practice to perform completion lymph node dissection based on recent prospective trials that showed no significant impact on melanoma-specific survival (MSS). Surgery is an important component in the multidisciplinary management of patients with clinically detected regional nodal disease and in select patients with distant metastases.
- Adjuvant radiation therapy (RT) reduces the risk of locoregional recurrence in patients with regionally metastatic disease but without significant impact on overall survival (OS). Radiation may provide palliative benefit in patients with distant metastases. Treatment decisions regarding radiation should be tailored based on potential risks, benefits, and multidisciplinary input.
- Several adjuvant systemic therapies reduce the risk of recurrence in patients with regionally metastatic disease. While adjuvant immune checkpoint inhibitor immunotherapy was first approved for the anti–CTLA-4 (cytotoxic T lymphocyte-associated antigen 4) antibody ipilimumab, adjuvant therapy with anti–PD-1 (programmed cell death protein 1) antibodies (nivolumab, pembrolizumab) was shown to be safer and more effective. Adjuvant targeted therapy with the combination of dabrafenib, a BRAF inhibitor, and trametinib, a MEK inhibitor, is approved for stage III melanomas with a BRAF V600 mutation. No prospective trials to date have compared adjuvant immunotherapy versus adjuvant targeted therapy. Both immunotherapy and targeted therapy are being investigated in the neoadjuvant setting.
- After decades without progress, in the past decade, multiple systemic therapies have been approved for the treatment for patients with stage IV or unresectable stage III disease. Ipilimumab was the first immunotherapy to be approved in this setting. Subsequent trials demonstrated improved safety and efficacy with single-agent nivolumab and with single-agent pembrolizumab versus ipilimumab, leading to their approval. Combination immunotherapy with ipilimumab and nivolumab is also more effective than ipilimumab and has been approved, but the combination has increased toxicity versus either agent alone. For patients with a BRAF V600 mutation, three different targeted therapy combinations of a BRAF and a MEK inhibitor (dabrafenib + trametinib; vemurafenib + cobimetinib; encorafenib + binimetinib) have been approved after demonstrating superiority compared to single-agent BRAF inhibitor therapy. The BRAF + MEK inhibitor combinations have not been compared in prospective clinical trials versus each other or versus immunotherapy. Intratumoral injection of talimogene laherparepvec is approved for patients with unresectable injectable metastatic disease.
- Although much progress has been made for patients with cutaneous melanoma, the efficacy of immune checkpoint inhibitors is much lower in patients with mucosal and with uveal melanoma. These tumor types also have a much lower prevalence of targetable mutations.

Melanoma is the most aggressive form of skin cancer. Although its incidence pales compared with basal cell carcinoma and squamous cell carcinoma (SCC), melanoma is the cause of approximately 75% of all skin cancer–related deaths. Most patients diagnosed with early-stage melanoma have very good outcomes

with appropriate surgical management. Patients with regional and distant metastases have historically had poor outcomes because of the ineffectiveness of traditional systemic therapies, particularly chemotherapy. However, the management and outcomes of patients with metastatic melanoma have improved dramatically because of the translation of improved understanding of molecular drivers and key regulators of the antitumor immune response in this disease.

EPIDEMIOLOGY AND RISK FACTORS

Melanoma is the fifth most common cancer in men and the sixth most common cancer in women in the United States. In 2019, there were an estimated 96,480 new cases of and more than 7000 deaths from melanoma.[1] The age-adjusted incidence for cutaneous melanoma in the United States from 2013 to 2017 was 22.7 per 100,000.[2] In contrast to the reduced incidence observed with almost all other major cancers, the annual incidence of melanoma continues to rise by approximately 2% to 3% per year and has increased more than 500-fold since the 1950s.[3]

Several factors correlate with an increased risk of being diagnosed with melanoma (Table 49–1). Based on epidemiological studies, many of these factors reflect a strong association between melanoma and ultraviolet radiation (UVR) exposure.[4] Consistent with this clinical association, whole-exome sequencing studies have shown that cutaneous melanomas overall have a higher somatic mutation rate than almost all other solid tumors and that the majority of these mutations bear the molecular signature of UVR-related DNA damage.[5] Several risk assessment aids have been developed to identify high-risk individuals, including the Melanoma Risk Assessment Tool, which is available online (http://www.cancer.gov/melanomarisktool).

Patients with dysplastic (atypical) nevi with irregular borders, multiple colors, and larger than 5 mm diameter have a 3- to 20-fold higher risk of developing melanomas than the general population.[6] Although most melanomas are sporadic, the familial atypical multiple mole and melanoma (FAMMM) syndrome is an autosomal dominant disorder characterized by the occurrence of melanoma in one or more first- or second-degree relatives and the presence of a high number of acquired nevi or atypical nevi. This syndrome is associated with germline mutations of the *CDKN2A* gene and an increased risk of other cancers, especially pancreatic cancer.[7] Congenital nevi can also be a precursor of melanoma, and individuals with large congenital nevi (>20 cm) have an increased risk of developing melanoma.[8]

CLASSIFICATION

Cutaneous melanomas are the most common manifestation of this disease, arising from melanocytes in the skin. The four major types of cutaneous melanoma are superficial spreading, nodular, lentigo maligna, and acral lentiginous melanoma. Desmoplastic melanomas represent a distinct subtype that arise from melanocytes in the skin regions with chronic sun exposure, which are characterized by highly invasive local growth that often tracks along the nerves. Melanomas can also arise from melanocytes in other areas, including the uveal tract of the eye (uveal melanomas) and mucosal surfaces throughout the body (mucosal melanoma). Very rare subtypes include primary central nervous system melanomas, which arise from melanocytes in the leptomeninges, and melanomas of soft parts (also known as clear cell sarcoma), which arise in soft tissues and dermis. Although the melanoma subtypes are not independent prognostic factors, they can be associated with distinct clinical (Table 49–2) and molecular (Table 49–3) features.[9]

TABLE 49–1 Factors Associated with Increased Risk of Melanoma

Risk Factor	Features
Personal history of melanoma	9× increased risk of developing a second melanoma (vs the general population)
Family history of melanoma	First-degree relatives have a higher risk, and 10% of all melanomas are familial (FAMMM syndrome and dysplastic nevus syndrome)
Total number of nevi	Relative risk of 5 to 17 with presence of >50 nevi
Congenital nevi	6% lifetime risk with large (>20 cm) congenital nevi
Dysplastic nevi	3- to 20-fold higher risk of developing melanoma than the general population
Immunosuppression	Chronic immune suppressant use, HIV infection, and organ transplantation
MC1R variants	Associated with fair skin, red hair, and freckles
Exposure to ultraviolet light	Tanning bed use, sunburn

FAMMM, familial atypical multiple mole and melanoma.

TABLE 49–2 Melanoma Subtypes

Type	Frequency (%)	Sites	Features
Cutaneous			
Superficial spreading	70	Any site (more common on the upper back in both sexes and the lower extremities in women)	Most common subtype of cutaneous melanomas
Nodular	15–30	Any site (common on the trunk or legs)	Presents with vertical growth phase without radial growth phase
Lentigo maligna	4–15	Sun-exposed area (the head, neck, and arms)	
Acral lentiginous	2–8	The palms, soles, and beneath the nail plates	More common in African Americans and Asians
Uveal	Rare	Uveal tract of the eye (iris, ciliary body, and the choroid)	Frequent, and often exclusive, metastatic involvement of the liver
Mucosal	Rare	Mucosal surfaces (head and neck, respiratory, gastrointestinal, and genitourinary tracts)	Poor prognosis, potentially because of delayed diagnosis and the rich lymphovascular supply of the mucosa
Desmoplastic	Rare	Areas with chronic sun exposure, especially the head and neck	High risk for local recurrence and growth along nerves
Primary CNS	Rare	Leptomeninges	
Melanoma of soft parts (clear cell sarcoma)	Rare	Soft tissues, dermis	Associated with fusions involving the *EWSR1* gene

CNS, central nervous system.

TABLE 49–3 Classification of Melanoma by Oncogenic Mutations

Melanoma Subtype	Mutations			
	BRAF (%)	*NRAS* (%)	*KIT* (%)	*GNAQ/GNA11* (%)
Cutaneous without CSD	50	15–20	1–2	—
Cutaneous with CSD	5–30	10–15	2–17	—
Acral lentiginous	10–15	10–15	15–20	—
Mucosal	5	5–10	15–0	—
Uveal	—	—	—	85

CSD, chronic sun damage.

MOLECULAR BIOLOGY

Cutaneous melanomas are characterized by an extremely high rate of somatic mutations. The first cutaneous melanoma analyzed by whole-genome sequencing identified more than 33,000 somatic changes in the tumor.[10] Most of the somatic changes detected in cutaneous melanomas are representative of DNA damage induced by UVR. Despite the challenges presented by this overall high background mutation rate, confirmed driver mutations are detectable in majority of the cutaneous melanomas. Recent research has extensively focused on identifying mutational changes of the signaling pathway components and a brief description of the most common mutational changes is provided below.

RAS-RAF-MEK-ERK Pathway

The RAS-RAF-MEK-ERK pathway promotes cellular proliferation and survival, and activation of this pathway has been implicated in multiple tumor types. Genetic events that activate this pathway are detected in almost all cutaneous melanomas.[11] The most common alterations detected are point mutations in the *BRAF* gene. The *BRAF* encodes a serine-threonine kinase

in the RAS-RAF-MEK-ERK cascade. Point mutations in *BRAF* are detected in approximately 45% of cutaneous melanomas, and approximately 95% of these mutations result in substitutions for valine at position 600 in the BRAF protein.[12] The most common mutations result in the substitution of a glutamic acid (*BRAF*,^{V600E} 70%) or lysine (*BRAF*,^{V600K} 20%) residue. These and other substitutions at codon 600 increase the kinase activity of the BRAF protein 200-fold or more and result in constitutive activation of downstream components of the RAS-RAF-MEK-ERK pathway. The *BRAF*^{V600E} mutation is also frequently detected in benign nevi, supporting that this molecular event occurs very early in melanoma development.[13] Consistent with this theory, *BRAF* mutation status is highly concordant between primary melanomas and their metastases. Mutations at other sites in *BRAF* (*BRAF*$^{Non–V600}$) are detected in approximately 5% of cutaneous melanomas. These mutations have variable effects on BRAF's catalytic activity, but preclinical data support that they still activate the RAS-RAF-MEK-ERK pathway.[14] Rarely, translocations involving the *BRAF* locus also occur in melanoma,[15] which generate fusion proteins that appear to activate the RAS-RAF-MEK-ERK pathway.

Mutations in *NRAS* are detected in 20% of cutaneous melanomas.[11] These mutations overwhelmingly occur in hotspot regions that result in substitutions at amino acid residues Q61 (~80%) or G12/G13 (~20%). Like *BRAF*,^{V600E} the mutant NRAS proteins potently activate the RAS-RAF-MEK-ERK pathway and are commonly detected in benign nevi. Notably, hotspot mutations in *NRAS* are mutually exclusive (<1% co-occurrence) with *BRAF*^{V600E} mutations but co-occur relatively frequently with *BRAF*$^{Non–V600}$ mutations.[16] Also, rare mutations are detected in other members of the RAS GTPase family, *KRAS* and *HRAS* (<2%). Loss-of-function mutations of *NF1*, a negative regulator of RAS, are detected in approximately 15% of cutaneous melanomas, predominantly in melanomas without *NRAS* or *BRAF*^{V600} mutations.[11]

Additional Pathways Implicated in Cutaneous Melanomas

The PI3K (phosphoinositide 3-kinase)-AKT pathway is a key regulator of many cellular processes, including proliferation, survival, motility, and metabolism.[17] The identification of *NRAS* mutations was the first evidence for PI3K-AKT activation in melanoma because oncogenic *RAS* mutations activate the PI3-AKT pathway in addition to RAS-RAF-MEK-ERK to transform cells. The PI3K-AKT pathway is also activated by loss of function of *PTEN*, which is a lipid phosphatase that normally inhibits the activation of the PI3K-AKT pathway. Loss-of-function mutations and deletions involving *PTEN* are detected in up to 30% of cutaneous melanomas.[18,19] Loss of *PTEN* appears to be mutually exclusive in melanomas with *NRAS* mutations, but it occurs frequently in tumors with concurrent *BRAF*^{V600} mutations. Experiments in preclinical models have shown that loss of *PTEN* cooperates with *BRAF*^{V600} mutations to promote transformation, invasiveness, and metastasis of melanocytes, providing functional support for this clinical association.[20] Rare (<2% each) activating mutations in *AKT1*, *AKT3*, and *PIK3CA* have also been detected in cutaneous melanomas, again generally in tumors with *BRAF*^{V600} mutations.[17]

Alterations in key cell cycle regulators are also pervasive in cutaneous melanomas.[11,21] Germline loss-of-function mutations in the *CDKN2A* gene are the most common events detected in familial melanoma. The *CDKN2A* gene encodes two different proteins, P14^{ARF} and P16.^{INK4A} P16^{INK4A} regulates cell cycle progression by binding to cyclin-dependent kinase 4 (CDK4). Point mutations in the gene encoding CDK4 are the most common germline events detected in familial melanoma cases without *CDKN2A* mutations. The mutations alter the site in CDK4 that binds to P16,^{INK4A} thereby promoting cell cycle progression.[22] Somatic mutations and copy number changes in both *CDKN2A* and *CDK4* are commonly detected in cutaneous melanomas. Cyclin D1, which forms a protein complex with CDK4 or CDK6 to promote cell cycle progression, can also be amplified in this disease.[23] Loss of function of P14^{ARF} inhibits the function of *TP53* via increased MDM2 activity. In addition, mutations in *TP53* are present in approximately 20% of cutaneous melanomas.[19]

Molecular Features of Noncutaneous Melanomas

Activating mutations in *BRAF* are relatively rare events in acral lentiginous (~15%) and mucosal (~5%) melanomas, and they are not detected at all in uveal melanomas.[9] However, several other prevalent oncogenic events have been identified in these melanoma subtypes.

KIT is a type III transmembrane receptor tyrosine kinase that activates several pro-survival signaling pathways following binding of its ligand, stem cell factor. *KIT* amplifications and mutations are more frequently (20%–30%) detected in acral, mucosal, and cutaneous melanoma with chronic sun-induced damage compared with cutaneous melanomas without chronic sun-induced damage (<5%).[24] The two most common *KIT* mutations in melanoma are *L576P* (34%) and *K642E* (15%) in exons 11 and 13, respectively, and overall, 70% of *KIT* mutations occur in exon 11, which encodes the juxtamembrane domain.[25] *KIT* mutations in exon 11 prevent the juxtamembrane domain's inhibitory function and induce the constitutive activation of KIT and its associated pathways.

GNAQ and *GNA11* encode regulatory subunits of G protein–coupled receptors that are frequently mutated in uveal melanomas. Hotspot mutations affecting residues Q209 (exon 5) and R183 (exon 4) in these genes are mutually exclusive events. Combined, mutations in either *GNAQ* or *GNA11* are present in 85% of uveal melanomas.[26] The mutant GNAQ/11 proteins hyperactivate several cellular signaling pathways, including RAS-RAF-MEK-ERK and PI3K-AKT. *GNAQ* and *GNA11* mutations appear to be extremely rare (≤1%) in cutaneous melanomas, but they have been detected in both blue nevi and primary CNS melanoma.

STAGING

After a patient is diagnosed with melanoma, staging of melanoma is important for prognosis and treatment. The eighth edition of the American Joint Committee on Cancer (AJCC) staging system for cutaneous melanoma was implemented in 2018 (Tables 49–4 and 49–5). In the updated staging system, primary tumor Breslow thickness and ulceration were predictive of melanoma-specific survival (MSS) in patients both with clinically localized disease and with regional metastases.[27] In contrast to the seventh edition, the primary tumor mitotic rate is no longer incorporated in the T staging system of the AJCC eighth edition. However, increasing mitotic rate is associated with decreased MSS in patients with node-negative and node-positive melanoma and remains associated with outcomes in tumors of all thickness categories.[27] For regional metastasis staging, the number of involved lymph nodes is the strongest predictor of outcome, but tumor burden (microscopic vs macroscopic), pattern of involvement (regional lymph node [RLN], satellite, microsatellite, and in-transit metastases), and primary tumor features (T stage) are also prognostic.[28] In patients with distant metastases, staging is organized into four subgroups (M1a, M1b, M1c, and M1d), reflecting the site(s) of metastasis. Serum lactate dehydrogenase (LDH) level remains a clinically significant factor associated with response, progression-free survival (PFS), MSS, and overall survival (OS),[29–32] and thus each M subcategory is modified based on whether LDH is elevated (designated as "(0)" for "not elevated" and "(1)" for "elevated".)

SURGICAL MANAGEMENT

For patients with primary cutaneous melanoma and clinically negative RLNs, surgery represents the mainstay of initial clinical management. It is useful to consider this approach in the context of two themes: (1) wide excision of the primary tumor site and (2) approach to the regional nodal basin. Before definitive surgery, it is important to identify other lesions suspicious for a synchronous cutaneous malignancy, evidence of regional metastasis, and signs

>1.0–2.0	1.0–2.0
>2.0	2.0

[a]Margins may be modified to accommodate individual or functional considerations.

and symptoms that may raise suspicion for distant metastatic disease. Such findings may alter treatment plans.

Recommended wide excision margins are based on primary tumor thickness (Breslow thickness), and they are measured from the melanoma biopsy site edges or residual intact disease.[33] Wide excision includes subcutaneous tissue down to the level of, but generally not including, underlying muscular fascia. Recommended margins of excision are summarized in Table 49–6.

The surgical approach to the RLN basin staging is guided by Breslow thickness, other tumor factors, and host factors, including the presence of ulceration or high mitotic rate. The technique of lymphatic mapping and sentinel lymph node biopsy (SLNB) is based on the observation that finite regions of skin drain via afferent lymphatics to RLNs and that the most common site of melanoma metastasis is the RLN basin. Additionally, because most RLN metastases are clinically occult, the technique of SLNB was developed to identify and selectively excise the RLNs most likely to contain occult metastatic disease (termed sentinel lymph nodes [SLNs]) if any are involved.[34] Overall, for patients with clinically negative regional nodes, the risk of RLN metastasis ranges from less than 1% for patients with very thin primary tumors to approximately 50% for patients with thick, ulcerated primary tumors. The American Society of Clinical Oncology and Society of Surgical Oncology clinical practice guidelines recommend that SLNB be considered for patients with T1b melanoma, after a thorough discussion with the patient of the potential benefits and risks associated with the procedure.[35] Routine SLNB is not recommended for patients with T1a melanoma because of the overall low risk of microscopic regional metastasis (<5%).[36,37] Preoperative or intraoperative lymphoscintigraphy is recommended to identify RLN basins at risk and to localize the sentinel nodes; a dual-modality approach (ie, in the United States, isosulfan blue dye and technetium-99 sulfur colloid) along with a handheld gamma probe is used intraoperatively.[34,38] After surgery, enhanced histologic analysis is performed, generally as a combination of step sectioning and immunohistochemical analysis. In contrast to many other solid tumors, intraoperative frozen section assessment is rarely employed.

SLN pathologic status is an important independent prognostic factor for disease-free survival (DFS) and MSS.[39,40] The Multicenter Selective Lymphadenectomy Trial-I (MSLT-I) prospective, randomized, clinical trial compared wide excision and SLNB (with completion lymph node dissection [CLND] for patients with positive a SLNB) versus wide excision and nodal observation (followed by therapeutic lymphadenectomy for patients who developed nodal recurrence). This trial confirmed the strong prognostic significance of SLNB in patients with early-stage melanoma but did not demonstrate an OS benefit for the procedure. However, subset analysis among all node-positive patients did show a survival advantage to SLNB-positive patients who had CLND compared with the patients who had nodal observation and subsequently recurred in regional nodes.[40] Thus, until recently, CLND (also known as completion lymphadenectomy or early therapeutic lymph node dissection) had been a standard of care for patients with a positive SLNB. However, CLND carries significant risks, including wound infections, wound dehiscence, and lymphedema. Furthermore, because only 10% to 20% of SLN-positive patients have tumor-involved non-SLNs at CLND,[41,42] SLNB alone may be sufficient to confer the survival benefit seen in a subset of MSLT-I patients. Thus, two multicenter randomized controlled trials German Dermatologic Cooperative Oncology Group - Selective Lymphadenectomy Trial (DeCOG-SLT), Multicenter Selective Lymphadenectomy Trial-II - (MSLT-II) compared immediate CLND with nodal observation in patients with positive SLNB.[41,43] Although CLND provided prognostic information and was associated with improved regional control, both studies showed that CLND did not improve MSS compared with nodal observation. Furthermore, CLND was associated with increased lymphedema. These results have been practice changing, with significantly fewer SLN-positive patients undergoing CLND. It is important to recognize, however, that nodal observation in MSLT-II mandated close follow-up, with physical examination and nodal basin ultrasound every 4 months for the first 2 years, then every 6 months for the next 3 years, and thereafter annually. Current National Comprehensive Cancer Network guidelines recommend either surveillance with physical exam and nodal basin ultrasound or consideration of CLND for patients with SLN-positive melanoma.[44]

For patients with suspected regional nodal metastasis on physical examination or imaging, core needle biopsy or fine-needle aspiration is recommended.[44] For patients with resectable regional nodal metastasis in the absence of distant metastasis, treatment remains wide local excision (with recommended margins summarized in Table 49–6) and therapeutic lymph

node dissection. For patients with clinical evidence of resectable satellite or in-transit lesions in the absence of distant metastasis, treatment options include resection with clear margins (with or without SLNB), intralesional Talimogene laherparepvec (TVEC) (see section on TVEC), or systemic therapy. Adjuvant therapy (see sections on adjuvant systemic therapy and adjuvant radiation therapy [RT]) may be considered and should be discussed in a multidisciplinary setting. For patients with bulky regional nodal metastasis, consideration should be given to clinical trials of neoadjuvant therapy (see section of neoadjuvant systemic therapy), which may facilitate resection if tumor shrinkage occurs and may improve local disease control and MSS. Additionally, the efficacy of neoadjuvant treatment can be evaluated preoperatively by monitoring tumor response and postoperatively by pathologic evaluation of resected tumor tissue to allow for tailoring of adjuvant therapy.[45]

Surgery for isolated distant metastases may be rarely considered in carefully selected patients upon multidisciplinary review, such as for palliation of symptoms (bleeding or obstructing small bowel metastasis), resection of residual lesion after a good overall response to systemic therapy, or as part of a clinical protocol.

ADJUVANT RADIATION THERAPY

Considerations for the Primary Site

Recurrences at the primary tumor site after surgery are rare and occur in fewer than 5% of cutaneous melanomas.[46] However, certain histopathologic features portend a higher risk of local recurrence, in which case RT may be used to mitigate the risk. In particular, desmoplastic melanomas have a rate of local recurrence of 20% to 50% after surgery alone.[46–50] Retrospective reports have demonstrated a significant decrease (17%–19%) in local recurrence with postoperative RT.[51,52] Therefore, adjuvant RT should be considered for patients with desmoplastic melanomas. Other features that correlate with increased risk of local recurrence include Breslow tumor thickness 4 mm or greater,[53–56] satellitosis,[57,58] and ulceration.[46,59,60] Primary tumor location in the head and neck region is also associated with increased risk, perhaps because wide excision is limited by critical normal anatomy in many cases.[53,60–62] For patients that have a higher risk of local recurrence, particularly if a salvage procedure for local recurrence would be unacceptably morbid, adjuvant RT should be considered.

Considerations for Nodal Basins

Similar to local relapse risk in primary site, some pathologic features confer a high risk of regional recurrence in the dissected nodal basin. One of the most important prognostic factors is the presence of extracapsular extension (ECE). Retrospective studies have reported a regional recurrence rate ranging from 24% to 63% in patients with ECE compared with as low as 9% in patients without ECE.[63–66] Other pathologic features associated with an increased risk of regional recurrence include higher number of involved lymph nodes (≥4 lymph nodes vs fewer, 46%–53% v. 14%–25%, respectively) and increased lymph node size (≥3 cm vs <3 cm, 42% vs 24%, respectively).[64,65] Additionally, similar to the data related to risk of a local primary recurrence, there is a higher risk of regional relapse with nodal involvement in the head and neck region compared with other sites (33%–43% cervical vs 9%–28% axilla vs 13%–23% inguinal).[64]

These retrospective and single-arm studies prompted the Australian and New Zealand Melanoma Trials Group (ANZMTG) and Trans-Tasman Radiation Oncology Group (TROG) to conduct a randomized study evaluating the role of adjuvant RT for 250 high-risk patients.[67] The trial included patients with palpable lymph node involvement and a high risk of further lymph node field relapse based on the number of involved nodes (≥1 parotid nodes, ≥2 cervical or axillary nodes, or ≥3 inguinal nodes), large nodal size (≥3 cm for cervical, or ≥4 cm for axillary or inguinal), or ECE. With a median follow-up period of 40 months, adjuvant RT significantly reduced the risk of regional recurrence (19% vs 31% for no adjuvant RT; hazard ratio [HR], 0.56; ; 95% confidence interval [CI] 0.32–0.98; P = .04). A subsequent update by Henderson and colleagues[68] confirmed this observation. Although these data demonstrate the benefit of adjuvant RT on local or regional relapse, there was no significant impact on the risk of distant metastasis or OS. The role of adjuvant RT is also less clear with the development of effective adjuvant systemic therapies, which were not available at the time of this study. Thus, the use of adjuvant RT for patients with regional metastases requires a multidisciplinary discussion regarding relative risks and benefits.

ADJUVANT SYSTEMIC THERAPY

Adjuvant Interferon

Early reports of activity of interferon (IFN) α-2b in metastatic melanoma led to an investigation of the efficacy of this agent in the adjuvant setting after definitive surgery. The Eastern Cooperative Oncology Group (ECOG) 1684 showed a statistically significant improvement in relapse-free survival (RFS) for high-dose interferon (HDI) compared with observation (1.72 years vs 0.98 years; P = .0023). Although HDI was

approved by the Food and Drug Administration (FDA) in 1995, the initial impact on OS was not significant with longer follow-up.[69,70] Pegylation of IFN provided a way to increase the half-life of the drug in the body, reduced dosing frequency compared with the standard HDI, and mitigated some of the associated toxicities. The European Organization for Research and Treatment of Cancer (EORTC)C 18991 phase III trial randomized patients to pegylated IFN (PEG-IFN) for 5 years versus observation.[71] PEG-IFN treatment resulted in improved recurrence-free survival (RFS; 34.8 months vs 25.6 months; $P = .01$) and was eventually approved by the FDA in 2011. However, PEG-IFN did not significantly impact time to distant relapse or OS.[72] Because of the lack of OS benefit and significant toxicity, neither HDI nor PEG-IFN was used widely, nor were they used on comparator arms for the registration trials of adjuvant checkpoint inhibitors and targeted therapies. The use of HDI and PEG-IFN as adjuvant therapy for patients with melanoma has ceased.

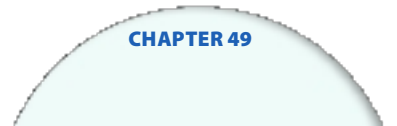
Adjuvant Ipilimumab

Cytotoxic T lymphocyte-associated antigen 4 (CTLA4) is an inhibitory immune checkpoint molecule that is expressed on the surface of activated and regulatory T-cells.[73] Ipilimumab is a fully human immunoglobulin (Ig) G1 anti-CTLA4 monoclonal Ab that binds to the T-cells and enhances antitumor immunity.[74] After being approved in 2011 for the treatment of patients with stage IV melanoma, ipilimumab received regulatory approval as an adjuvant treatment for patients with high-risk resected stage III melanoma in 2015 (Table 49–7). This approval was based on the results of the double-blind, phase III EORTC 18071 trial for patients with melanoma with AJCC seventh edition stage III melanoma who had undergone CLND and had not received adjuvant RT. A total of 951 patients were randomized one to one to treatment with ipilimumab (10 mg/kg) ($n = 475$) or placebo ($n = 476$) every 3 weeks for four infusions and then every 3 months for up to 3 years. Notably, the dose of ipilimumab used in this trial was threefold higher than the dose approved for patients with stage IV melanoma.[75] The trial showed that adjuvant ipilimumab significantly improved RFS, distant metastasis-free survival (DMFS), and OS vs placebo. However, adjuvant ipilimumab was resulted in grade 3 or 4 adverse events (AEs) in 54% of patients, including five treatment-related deaths. Different doses of ipilimumab (high dose at 10 mg/kg and low dose at 3 mg/kg) versus HDI were compared in the **E1609 trial, which was** a multicenter phase 3 study.[76] Interestingly, low-dose ipilimumab (3 mg/kg) significantly improved OS (HR, 0.78; 95.6% repeated CI, 0.61–0.99; $P = .044$) and RFS (HR, 0.85; 99.4% CI, 0.66–1.09; $P = .065$) versus HDI, but high-dose ipilimumab (10 mg/kg) did not. Furthermore, nearly 60% of patients experienced toxicities when treated with ipilimumab 10 mg/kg. Thus, even though ipilimumab 10 mg/kg was approved as adjuvant therapy for patients with stage III melanoma, concerns about its toxicity and cost generally limited its use, particularly with the emergence of safer alternatives.

Adjuvant Nivolumab

Programmed death 1 protein (PD-1) has emerged as another important immune checkpoint receptor expressed on the surface of activated T-cells. PD-1 has two known ligands, programmed cell death ligand 1 (PD-L1; B7-H1) and PD-L2 (B7-DC). The PD-1–PD-L1 interaction inhibits T-cell proliferation and activation and induces apoptosis of antigen-specific T-cells to prevent collateral tissue damage and autoimmune disease. The PD-1–PD-L1 pathway is hijacked by tumor cells to suppress antitumor immunity.[77] Therefore, blocking the interaction of PD-1 and PD-L1 has been studied as a therapeutic approach for cancers.

Nivolumab (anti–PD-1), which was approved for patients with stage IV melanoma in 2014, received regulatory approval as adjuvant therapy for patients with stage III melanoma in 2017 based on the results of the CheckMate 238 trial[78] (see Table 49–7). In this double-blind, phase III, randomized controlled trial patients with melanoma with surgically resected AJCC seventh edition stage IIIB, IIIC, or stage IV melanoma were treated with nivolumab ($n = 453$) 3 mg/kg every 2 weeks or ipilimumab ($n = 453$) 10 mg/kg (dosed every 3 weeks for four doses and then every 12 weeks), each for a maximum of 1 year. Treatment with nivolumab significantly improved RFS versus ipilimumab (HR for disease recurrence or death, 0.65; 97.56% CI, 0.51–0.83; $P < .001$). This difference was seen in patients both with high and low PD-L1 expression. Importantly, adjuvant nivolumab was much safer than ipilimumab, with lower rates of grade 3 or 4 AEs (14.4% vs 45.9%) and treatment discontinuation for toxicity (9.7 vs 42.6%) and was associated with no deaths because of toxicity (2 with ipilimumab).[78]



Adjuvant Pembrolizumab

Pembrolizumab (anti–PD-1) (approved for stage IV melanoma in 2014) was approved as adjuvant therapy for stage III melanoma patients in 2019 based on the EORTC 1325/KEYNOTE-054 phase III trial[79] (see Table 49–7). Patients ($n = 1019$) with stage IIIA, IIIB, or IIIC melanoma (AJCC seventh edition) who had undergone CLND were randomized one to one to treatment with pembrolizumab 200 mg intravenously ($n = 514$) or placebo ($n = 505$) every 3 weeks for up to 1 year. Pembrolizumab significantly improved RFS vs placebo (HR, 0.57; 98.4% CI, 0.43–0.74; $P = .001$) regardless of PD-L1 status. The grade 3 or higher AE rate

for pembrolizumab was 14.7%, very similar to that observed with adjuvant nivolumab. Immune-related adverse events (irAEs) of any grade occurred in 37.3% patients, which were mostly endocrine disorders, including hypothyroidism (14.3%), hyperthyroidism (10.2%), and thyroiditis (3.1%). One treatment-related death was reported in the pembrolizumab arm due to myositis. Notably, because the CheckMate 238 and the KEYNOTE-054 studies differed in both their patient populations and their control groups, meaningful cross-trial comparisons of adjuvant nivolumab and pembrolizumab are challenging, if not impossible.

Adjuvant Dabrafenib and Trametinib

As noted previously, *BRAF*^{V600} mutations are detected in about 50% of cutaneous melanomas. As will be discussed later, multiple targeted therapy regimens combining BRAF and MEK inhibitors have been approved for the treatment of BRAF-mutant patients with stage IV melanoma. Among these regimens, only combination treatment with dabrafenib and trametinib has also been approved by the FDA as adjuvant therapy for BRAF-mutant patients with stage III disease (see Table 49–7). This approval in 2018 was based on the results of the COMBI-AD trial, which was a double-blind, phase III trial that randomized 870 patients with *BRAF*$^{V600E/K}$ mutant stage IIIA, IIIB, r IIIC melanoma (AJCC seventh edition) who had undergone CLND to receive either dabrafenib (150 mg twice daily) and trametinib (2 mg once daily) or placebo for up to 1 year.[80] Treatment with dabrafenib and trametinib improved the RFS (HR, 0.47; P <.001) and DMFS (HR, 0.51; P <.001) versus placebo.[81] Recent analysis at a median follow-up period of 60 months showed that the median RFS for dabrafenib and trametinib had not been reached (not reached, NR; 95% CI, 47.9 months–NR) versus 16.6 months in the placebo arm (95% CI, 12.7–22.1 months).[82] The 4- and 5-year RFS rates were 55% (95% CI, 50%–60%) and 52% (95% CI, 48%–58%) with dabrafenib and trametinib versus 38% (95% CI, 34%–43%) and 36% (95% CI, 32%–41%) with placebo.

Dabrafenib and trametinib did have a higher rate of grade 3 or 4 toxicities (41% vs 14%) and toxicity-related treatment discontinuation (26% vs 3%) versus placebo. Although the toxicity rates with targeted therapy appear higher than with the PD-1 antibodies, the toxicities almost always resolve with treatment discontinuation, but toxicities with immunotherapy are sometimes long-lasting.

Adjuvant Chemotherapy

Although adjuvant chemotherapy is not approved for patients with cutaneous melanoma, there is evidence to support benefit in patients with mucosal melanoma. A randomized three-arm phase II trial assigned 189 patients with surgically resected mucosal melanoma (clinically localized or regionally metastatic) to observation, HDI (for 1 year), or chemotherapy (cisplatin 25 mg/m^2 on days 1–3 and temozolomide 200 mg/m^2 on days 1–5 every 3 weeks for six cycles).[83] Adjuvant cisplatin and temozolomide significantly improved RFS and OS compared with both HDI and observation. HDI also improved RFS and OS versus observation. Whereas fever and fatigue were more common toxicities in the HDI arm, anorexia and nausea and vomiting were more common with chemotherapy.

NEOADJUVANT THERAPY

The current standard of care for patients with clinical stage III melanoma to date is surgery followed by consideration of adjuvant systemic therapy (anti-PD-1 or targeted therapy) and/or potentially adjuvant radiation. However, several recent studies have demonstrated the feasibility and potential benefit of upfront neoadjuvant treatment with systemic therapy followed by surgery. Neoadjuvant approaches have the potential benefit of reducing surgical morbidity because of tumor shrinkage, personalizing adjuvant therapy based on pathologic response assessment, and facilitating insights into treatment resistance through the collection and analysis of biospecimens.[19] Neoadjuvant therapy is currently investigational for melanoma, but this strategy has become a pathway to drug approval in other diseases.

Neoadjuvant Immunotherapy

The effects of a single dose of neoadjuvant pembrolizumab before definitive surgery was evaluated in 27 patients with resectable stage IIIB/C or stage IV melanoma. All patients underwent surgery and then received adjuvant pembrolizumab for up to 1 year. A complete pathologic response (pCR) or near-complete pathologic response (near pCR) was observed in 8 of 27 patients (30%), all of whom remained recurrence free at a median follow-up period of 25 months after surgery. The DFS and OS rates at 2 years were 63% and 93%, respectively. The treatment was well tolerated, with no reported increase in postoperative complications.[84]

Combination neoadjuvant immunotherapy with nivolumab (anti–PD-1) and ipilimumab (anti–CTL-4) was studied in the phase II OpACIN-neo trial, which evaluated three different dosing schedules.[85,86] Patients with resectable stage III melanoma (n = 86) were randomized to two cycles of ipilimumab 3 mg/kg with nivolumab 1 mg/kg once every 3 weeks (group A), two cycles of ipilimumab 1 mg/kg with

nivolumab 3 mg/kg once every 3 weeks (group B), or two cycles of ipilimumab 3 mg/kg once every 3 weeks followed by two cycles of nivolumab 3 mg/kg every 2 weeks (group C). The pCR rates were 80%, 77%, and 65% in groups A, B, and C, respectively, and no pCR patients had recurred after a median follow-up period of more than 8 months. At a median follow-up period of 24.6 months, the median RFS and EFS were not reached in any of the three arms. Estimated 24-months RFSs were 84% (95% CI, 76%–92%) for the total population, 97% (95% CI, 93%–100%) for patients with a pathological response, and 36% (95% CI, 17%-74%) for patients without a pathological response. Group B regimen, which consisted of two cycles of neoadjuvant treatment with ipilimumab 1 mg/kg and nivolumab 3mg/kg, was well tolerated with only 20% grade 3 or 4 irAEs and a pathologic response rate of 77%.

Another trial evaluated neoadjuvant nivolumab as a single agent and in combination with ipilimumab followed by adjuvant nivolumab.[72] Patients (n = 23) with resectable stage III or oligometastatic stage IV melanoma were randomized to receive either neoadjuvant nivolumab (3 mg/kg) for four doses or neoadjuvant nivolumab (1 mg/kg) and ipilimumab (3 mg/kg) for three doses before definitive surgery. Neoadjuvant combination therapy achieved higher response rates (overall response rate [ORR], 73%; pCR, 45%) compared with single-agent neoadjuvant nivolumab (ORR, 25%; pCR, 25%) but also incurred much higher grade 3 to 4 toxicity (8% for monotherapy, 73% for combination). The trial was stopped early because of concerns regarding the efficacy of nivolumab monotherapy and the toxicity of nivolumab with ipilimumab.

Neoadjuvant Targeted Therapy

The safety and efficacy of neoadjuvant dabrafenib and trametinib have been evaluated in two phase II trials in patients with resectable *BRAF*$^{V600E/K}$ mutant clinical stage III or oligometastatic stage IV disease. In the NeoDT study, patients were randomized to standard-of-care surgery and adjuvant therapy (which at that time did not include adjuvant PD-1 or adjuvant dabrafenib and trametinib) or to neoadjuvant (8 weeks) and adjuvant (44 week) treatment with dabrafenib and trametinib.[87] Although initially planned for enrollment of 84 patients, the trial was halted early because the patients receiving neoadjuvant and adjuvant dabrafenib and trametinib (n = 14) had a markedly reduced risk of relapse compared with the control (n = 7) arm (HR, 0·016; 95% CI, 0.00012–0.14; P <.0001).[88] The radiographic response rate with neoadjuvant treatment was 85%, and the pCR rate was 58%. None of the patients with a pCR had developed evidence of distant metastasis in the initial report of the study (median follow-up, 7.1 months).[87]

In the single-arm NeoCombi study,[89] 35 patients with stage IIIB–C *BRAF*^{V600} mutant melanoma were treated with neoadjuvant (12 weeks) and adjuvant (40 weeks) dabrafenib and trametinib. At the median follow-up period of 27 months (interquartile range, 21–36), 35 patients had no evidence of clinical or radiologic progression during resection of the pretherapy tumor bed. All 35 patients achieved a pathological response after resection and pathological evaluation, with 17 (49%) patients achieving pCR and 18 (51%) achieving noncomplete pCR.

MANAGEMENT OF METASTATIC DISEASE

After decades of minimal progress, multiple immune and targeted therapies have received FDA approval for the treatment of patients with unresectable stage III or stage IV disease since 2011. These advances have improved the management and outcomes for patients dramatically.

Immunotherapy

Interleukin-2

Interleukin-2 (IL-2) is a growth factor normally secreted by CD4 T-helper cells that can activate effector CD8 T-cells and natural killer cells. Importantly, IL-2 provided the proof of principle that immunotherapy can achieve long-term cures in patients with stage IV melanoma, albeit only in about 5% (Table 49–8).[90] In addition to this low cure rate, IL-2 causes many toxicities, requiring hospitalization to administer and incurring a 1% to 2% treatment-related mortality rate. Thus, IL-2 is rarely used outside clinical trials, particularly in combination with adoptive T-cell therapy.[91]

Ipilimumab (Anti–Cytotoxic T Lymphocyte-Associated Antigen 4 Ab)

Ipilimumab was the first agent to significantly improve the OS of patients with stage IV or unresectable stage III metastatic melanoma. In the first positive phase III study in patients with melanoma, previously treated patients with advanced melanoma were randomized to receive gp100 vaccine, ipilimumab (3 mg/kg every 3 weeks for four doses), or ipilimumab with gp100 vaccine.[92] The response rates were 10.9% for ipilimumab and only 5.7% for ipilimumab with gp100. Both ipilimumab containing regimen improved OS (ipilimumab and gp100: median, 10 months; HR, 0.68; P <.001; ipilimumab single agent: median, 10.1 months; HR, 0.66;

FDA, Food and Drug Administration; N/A, not applicable; ORR, overall response rate; OS, overall survival; PFS, progression-free survival.

P = .003) compared with gp100 (median, 6.4 months). No difference in OS was detected between the ipilimumab groups (HR with ipilimumab plus gp100 ,1.04; P = .76).

Although the improvement in OS was important, gp100 was not a standard agent for the treatment of patients with this disease. Thus, 502 treatment-naïve patients with metastatic melanoma were randomized to treatment with dacarbazine alone or in combination with ipilimumab in another phase III study.[93] Ipilimumab was dosed at 10 mg/kg for four doses followed by maintenance therapy every 12 weeks. Both OS (median, 11.2 vs 9.1 months; HR, 0.72; P <.001) and PFS (HR, 0.76; P <.006) were significantly improved in the patients receiving ipilimumab. The ORRs were 15.2% with ipilimumab plus dacarbazine and 10.3% with dacarbazine alone. Although the response rate with ipilimumab was relatively low in both phase III studies, long-term follow-up has shown that the majority of these responses last more than 5 years and may even represent cures.[94] Ipilimumab (3 mg/kg every 3 weeks for four doses) was approved in 2011 for the treatment of patients with metastatic melanoma (see Table 49–8). Ipilimumab is associated with significant grade 3 and 4 toxicities,[95] with the most common irAEs being dermatitis (pruritus, rash), enterocolitis, endocrinopathies (hypophysitis, thyroiditis), and liver abnormalities (elevated serum liver test results, hepatitis) in approximately 20% of patients.

Anti–Programmed Death-1 Protein Antibodies

Pembrolizumab

Pembrolizumab was approved by the FDA in 2014 for patients with metastatic melanoma with disease progression after ipilimumab (and BRAF inhibitor therapy if $BRAF^{V600}$ mutation positive)[96] (see Table 49–8). The initial approval was based on a phase I trial comparing the efficacy of two different doses of pembrolizumab (2 mg/kg vs 10 mg/kg every 3 weeks) in patients with ipilimumab-refractory advanced melanoma. Both treatments achieved a 26% clinical response rate.[96,97] Notably, most clinical responses to pembrolizumab were ongoing at the time of those reports, and the median OS had yet to be reached. Subsequently, a phase III trial randomized 834 patients to treatment with pembrolizumab (2 mg/kg every 2 weeks or every 3 weeks for up to 2 years) versus ipilimumab (3 mg/kg every 3 weeks for four cycles). Pembrolizumab achieved significant improvements in response rate (33% for both dosing regimens vs 12%; P <.001), PFS (HR, 0.58; P <.001 for both dosing regimens) and OS (HR, 0.63; P <.0005 for every-2-week dosing; HR, 0.69; P <.0036 for every 3-week dosing).[97] In addition to being more active than ipilimumab, pembrolizumab was also safer because fewer than 5% of patients treated with pembrolizumab experienced grade 3 or 4 irAEs, and only approximately 10% experienced grade 3 or 4 toxicity of any kind.

Nivolumab

Nivolumab was also approved in 2014 for the treatment of patients with metastatic melanoma previously treated with ipilimumab (and a BRAF inhibitor for patients with a $BRAF^{V600}$ mutation)[98] (see Table 49–8). In a phase I study, 296 previously treated patients with advanced solid cancers received nivolumab at a dose of 0.1 to 10 mg/kg every 2 weeks for up to 2 years.[99] Objective responses were observed in 28% of 96 evaluable patients with melanoma, and the responses were durable, lasting at least 1 year in 13 of 18 patients treated for 1 year or more.

Nivolumab has also been shown to be more effective than chemotherapy in treatment-naïve patients. In a randomized phase III study of 418 previously untreated patients with metastatic melanoma, the 1-year OS rates were 72.9% with nivolumab and 42.1% with dacarbazine (HR, 0.42; P <.001)[100] The response rates with nivolumab and dacarbazine were 40% and 14%, respectively, and the median PFS times were 5.1 and 2.2 months, respectively (HR, 0.43; P <.001). Grade 3 or 4 treatment-related AEs were also less common with nivolumab (11.7%) than with dacarbazine (17.6%). At minimum follow-up periods of 38.4 months, 3-year OS rates remained higher for nivolumab compared with dacarbazine (51.2% vs 21.6%, respectively).[101]

Combination Immunotherapy: Anti–PD-1 with Anti–CTLA-4

Combination immunotherapy with nivolumab and ipilimumab received FDA approval in 2016 based on CheckMake-067 study.[102] In this randomized, three-arm, double-blind, phase III study, 945 previously untreated patients with stage IV or unresectable stage III metastatic melanoma received nivolumab -ipilimumab (n = 314), nivolumab monotherapy (n = 316) or ipilimumab monotherapy (n = 315) until progression or unacceptable toxic effects were observed, with PFS and OS as primary endpoints. Patients were randomly assigned one to one to one to receive intravenous nivolumab 1 mg/kg plus ipilimumab 3 mg/kg every 3 weeks for four doses followed by nivolumab 3 mg/kg every 2 weeks, nivolumab 3 mg/kg every 2 weeks plus placebo, or ipilimumab 3 mg/kg every 3 weeks for four doses plus placebo. The trial was powered to compare single-agent nivolumab and nivolumab plus ipilimumab treatments versus the ipilimumab monotherapy

arm. Randomization was stratified based on BRAF mutation status, metastasis stage, and PD-L1 status. A longer PFS was observed for nivolumab -ipilimumab (median, 11.5 months; 95% CI, 8.7–16.7) and for nivolumab immunotherapy (median, 6.9 months; 95% CI, 4.3–9.5) compared with ipilimumab monotherapy (median, 2.9 months; 95% CI, 2.8–3.4). Response rates were 58% for the combination, 45% for nivolumab, and 19% for ipilimumab. Treatment with nivolumab plus ipilimumab, however, also resulted in a higher rate (55%) of grade 3 or 4 AEs than nivolumab (16.3%) or ipilimumab (27.3%). Importantly, encouraging results were also seen in follow-up reports for the trial at both 3 years[103] and 5 years.[104] At 5-year minimum follow-up, the OSs were 52% in the nivolumab plus ipilimumab group, 44% in the nivolumab group, and 26% in the ipilimumab group.[104] The median OSs were more than 60 months (median not reached) in the nivolumab plus ipilimumab group and 36.9 months in the nivolumab group compared with 19.9 months in the ipilimumab group (HR for death with nivolumab plus ipilimumab vs ipilimumab, 0.52; HR for death with nivolumab vs ipilimumab, 0.63). No new toxicity concerns were noted, but grade 3 or 4 AEs were seen in 59% of patients in the nivolumab plus ipilimumab group, in contrast to 23% and 28% for single-agent nivolumab or ipilimumab, respectively. Of note, this study compared ipilimumab treatment with nivolumab -plus ipilimumab and nivolumab monotherapy, but it was not powered to directly compare the combination therapy with nivolumab monotherapy. An earlier randomized double-blind study in advanced untreated patients with melanoma compared nivolumab plus ipilimumab combination with single-agent ipilimumab and showed a similar significantly higher response rates and longer PFS rates for combination group than ipilimumab alone.[105]

In an effort to lower toxicity associated with the combination strategy, the CheckMate 511 study investigated whether nivolumab 3 mg/kg combined with ipilimumab 1 mg/kg (NIVO3 + IPI1) versus the inversed doses of the same drugs (ipilimumab 1 mg/kg, nivolumab 3 mg/kg: NIVO1 + IPI3) was associated with an improved safety profile.[106] Patients were randomly assigned to receive the investigated dose (NIVO1 + IPI3; $n = 180$) or the inversed dose (NIVO3 + IPI1; $n = 178$) once every 3 weeks for four doses. After 6 weeks, all patients received NIVO 480 mg once every 4 weeks until disease progression or unacceptable toxicity. The primary endpoint was incidence comparison the rate of grade 3 to 5 AEs between the treatment groups and results showed a much better safety profile for the NIVO3 + IPI1 group compared with its counterpart. The incidence of grade 3 to 5 AEs was 34% for the investigated doses compared with 48% with the NIVO1 + IPI3 arm ($P = .006$). Interestingly, OS, ORR, and median PFS were similar between the two arms. Although the efficacy endpoints were descriptive and secondary, this study suggests that low doses of ipilimumab can decrease toxicity without risking the established clinical benefit of combination therapy.

Pembrolizumab (2 mg/kg) was also tested in combination with low-dose ipilimumab (1 mg/kg) in the KEYNOTE-029, a phase 1b trial.[107] Most of the 153 patients enrolled (87%) were treatment naïve; however, some received prior targeted therapy or chemotherapy. ORR reached 61%, which is similar to that observed with nivolumab and ipilimumab combination therapy.[108] The estimated 1-year PFS and OS were 69% and 89%, respectively. Treatment-related grade 3 and 4 AEs occurred in 45% of patients.

Taken together, in patients without brain metastases, there is still uncertainty about which patients will benefit sufficiently from single-agent anti–PD-1 and in which patients the addition of ipilimumab is preferred or needed. However, in patients with brain metastases, the combination of ipilimumab and nivolumab is the preferred option despite the toxicity associated with this regimen. Trials with single-agent anti–PD-1 in patients with melanoma with asymptomatic brain metastases have reported overall intracranial response rates of about 20%.[109–111] Although the responses were durable, this response rate is about 50% lower than was reported in patients without brain metastases. In contrast, clinical trials evaluating the combination of ipilimumab (3 mg/kg) and nivolumab (1 mg/kg) in patients with melanoma reported durable intracranial responses in 50% to 55%, which is similar to results in previous studies in patients without brain metastases.[111,112] Although the combination regimen had a toxicity rate similar to previous trials, no new or unexpected toxicities were observed in patients with brain metastases. These results have led to ipilimumab plus nivolumab being considered as the standard systemic therapy option for patients with asymptomatic brain metastases.

Targeted Therapy

Targeted therapies are agents that inhibit the proteins or pathways (or both) that are activated in tumors by oncogenic events. Targeted therapies demonstrated efficacy in several cancers in which critical oncogenes have been identified, including melanoma, chronic myelogenous leukemia (*BCR-ABL*), breast cancer (*HER2/neu*), and gastrointestinal stromal tumors (GISTs; *KIT*), among others.

BRAF Inhibitors

As noted previously, point mutations that cause substitutions at the V600 residue of the BRAF protein ($BRAF^{V600}$) are the most common oncogenic events in

cutaneous melanoma. Vemurafenib was the first BRAF inhibitor to be approved for patients with this mutation, based on the results of the BRIM-3 phase III trial. In this study, 675 patients with metastatic melanoma with a *BRAF*^{V600E} mutation were randomized to treatment with vemurafenib or dacarbazine.[113] This trial was terminated at its first interim analysis because vemurafenib treatment significantly improved PFS (median, 5.3 months vs 1.6 months; HR, 0.26; P <.001) and OS (HR, 0.37; P <.001). The extended follow-up showed the ORRs were 57% for vemurafenib and 9% for dacarbazine treatments.[114] Vemurafenib also improved OS and thus was approved for the treatment of metastatic melanoma patients with a *BRAF*^{V600} mutation in 2011 (see Table 49–8).

Dabrafenib, another BRAF inhibitor, was evaluated in the BREAK-3 phase III trial in which 250 patients with *BRAF*^{V600E} mutant metastatic melanoma were randomized to treatment with dabrafenib or dacarbazine.[115] The ORRs were 50% for dabrafenib and 6% for dacarbazine, and dabrafenib treatment significantly improved PFS (median, 5.1 months vs 2.7 months; HR, 0.30; P <.0001), and OS (HR, 0.61; 95% CI, 0.25–1.48). At 5 years, PFS was 12% in the dabrafenib arm, whereas all dacarbazine-arm patients progressed or were censored.[82] Dabrafenib was approved for the treatment of patients with metastatic melanoma with a *BRAF*^{V600} mutation in 2013 (see Table 49–8).

Although most patients with metastatic melanoma with a *BRAF*^{V600} mutation achieve clinical benefit with single-agent BRAF inhibitor treatment, the median duration of response was only about 6 months, and about 90% of patients develop resistance by 1 year.[113,115] Multiple studies showed that the most common feature of the tumors at the time of resistance is reactivation of the MAPK (mitogen-activated protein kinase) signaling pathway, which is caused by a variety of mechanisms. Importantly, preclinical studies showed that inhibition of MEK, which is an effector of BRAF, could inhibit the growth of melanomas with acquired resistance to single-agent BRAF inhibitor treatment. This finding supported the rationale to determine if combining BRAF and MEK inhibitors was more effective than single-agent BRAF inhibitor treatment.[116] Interestingly, preclinical studies also suggested that MEK inhibitors could decrease the skin toxicity that was a unique side effect of the BRAF inhibitors[116] because up to 20% of patients developed proliferative skin lesions, including SCCs or keratoacanthomas.

Combination Therapy with BRAF and MEK Inhibitors

The first combination targeted therapy regimen to be tested in patients with metastatic melanoma with a *BRAF*^{V600} mutation was dabrafenib and trametinib. As noted earlier, single-agent dabrafenib was approved in the setting, with an approved dosage of 150 mg twice a day. Trametinib, a potent inhibitor of MEK1/2, was also approved for the treatment of patients with metastatic melanoma with a *BRAF*^{V600} mutation based on a randomized trial versus chemotherapy, at a dosage of 2 mg/day.[117] Although trametinib was more effective than chemotherapy, it had a lower response rate than single-agent BRAF inhibitors and more toxicity, and thus was generally not used as a single agent. In a phase I/II study, it was shown that combined treatment with dabrafenib and trametinib was well tolerated at the full dose of each drug.[118] Consistent with preclinical studies, the incidence of cutaneous SCC was 5% with dabrafenib combined with trametinib (D/T) and 17% with dabrafenib alone. Although toxicity was decreased, the most common side effect with D/T was pyrexia, which occurred more frequently with the combination (71%) than with dabrafenib alone (26%). Importantly, treatment with D/T was more effective than dabrafenib. Treatment with D/T resulted in significant improvements in response rate (76% vs 54%), with all patients achieving disease control, and PFS (median, 9.4 vs 5.8 months; HR, 0.39; P <.001).[118] These results formed the basis for comparison of D/T with single-agent dabrafenib and with single-agent vemurafenib in two separate phase III trials (COMBI-D and COMBI-V, respectively).[119,120] Combination treatment with D/T resulted in significant improvements in both PFS and OS compared with vemurafenib (HR, 0.56 for PFS; HR, 0.69 for OS) and dabrafenib (HR, 0.75 for PFS; HR, 0.63 for OS). Based on these results, D/T was approved for metastatic melanoma patients with a *BRAF*^{V600} mutation in 2014 (see Table 49–8). A recent pooled analysis of patients (n = 563) treated with D/T in the phase III studies with at least 5 years of follow-up showed that the median PFS was 11.1 months (95% CI, 9.5–12.8), and the median OS was 25.9 months (95% CI, 22.6–31.5). The 5-year PFS and OS rates were 19% and 34%, respectively. Thus, although many patients progress, a subset may achieve long-term disease control and survival with D/T.[121] D/T was also evaluated in patients with a *BRAF*^{V600} mutation with brain metastases in the COMBI-MB study.[122] In patients with a previously untreated brain metastases and a *BRAF*^{V600E} mutation, treatment with D/T achieved an intracranial response rate of 58% and an intracranial disease control rate of 78%, with no new or unexpected toxicities. Although these results were similar to those seen in previous studies, the median duration of response was 6.5 months, which was much shorter than that reported in patients without brain metastases in previous trials, and in contrast to the duration of intracranial responses reported for immunotherapies. The cause of the shorter duration of responses in brain metastases with D/T is currently unknown.

Combination therapy with vemurafenib and cobimetinib (V/C), another MEK1/2 inhibitor, was also superior to single-agent vemurafenib treatment in a phase III trial (see Table 49–8).[123] Both median PFS (9.9 vs 6.2 months; HR, 0.51; P <.001) and response rates (68% vs 45%; P <.001) were higher in the V/C group. Importantly, although slightly more grade 3 and 4 AEs were observed with V/C, there was no significant difference in the rate of study-drug discontinuation, and the number of secondary cutaneous cancers decreased with the combination therapy. V/C has less pyrexia than D/T but more photosensitivity.

The third approved BRAF–MEK combination, encorafenib and binimetinib (E/B), was approved by the FDA in 2018.[124] In the COLUMBUS phase III trial, patients with $BRAF^{V600E}$ and/or $BRAF^{V600K}$ mutated melanoma were randomly assigned to receive encorafenib 450 mg orally once daily with binimetinib 45 mg orally twice daily (n = 192), encorafenib 300 mg orally once daily (n = 194), or vemurafenib 960 mg orally twice daily (n = 191).[124,125] In the first head-to-head comparison of BRAF inhibitors, treatment with encorafenib achieved improved OS compared with vemurafenib (median, 23.5 months vs 16.9 months; HR, 0.76; P = .03). Although the maximum tolerated dose of single-agent encorafenib was 300 mg/day, a higher dose (450 mg/day) was feasible when it was given in combination with binimetinib. Consistent with other combinations, treatment with E/B achieved improved ORR (64% vs 41%), PFS (median, 14.9 months vs 7.3 months; HR, 0.51; 95% CI 0.39–0.67; P <.0001), and OS (median, 33.6 vs 16.9 months; HR, 0.54; 95% CI 0.41–0.71; P <.0001) compared with single-agent BRAF inhibitor (vemurafenib). Despite the use of the higher dose of encorafenib, E/B treatment had a slightly lower rate of grade 3 and 4 AE toxicities (58%) than either single-agent vemurafenib (63%) or encorafenib (66%).

KIT Inhibitors

Phase II studies of imatinib in metastatic melanoma patients with *KIT* mutations or amplifications have demonstrated much more promising results than observed in unselected patients.[126–128] The response rates reported in these trials range from 15% to 30%, with subgroup analyses demonstrating response rates of up to 50% in patients with the most common recurrent mutations detected in melanomas. Although these results are a marked improvement compared with those observed in unselected patients, the response rates are not as high as those in patients with GISTs with *KIT* mutations treated with the same inhibitors. Studies are ongoing to identify the KIT-mutant melanoma patients who are most likely to benefit from KIT inhibitors and combinatorial strategies that are more effective.

Other Therapies

Talimogene Laherparepvec

TVEC is an attenuated and genetically coded herpes simplex virus type 1 (HSV-1) engineered to express human granulocyte-macrophage colony-stimulating factor (GM-CSF) and designed to selectively replicate in tumor cells to facilitate antigen release, presentation, and systemic antitumor immune response.[129,130] Local GM-CSF expression promotes the migration and maturation of dendritic cells, aiding in antigen presentation specific to CD4 T-helper and CD8 C cytotoxic T-cells, initiating an immune response by activating both adaptive and innate immune cells.[130,131] TVEC was approved in 2015 for the local treatment of unresectable cutaneous, subcutaneous, and nodal lesions in patients with recurrent melanoma after initial surgery based on the results of the OPTiM trial. In this multicenter international phase III trial, 436 patients with unresectable stage IIIB to IV melanoma were randomly assigned to receive either TVEC (n = 295) or GM-CSF (n = 141).[132] TVEC was injected directly into the tumors, and subsequent doses were administered 3 weeks after the first dose and then once every 2 weeks. GM-CSF was administered subcutaneously every day for 14 days in 28-day cycles. The ORR in the TVEC group was 26.4% compared with 5.7% in the GM-CSF group. Furthermore, responses were more durable in the TVEC arm (16.3% vs 2.1%; P <.001) with 10.8% of complete responses. The OS was 23.3 months compared with 18.9 months with GM-CSF (P = .051). No unexpected or new toxicities were reported and included fatigue, chills, low-grade fevers, nausea, flulike symptoms, and pain at the injection site.

Although TVEC achieved a high rate of local responses, it had very low activity against distant metastases and in patients with advanced stage IV disease. Thus, clinical trials have tested if combining TVEC with systemic immunotherapy would prove more effective. In one study, 198 patients were randomized to treatment with ipilimumab alone or with TVEC.[133] Although the combination arm achieved a higher response rate (39% vs 18%; odds ratio, 2.9; P = .002), there was no significant improvement in PFS (median, 8.2 months vs 6.4 months; HR, 0.83; P = .35). Trials evaluating TVEC in combination with anti–PD-1 antibodies are ongoing after promising results in initial small studies.[134]

Chemotherapy

Dacarbazine is the only chemotherapy agent approved by the FDA for the treatment of metastatic melanoma[135] (see Table 49–8). Approved in 1975, dacarbazine achieves clinical responses in 5% to 10% of patients. The overwhelming majority of these responses are

short-lived, and dacarbazine has never been proven to be superior to another agent in a phase III trial. Temozolomide is an orally available prodrug that is metabolized to the same active intermediate as dacarbazine. Temozolomide was shown to be noninferior to dacarbazine in a phase III trial.[136] Temozolomide has the ability to cross the intact blood–brain barrier, but a large phase II trial failed to show significant efficacy.

In addition to these single agents, a variety of combination chemotherapy regimens have been evaluated in patients with melanoma.[137] Although these regimens achieve clinical responses in up to 20% to 25% of patients, none has been shown to significantly improve OS versus single-agent chemotherapy, and all are associated with increased toxicity.

SPECIAL CLINICAL SCENARIOS

Mucosal Melanoma

Unlike cutaneous melanoma, mucosal melanomas are rare and only represent only about 1 % of all melanomas.[138] Mucosal melanomas can originate in almost any part of mucosal membranes, but they most often arise from the mucosa of the nasal cavity and accessory sinuses, oral cavity, anorectum, vulva, and vagina. Surgical resection is the primary treatment modality if complete resection is feasible.

Overall, patients with metastatic mucosal melanoma have a significantly worse prognosis than patients with cutaneous melanomas.[139] Retrospective studies have reported median OS of only 6 to 18 months after treatment with checkpoint inhibitors and a decreased response rate compared with cutaneous melanomas.[140–143] Although *BRAF* mutations are common in patients with cutaneous melanomas, they are quite rate in mucosal melanomas.[144] *KIT* mutations are more frequent in this disease, and they represent a possible therapeutic target.[24,145,146] As described earlier in this chapter, KIT inhibitors have shown some efficacy in mucosal melanoma with certain *KIT* mutations.[127,147] Finally, different chemotherapy regimen have been used in patients with mucosal melanoma; however, no systemic therapy has been shown to significantly improve outcomes.[148]

Uveal Melanoma

Uveal melanomas, which include melanomas arising in the choroid, ciliary body, and iris of the eye, represent the most common primary intraocular malignancy in adults.[149] Approximately 1500 new cases are diagnosed in the United States each year.[150] BRAF mutations are not detected in these tumors, but more than 80% have an activating mutation in either the GNAQ or *GNA11 gene*.[26,151] For uveal melanoma restricted to the eye, treatment options include brachytherapy, external-beam radiotherapy, photon-based radiation, or surgical approaches (ie, local resection and enucleation of the affected eye). However, about 50% of patients eventually develop metastatic disease.[152] Interestingly, uveal melanoma has a high propensity to metastasize to the liver, with more that 90% of patients with metastatic uveal melanoma found to have hepatic involvement.[153] Treatment options for metastatic patients remain unsatisfactory because even the checkpoint inhibitor combination with ipilimumab and nivolumab have showed poor ORRs in this subtype.[154–156]

MD ANDERSON PRACTICE TIPS

- A standardized and contemporary melanoma staging system allows accurate risk stratification and prognostication to guide and personalize patient management. The eighth edition of the AJCC melanoma staging system, which was formally implemented in January 2018, included several changes from the seventh edition staging system. Revisions were based on analysis of a large international melanoma database and reflect our contemporary understanding of the natural history of metastatic melanoma and the clinical management of patients with cutaneous melanoma.
- The publication of prospective clinical trials showing that CLND did not improve MSS and resulted in increased toxicities (ie, lymphedema) rapidly led to the general discontinuation of this practice in patients with a positive SLNB. However, CLND provides prognostic information (ie, number of involved lymph nodes), and such surgery was required for participation in many adjuvant therapy registration studies. This change in practice needs to be considered when discussing prognosis and treatment outcomes.
- Although neoadjuvant therapy has not achieved regulatory approval in melanoma, this approach is used in many diseases to personalize adjuvant therapy, and early results in patients with melanoma are very promising. Patients with high-risk stage III disease should be managed using a multidisciplinary approach, with strong consideration for clinical trial participation when feasible.
- For patients with a BRAF V600 mutation, both immunotherapy and targeted therapy treatments yield significant benefit as adjuvant therapy for resectable stage III disease and as definitive therapy for stage IV or unresectable stage III disease. The treatments differ in many ways, including route of administration; rates, kinetics, and duration of clinical responses; and the types, duration, and management of toxicities. Both immunotherapy and targeted therapy have shown efficacy in the second-line setting after failure of the other modality. Treatment selection for patients with a BRAF V600 mutation requires an understanding of the relative risks and benefits of each approach, ideally integrating disease features and patient comorbidities, to inform treatment decisions.
- Single-agent anti–PD-1 antibody therapy and combination immunotherapy with ipilimumab and nivolumab were both approved for patients with stage IV or unresectable stage III melanoma based on superior outcomes compared with single-agent anti–CTLA-4 antibody treatment. Definitive data comparing anti–PD-1 versus combination ipilimumab and nivolumab is currently lacking, although the available data do strongly suggest superiority for the combination in patients with asymptomatic brain metastases. Selection of single-agent versus combination immunotherapy should include consideration of efficacy, toxicity, support systems, and sites of disease.
- The trials that led to the approval of the described immunotherapies for metastatic disease were largely conducted in patients with cutaneous melanoma. These agents are approved for patients with mucosal and uveal melanoma but yield significantly lower response rates in such patients.

Vinod Ravi
Shreyaskumar Patel

KEY CONCEPTS

- Sarcomas represent a heterogenous group of more than 70 tumor types, many with unique disease biology, natural history, and chemotherapeutic sensitivity, driving a growing awareness and interest in subtype-specific therapy.
- Tumor histology, size, location, and the presence or absence of metastasis at diagnosis are the most important and well-established prognostic factors for patients with soft tissue sarcoma (STS).
- Although the role of adjuvant chemotherapy remains controversial, adjuvant chemotherapy containing anthracyclines in combination with ifosfamide is associated with improved disease-free and overall survival among patients with high-risk STS.
- The majority of gastrointestinal stromal tumors harbor activating mutations in either *KIT* or *PDGFRA*, conferring sensitivity to imatinib as well as other tyrosine kinase inhibitors. Mutational testing is recommended for both prognosis and to guide treatment selection.
- Patients with osteosarcoma and other high-grade bone sarcomas often present with micrometastatic disease at the time of diagnosis. Contemporary treatment consists of neoadjuvant chemotherapy followed by limb-sparing surgery and additional adjuvant chemotherapy.
- The lung is the most common site of relapse and metastasis for patients with sarcomas after completion of primary treatment. Surgery with or without additional chemotherapy should be pursued in patients with resectable lung metastases and can result in cure in a subset of patients who can be rendered disease free.

INCIDENCE

Sarcomas are a rare and heterogeneous group of tumors that arise from mesenchymal tissues. According to the estimates of the American Cancer Society, approximately 1.8 million people were projected to be diagnosed with cancer in the United States in the year 2020; an estimated 16,730 new sarcoma cases accounts for just less than 1% of new cancer cases and approximately 1% of cancer-related deaths in the United States annually.[1] Approximately 80% (13,130) of new sarcoma cases arise in soft tissue, and the remaining 20% (3600) are of bone origin.

EPIDEMIOLOGY AND PATHOGENESIS

The etiology and pathogenesis of most sarcomas are not well understood. Multiple environmental factors, including radiation and chemical exposures, trauma, and infection, have been associated with the development of soft tissue and bone sarcomas. Both sporadic and inherited molecular and genetic aberrations have been identified in specific subsets of sarcoma and have been implicated in sarcomagenesis.

Several inherited familial cancer syndromes have been associated with a predisposition to development of soft tissue and bone sarcomas. The Li-Fraumeni syndrome resulting from a germline mutation of the *TP53* tumor suppressor gene is associated with increased risk of soft tissue sarcomas (STS) and osteosarcoma among several other cancers in children and young adults.[2] Hereditary retinoblastoma is also associated with the development of sarcomas, both osteosarcoma and STS.[3] Neurofibromatosis type 1 (NF1) is associated with an increased risk of development of sarcoma in a preexisting neurofibroma, resulting in a malignant peripheral nerve sheath tumor.[4] Sarcomas have been associated

with other rare cancer predisposition syndromes, including Werner syndrome, familial adenomatous polyposis, and Gardner syndrome, among others. A more recent genetic study of multiple sarcoma cohorts identified pathogenic germline variants in about half of sarcoma patients, including alterations in *TP53, ATM, ATR,* and *BRCA* as well as other novel cancer genes, revealing the hereditary nature of most cases.[5]

Recurrent cytogenetic abnormalities have been identified in many sarcomas and are thought to contribute to sarcomagenesis. Genetic profiling of bone and STS has expanded the characterization of mesenchymal tumors beyond translocation-positive and translocation-negative categorizations to identify three distinct groups: (1) genetically unstable sarcomas with complex karyotypes; (2) tumors with specific, recurrent genetic alterations such as translocations, deletions, or copy number variations; and (3) tumors with molecular aberrations such as amplifications, mutations, or loss of heterozygosity (Table 50–1). These alterations serve an important role in diagnosis and prognosis and have potential implications for therapy.

TABLE 50–1 Selected Genetic Alterations in Soft Tissue Sarcomas

Tumor	Cytogenetic Abnormality	Gene Product
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14) t(1;13)(p36;q14) t(X;2)(q13;q35)	*PAX3-FOXO1A* *PAX7-FOXO1A* *PAX3-AFX*
Alveolar soft parts sarcoma	t(X;17)(p11.2;q25)	*ASPL-TFE3*
Clear cell sarcoma	t(12;22)(q13;q12) t(2;22)(q32;q12)	*EWSR1-ATF1* *EWSR1-CREB1*
Congenital fibrosarcoma	t(12;15)(p13;q25)	*ETV6-NTRK3*
Dermatofibrosarcoma protuberans	t(17;22)(q22;q13)	*COL1A1-PDGFB*
Desmoplastic small round cell tumor Epithelioid hemangioendothelioma	t(11;22)(p13;q12) t(1;3)(p36;q25)	*EWSR1-WT1* *WWTR1-CAMTA1*
Endometrial stromal sarcoma	t(7;17)(p15;q11)	*JAZF1-SUZ12*
Gastrointestinal stromal tumor	Activating mutations Overexpression Loss of 14q LOH of 22q Loss of 1p	*KIT, PDGFR, BRAF* *ETV1*
Inflammatory myofibroblastic tumor	t(1;2)(q22-23;p23) t(2;19)(p23;p13.1)	*TPM3-ALK* *TPM4-ALK*
Low-grade fibromyxoid sarcoma	t(7;16)(q32–34;p11) t(11;16)(p11;p11)	*FUS-CREB3L2* *FUS-CREB3L1*
Lipoma	t(3;12)(q27-28, q14-15)	*HMGA2-LPP*
Malignant peripheral nerve sheath tumor	Inactivating	Deletion of *NF1*

Molecular testing has become more widely used for diagnosis in STS, identifying specific abnormalities in certain histologic subtypes.[6] For example the t(x;18) translocation is a specific marker for synovial sarcomas. The transcript formed from this translocation (*SYT-SSX*) can be detected using polymerase chain reaction testing. In one study, the *SYT-SSX* transcript was positive in 84.5% of tumors in which the diagnosis of synovial sarcoma was certain based on histology and 24.3% of tumors in which synovial sarcoma was considered but not first in the differential diagnosis.[7] Other examples include the *FUS-DDIT3* translocation in myxoid liposarcoma or presence of *MDM2* amplification in dedifferentiated liposarcoma.

Specific translocations have also been investigated as prognostic biomarkers and potential therapeutic targets. Perhaps the best known is the *EWS-FLI1* transcript in Ewing sarcoma was previously identified as an independent prognostic factor,[8] but more recent studies have not found an association, potentially because of improved therapeutic regimens.[9] Alternatively, in alveolar rhabdomyosarcoma, translocation-negative tumors have better outcomes than translocation-positive tumors despite histologic appearance.[10] More recently, a subset of sarcomas harboring *NTRK* fusions have been identified in which the presence of an oncogenic *NTRK* fusion is a predictive biomarker that confers sensitivity to *NTRK* inhibitors.[11]

SOFT TISSUE SARCOMA

Soft tissues include fibrous, adipose, and vascular structures as well as muscles and tendons and are mesenchymal in origin. STS are a heterogeneous group encompassing approximately 70 different histologic subtypes based on their resemblance to normal tissues rather than the tissue of origin.

Clinical Presentation

STS can occur in any anatomic region. The majority of STS arise from the extremities (60%) followed by the trunk (30%) and the head and neck region (10%). The most common presenting symptom is a soft tissue mass or swelling. Pain is reported by only about one third of patients at presentation. Patients with a soft tissue mass that is increasing in size, a mass larger than5 cm, or a mass that is deep to deep fascia, regardless of pain, should be referred for evaluation of a suspected STS.

Evaluation

Evaluation of a suspected STS begins with a comprehensive history and physical examination. Imaging evaluation is dependent on the site of disease. For soft tissue tumors of the extremities, head and neck, and pelvis, magnetic resonance imaging (MRI) is preferred. STS found in the retroperitoneum and abdomen are generally best evaluated by contrasted computed tomography (CT). Positron emission tomography (PET) imaging can distinguish histologic grade to a degree based on tumor standardized uptake values (SUVs).[12] For both STS and bone sarcomas, PET imaging is also useful for early response assessment where it has been shown to predict survival after initial cycle of therapy among patients receiving neoadjuvant chemotherapy for high-grade STS.[13]

A biopsy is essential to diagnosis, and the method of biopsy chosen should be the least invasive technique available to make a definitive diagnosis. A core-needle biopsy is sufficient; however, multiple cores should be obtained to improve diagnostic yield. If an open biopsy is performed, it should be planned such that the biopsy tract can be removed at the time of definitive surgical resection to reduce the risk of seeding and recurrence. An excisional biopsy may be used for small or superficial lesions; however, careful examination of margins and planning of the orientation of the resection should always be performed. Fine-needle aspiration is not recommended but can be useful in confirming recurrence, assuming that an experienced sarcoma cytopathologist is available.[14]

Pathology

Sarcomas are classified primarily according to their tissue appearance and histologic grade and sometimes the cell of origin. This can be difficult because approximately 70 different histologic types of STS are recognized. Histologic diagnosis is classified by the updated 2020 World Health Organization criteria.[15]

Pathologists often separate sarcomas into three histologic grades using the Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) grading system, which is determined by differentiation, mitotic activity, and necrosis. Natural history and prognosis can be predicted based on histologic grade, and this spectrum varies among the histologic subtypes of sarcoma.[16] Immunohistochemistry, cytogenetics, and molecular pathology can aid in making a diagnosis.

Staging and Prognosis

The American Joint Committee on Cancer (AJCC) staging system may be used for STS and includes tumor, node, metastasis stage as well as histologic grade (G) (https://www.cancer.org/cancer/soft-tissue-sarcoma/detection-diagnosis-staging/staging.html).[17] The updated eighth edition has established separate T stage and prognostic groups for STS arising in the

extremity and trunk or retroperitoneum. In addition, sarcomas of the head and neck or viscera have separate specific T staging. The staging of gastrointestinal stromal tumors (GISTs) is considered separately.

Several clinicopathologic factors are important for treatment planning and prognosis assessment including tumor grade, size of the primary tumor, depth of invasion, and extent of disease. High-risk features for local recurrence or distant metastases are high-grade lesions, primary tumor larger than 5 cm, and deep tumor location. Approximately 50% of patients with intermediate- and high-grade STS will develop metastatic disease requiring systemic therapy.[18] The 5-year overall survival (OS) for STS is around 50%, with local control and distant disease being the key determinants.

Because of limitations with the AJCC staging system, multiple nomograms and prognostic tools have been developed to aid clinicians in risk stratification for both extremity and retroperitoneal sarcomas. The Sarculator is one such publicly available app-based nomogram derived from an international cohort of patients with sarcoma treated in major sarcoma centers that allows for prediction of OS and distant metastasis in patients after surgical resection of STS of the extremity.[19] It also includes a second nomogram for patients with primary retroperitoneal sarcomas to predict histology-specific disease-free survival (DFS) and OS.[20]

Treatment

Treatment of patients with sarcoma requires a multidisciplinary approach with experienced medical, surgical, and radiation oncologists, pathologists, and radiologists. An improved understanding of STS subtypes in regard to natural history, response to chemotherapy, and potential for targeted therapies has led to more subtype-specific treatment according to individual histology.

Treatment of Local Disease

Surgery

For local disease, surgical resection is the mainstay of treatment. Sarcomas tend to expand and compress tissue planes, which produce a pseudo-capsule comprising normal tissue interlaced with tumor tissue. Wide local excision is preferred with the ideal surgical margins being 2 to 3 cm. If positive margins are confirmed by pathology, re-excision to obtain negative margins is important when feasible to improve local control and relapse-free survival. For patients with borderline resectable tumors, consideration should be given to neoadjuvant therapy depending on the tumor histology, patient's performance status, and comorbidities.

Importantly, sarcomas have a less than 4% prevalence of lymph node metastases.[21] For this reason, routine regional lymph node dissection is often not required. However, patients with synovial sarcoma, clear cell sarcoma, rhabdomyosarcoma, angiosarcoma, and epithelioid sarcomas have a higher incidence of lymph node metastases and should be evaluated closely for lymphadenopathy.

Improved surgical techniques and multimodality treatment have resulted in a decrease in radical resection of extremity tumors with a corresponding rise in limb-sparing procedures combining wide local resection with preoperative or postoperative chemotherapy, radiotherapy, or both. The vast majority of patients with localized sarcomas of the extremities can safely undergo limb-sparing procedures to preserve limb function and adequately maintain local control without compromising OS.[22]

Radiation

Although radiation is not effective for the treatment of gross disease, it has been a useful adjunct to surgery in the treatment of microscopic local disease and for palliation of symptoms. Radiation therapy is commonly used in the preoperative or postoperative adjuvant setting. Because there are pros and cons as to the timing of radiation therapy, this topic remains controversial; appropriate discussion between radiation oncologists, medical oncologists, and surgeons is required in planning the treatment of each patient.

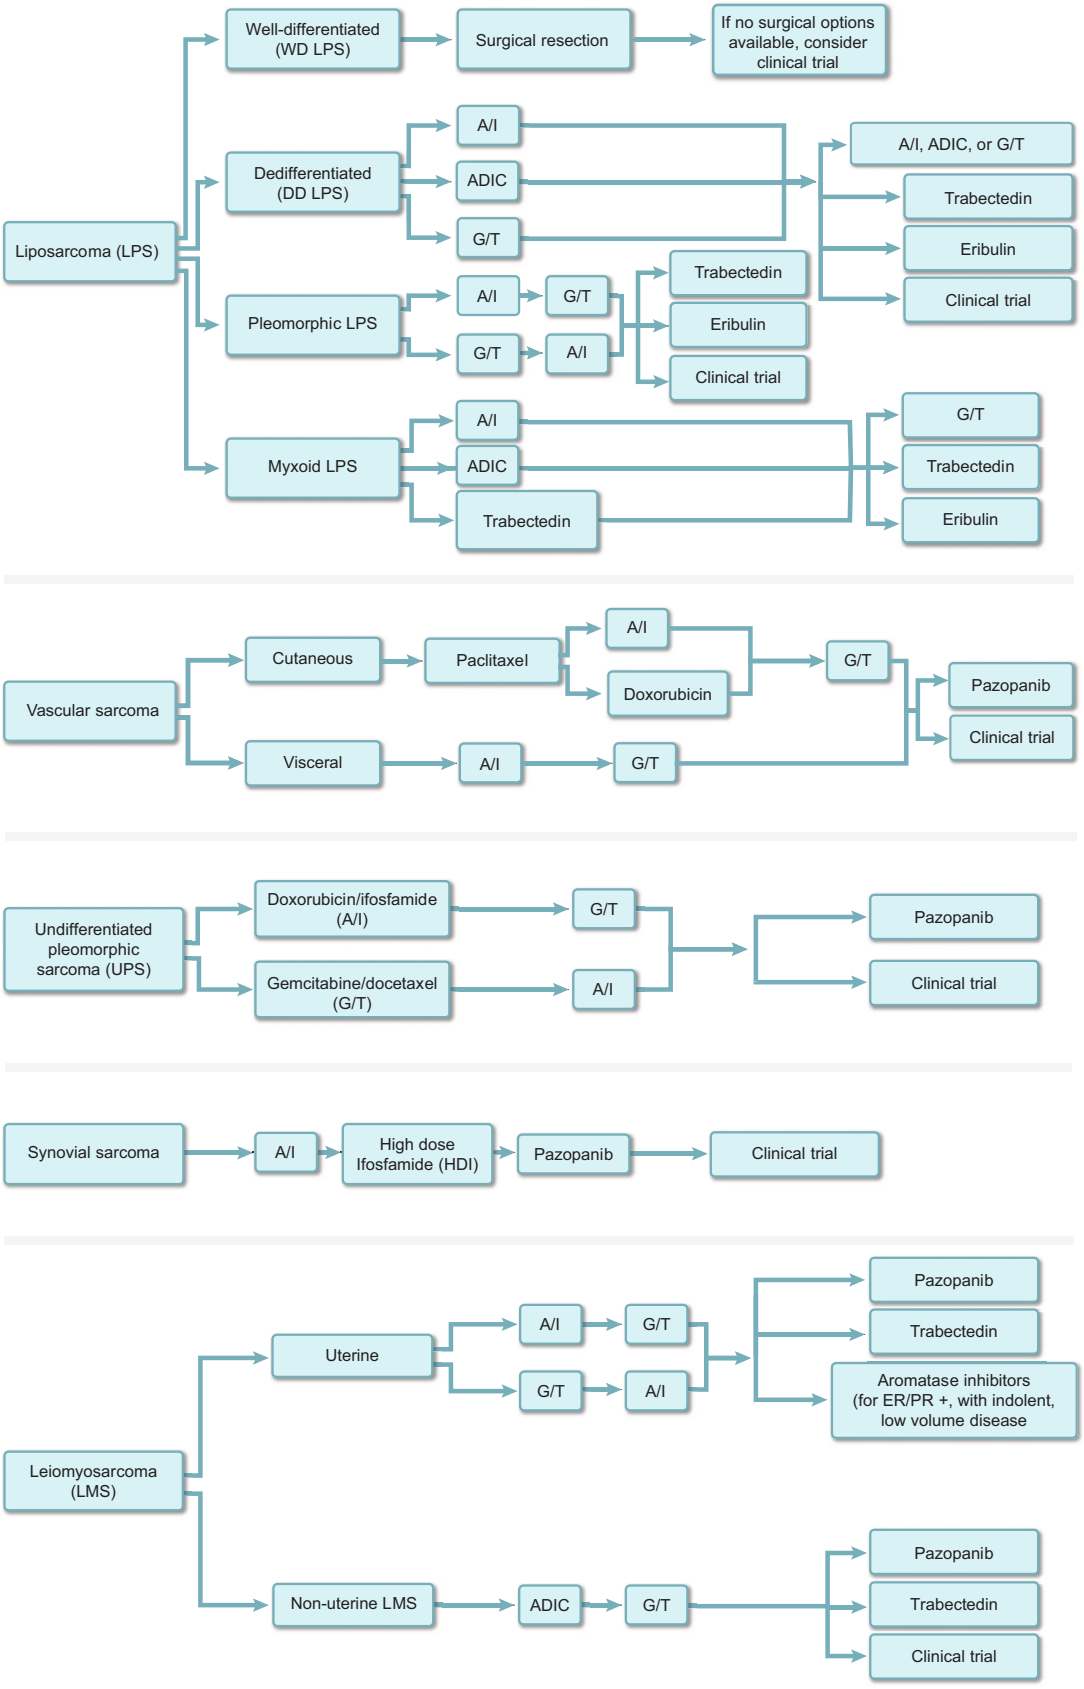
Preoperative radiation has several advantages over postoperative radiation, including smaller radiation portals, conversion to a limb-sparing procedure, reduction of the extent of the surgical procedure, and lower radiation doses, which can be used because there are theoretically fewer radio-resistant hypoxic cells within the tumor, and surgical removal can supplement the boost.[23] Preoperative radiation can improve local control, especially with larger tumors that were initially considered unresectable. However, preoperative radiotherapy may lead to difficulty in assessing pathologic responses to preoperative chemotherapy and may also contribute to delayed wound healing. The modality of choice is external-beam radiotherapy (EBRT), and a dose of 50 Gy or more is often required to obtain local control. At these dose levels, the entire circumference of the extremity must not be irradiated to avoid lymphedema. A period of 4 to 6 weeks is needed after preoperative radiation to prevent wound complications. After the surgical resection, close or positive margins could be treated with a radiation boost if feasible. Brachytherapy, EBRT, or intraoperative radiotherapy can be used by experienced clinicians in appropriate situations.

Intensity-modulated proton therapy (IMPT) has become a tool with anatomic specific indications in

patients with sarcoma. Specifically, this modality is frequently used to treat chordomas and chondrosarcomas of the skull base, where a complete resection may not be possible or associated with significant morbidity. In one large study involving 222 patients with chordomas and chondrosarcomas, a mean dose of 72.5 with or without 2.2 Gy relative biologic effectiveness (RBE) was associated with 7-year local control rates of 70.9% and 96.6%, respectively.[24] Pediatric patients with rhabdomyosarcoma may receive IMPT to the parameningeal space or orbital region to effectively target the tumor while reducing morbidity to surrounding structures. In 1 of 83 children with rhabdomyosarcoma (RMS) treated with proton therapy, a median dose of 54 Gy (RBE) was associated with a 5-year local control rate of 78.5% and a 5-year OS of 80.6%.[25]

Postoperative radiation therapy should be considered in patients with high-grade STS of the extremities with positive microscopic margins (<1 mm from the inked margin). In this setting, adjuvant radiation improved the 5-year local control rate compared with the no RT group (74% vs 56%; P =.01).[26] Adjuvant IMRT has been shown to reduce local recurrence as compared with conventional EBRT for primary STS of the extremity (hazard ratio [HR], 0.46; P =.02).[27] The interval of time between surgery and initiation of radiation therapy is a controversial but legitimate concern. The most recent STS guidelines issued by the National Comprehensive Cancer Network (NCCN) suggest the interval should be no greater than 6 weeks.[28]

Radiation therapy is occasionally used as the sole treatment modality for palliation for some patients with STS. These patients are often those who have unresectable disease or who are not appropriate candidates for surgery or chemotherapy. There have been reports of 5-year survival rates ranging from 25% to 40% with radiation therapy alone and of local control rates of approximately 30%, depending on the primary tumor's size and biology.[29] For patients with oligometastatic disease involving the lungs, liver, or musculoskeletal sites, stereotactic body radiation therapy (SBRT) offers a means to exert control with minimal rates of late toxicities. At times it may be used to treat a single chemotherapy-resistant lesion while all other sites of disease may be responding to chemotherapy. Typical doses range from 30 to 60 Gy in 1 to 8 fractions for lesions with a median size of 2 to 12 cm^3.[30] Local control rates at 2 years for selected sites range from 86% to 98%. In addition, an analysis of several multicenter phase I/II trials involving SBRT with long-term follow-up demonstrated grade 3 or greater toxicities at 2 years of 2% and no grade 3 or greater toxicities at 3 years.[31] These toxicities were limited to neurologic adverse events such as radiculopathy.



Chemotherapy

Systemic therapy is primarily used in the metastatic or advanced disease setting as well as neoadjuvant or adjuvant therapy for selected patients with high-risk STS. Treatment relies primarily on conventional chemotherapy agents, which are largely unchanged over the past three decades. In general, tumors with a higher grade are more likely to respond to chemotherapy; however, chemosensitivity varies based on histologic subtype (Table 50–2). An understanding of chemosensitivity and molecular aberrations based on sarcoma subtype has led to histology-driven treatment algorithms for specific STS such as leiomyosarcoma (LMS), myxoid liposarcoma, and angiosarcomas (Fig. 50–1). This approach is particularly important in considering targeted therapies for specific subtypes that are considered chemoresistant such as alveolar soft parts sarcoma (ASPS).

The two most active agents in the treatment of STS are doxorubicin and ifosfamide, both of which exhibit a dose-dependent response curve. Doxorubicin is most active at doses of 75 mg/m^2 or greater with single-agent response rates of approximately 20% to 35%.[32] Ifosfamide has been shown to

TABLE 50–2 Relative Chemosensitivity of Soft Tissue Sarcomas

Relative Chemosensitivity	Example
Highly sensitive (chemotherapy standard of care in management)	Ewing sarcoma family of tumors Embryonal and alveolar rhabdomyosarcoma Desmoplastic small round cell tumor (DSRCT)
Sensitive to chemotherapy	Synovial sarcoma Small cell sarcoma Myxoid or round cell liposarcoma Uterine leiomyosarcoma
Moderate sensitivity to chemotherapy	Undifferentiated pleomorphic sarcoma Pleomorphic liposarcoma Myxofibrosarcoma Pleomorphic rhabdomyosarcoma Leiomyosarcoma Malignant peripheral nerve sheath tumor Angiosarcoma
Insensitive to chemotherapy	Dedifferentiated liposarcoma Clear cell sarcoma Endometrial stromal sarcoma Epithelioid sarcoma
Chemoresistant (chemotherapy risk clearly outweighs benefit)	Gastrointestinal stromal tumor Alveolar soft parts sarcoma Extraskeletal myxoid chondrosarcoma Well-differentiated liposarcoma

produce single-agent response rates similar to those of single-agent doxorubicin when used at doses of 10 g/m^2 or higher.[33] The response rate in patients with STS whose disease failed doxorubicin-based therapy and who then received high-dose ifosfamide as a single agent was 29%. Therefore, high-dose ifosfamide as a single agent at doses of 14 g/m^2 is sometimes used as a salvage regimen at the University of Texas MD Anderson Cancer Center (MDACC) for selected histologies.

Combination therapy with dose-intense doxorubicin and ifosfamide has been shown to improve response rates, progression-free survival (PFS), and possibly OS. The combination of doxorubicin (75 or 90 mg/m^2) and ifosfamide (at 10 g/m^2) was evaluated at MDACC in patients with STS and demonstrated a 75% response rate (95% confidence interval [CI], 59%–71%; complete response [CR], 12%) in patients with primary tumors of the extremities and a 68% response rate (95% CI, 56%–80%; CR, 12%) in patients with primary disease at any site.[34] The response rates according to histology were as follows: malignant fibrous histiocytoma, 69%; synovial sarcoma, 88%; unclassified sarcomas, 60%; nongastrointestinal LMS, 50%; liposarcomas, 56%; angiosarcomas, 83%; and neurogenic sarcomas, 40%; other miscellaneous histologies demonstrated objective response rates of 45%. In the large, randomized phase III European Organization for Research and Treatment of Cancer (EORTC) 62012 trial comparing single-agent doxorubicin with doxorubicin in combination with ifosfamide, the combination group had a significantly higher response rate (26% vs 14%) and increased median PFS (7.4 months vs 4.6 months) but also had an increase it grade 3 and 4 toxicities. Although OS at 1 year was increased in the combination group (60% vs 51%; P =.076), this failed to meet statistical significance.[35] These findings have led some sarcoma centers to favor single-agent doxorubicin over combination based on decreased toxicity and lack of statistically significant improvement in OS. At our center, we continue to use combination dose-intense doxorubicin and ifosfamide in appropriately selected patients with metastatic disease and preferentially in the neoadjuvant or adjuvant setting for high-risk (ie, large [≥5 cm], high-grade) resectable STS where regimens that combine anthracycline and ifosfamide remain the standard.

Dacarbazine has activity as a single agent, with response rates of 10% to 15%. The three-drug regimen MAID (mesna, doxorubicin [Adriamycin], ifosfamide, and dacarbazine) has been studied and has shown response rates varying from 25% to 47%.[36] When the MAID regimen was studied at MDACC, significant toxicities related to the addition of dacarbazine were seen.[37] The combination of doxorubicin and dacarbazine (ADIC) is often used in extrauterine LMS or as a second-line regimen in other STS. Response rates for the combination vary up to 30% depending on the histology. In a recent large retrospective study of patients with advanced LMS, ADIC was shown to have favorable activity in comparison with either single-agent doxorubicin or doxorubicin and ifosfamide combination, further supporting its use in this setting.[38]

Gemcitabine alone or in combination with docetaxel is frequently used for the treatment of patients with advanced, recurrent, or metastatic disease after patients fail doxorubicin- and ifosfamide-based therapy or in patients who may not tolerate intensive chemotherapy. An initial phase II study using gemcitabine as a single agent demonstrated a response rate of 18% (95% CI, 7%–29%), including many pretreated patients.[39] The synergistic effect of docetaxel when added to gemcitabine was evaluated in a randomized phase II study, SARC002.[40] By RECIST (Response Evaluation Criteria in Solid Tumours), response rates for the gemcitabine–docetaxel arm and gemcitabine arm were 16% and 8%, respectively. Furthermore, an improvement in median PFS (6.2 months vs 3.0 months) and OS (17.9 months vs 11.5 months) was noted in the gemcitabine–docetaxel arm compared with the gemcitabine arm. The two histologies most responsive to the gemcitabine–docetaxel arm were LMS and high-grade undifferentiated pleomorphic sarcoma (UPS).

Trabectedin, an alkylating agent specifically affecting the minor groove of DNA, has shown activity in the second-line treatment of patients with STS. The mechanism of action of trabectedin is complex but is thought to involve displacement of transcription factors from their promoter.[41] The efficacy and optimal dose schedule of trabectedin in sarcoma were established in a phase II study comparing 1.5 mg/m^2 as a 24-hour infusion every 3 weeks or trabectedin 0.58 mg/m^2 as a weekly 3-hour infusion in which the 24-hour infusion was shown to have greater efficacy among patients with liposarcoma or LMS who had previously received anthracyclines and ifosfamide.[42] A subsequent phase 3 trial of trabectedin versus dacarbazine in this patient population demonstrated an improvement in median PFS (4.2 vs 1.5 months) and a clinical benefit rate of 34%, leading to its U.S. Food and Drug Administration (FDA) approval for the treatment of patients with unresectable or metastatic liposarcoma and leiomyosarcoma (L-type sarcomas) who have received a prior anthracycline-based regimen.[43]

Eribulin is a synthetic analog of halichondrin B that interferes with microtubule assembly.[44] In a randomized, multicenter, phase III clinical trial of 452 patients comparing eribulin with dacarbazine for L-type (liposarcomas and leiomyosarcomas) patients with sarcoma with advanced or metastatic disease refractory to anthracycline-based therapy, eribulin was associated with an OS of 13.5 months, but the dacarbazine arm was associated with an OS of 11.5 months.[45]

Interestingly, there was no statistical difference with regard to PFS. An unplanned subgroup analysis by histology revealed a survival benefit for patients with liposarcomas only.[46] This led to an FDA approval specifically for the treatment of liposarcoma patients with advanced or metastatic disease refractory to anthracycline-based therapies. As such, we typically use eribulin as an option for patients with dedifferentiated liposarcoma or pleomorphic liposarcoma who have become resistant or intolerant to doxorubicin-based frontline chemotherapy.

Adjuvant and Neoadjuvant Chemotherapy

The goals of chemotherapy in the treatment of patients with high-risk local disease are to eradicate micrometastasis, decrease risk of local recurrence, and downsize tumors to facilitate either limb-sparing procedures for extremity tumors or resection for tumors initially deemed unresectable (Fig. 50–2). At MDACC, preoperative chemotherapy is preferred in patients with high-risk (>5 cm and high-grade) tumors and in patients who are considered borderline resectable with chemosensitive STS subtypes.

Postoperative chemotherapy and its benefits continue to be controverted because trials of adjuvant therapy have yielded conflicting results. Data from several small studies were pooled and analyzed in an initial meta-analysis published by the Sarcoma Meta-Analysis Collaboration showing improvements in local recurrence, distant recurrence, and recurrence-free survival with adjuvant chemotherapy.[47] This analysis was updated in 2008 to include trials that evaluated anthracycline- and ifosfamide-containing regimens.[48] In the updated analysis, the risk of local recurrence was significantly decreased for all patients receiving chemotherapy, risk of distant recurrence was also decreased for patients receiving doxorubicin-based chemotherapy, and patients receiving doxorubicin- and ifosfamide-containing chemotherapy demonstrated the greatest survival benefit with an improved hazard ratio of 0.56. The absolute risk reduction for death was 11% in the doxorubicin and

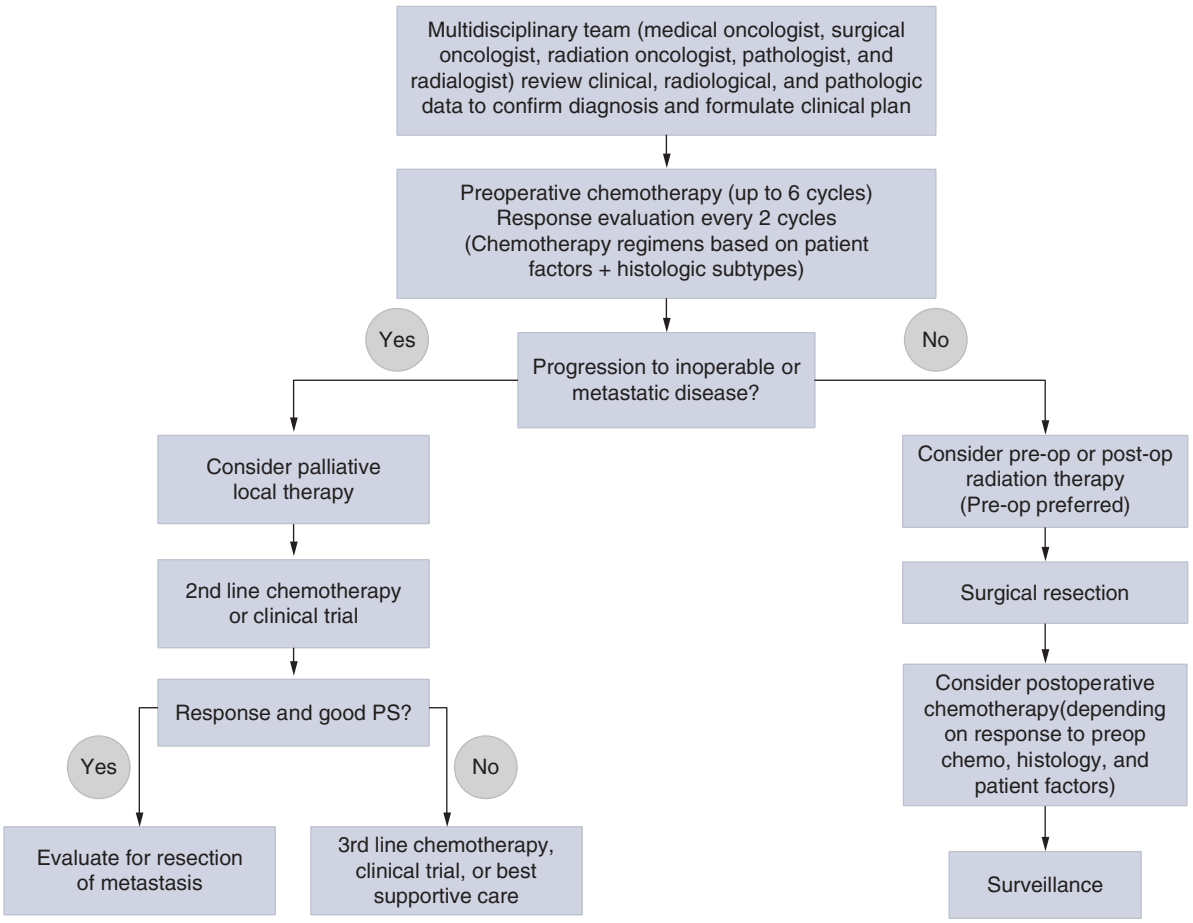

FIGURE 50–2 **Treatment approach for patients with stage III soft tissue sarcomas. © 2015 the University of Texas MD Anderson Cancer Center.**

ifosfamide group as compared with placebo. A subsequent randomized trial of adjuvant chemotherapy conducted by the EORTC randomized patients with intermediate- or high-grade STS to receive five cycles of doxorubicin 75 mg/m^2 and ifosfamide 5 g/m^2 vs no adjuvant therapy.[49] There was no observed benefit of adjuvant chemotherapy in regard to relapse-free survival or OS; however, this lack of benefit may have been due in part to an overestimate of the expected absolute benefit (powered to detect a 15% difference in 5-year OS) as well as the inclusion of patients with small tumors in whom the risks of relapse and death are lower. A subsequent risk stratified analysis of this trial using a validated nomogram (Sarculator) found that high-risk patients (those with a predicted OS <60%) derived a significant DFS and OS benefit from adjuvant chemotherapy supporting the role of chemotherapy among those with high-risk disease.[48] With a move toward subtype-specific treatment of STS, a recent international phase 3 trial evaluated the benefit of histotype-specific neoadjuvant chemotherapy compared with three cycles of standard chemotherapy consisting of epirubicin–ifosfamide among patients with localized myxoid liposarcoma, UPS, LMS, synovial sarcoma, or malignant peripheral nerve sheath tumors.[49] There was no improvement in DFS or OS with histotype-specific chemotherapy compared with anthracycline–ifosfamide within these five STS histologic subtypes.

Although the data regarding adjuvant therapy are conflicting, within our institution, we continue to offer adjuvant therapy with doxorubicin in combination with ifosfamide to healthy patients with intact organ function who have high-risk disease (tumor size >5 cm, high-grade histology, and deep soft tissue involvement).

Targeted Therapy

As in other tumor types, increased knowledge of cancer genomics and identification of oncogenic driver mutations in STS have led to much enthusiasm and investigation of molecular-based targeted therapies. A comprehensive review of targeted therapies under development for STS is beyond the scope of this chapter; therefore, the focus will be on currently approved therapies. Targeting cKIT with the tyrosine kinase inhibitor (TKI) imatinib in GISTs is perhaps the best-known and most successful example in sarcoma. Although targeted agents have shown promise in specific histologies, the multitargeted TKI pazopanib has shown activity across multiple subtypes of STS. Pazopanib is a small-molecule inhibitor with activity against VEGF1-3, PDGFRA, PDGFRB, and KIT. A phase II trial of pazopanib in advanced STS evaluating 12-week PFS as the primary end point showed benefit in LMS (44%), synovial sarcoma (49%), and other nonlipomatous STS (39%).[50] Subsequently, a placebo-controlled phase III trial of pazopanib in metastatic STS demonstrated a low response rate (partial response [PR], 6%) but significant improvement in PFS (4.6 months vs 1.6 months with placebo; HR, 0.31; P <.0001).[51] In a multivariate Cox model, favorable prognostic factors in patients treated with pazopanib were good performance status and low or intermediate tumor grade. Additional targeted therapies in STS are primarily being developed and studied in specific STS subtypes.

Metastatic Disease and Metastasectomy

Chemotherapy is the mainstay of therapy for patients with metastatic disease, although surgical resection of residual oligometastatic disease may be pursued on a case-by-case basis. Patients with metastatic disease involving multiple organs are generally incurable and considered appropriate for palliative systemic therapy. The subset of patients with lung-only metastatic disease, especially those with a greater than 12-month disease-free interval, have a favorable biology and prognosis and therefore should be considered for resection if feasible. This approach results in 3- to 5-year survival rate of up to 20%. The sequencing of chemotherapy is similar to that used for patients with localized disease. In a study conducted at MDACC, patients with metastatic disease showed a 57% response rate to doxorubicin (75–90 mg/m^2) and ifosfamide (10 g/m^2).[52] If patients fail this regimen, the choice of treatment depends on the histology of the tumor, performance status, and comorbid conditions.

Specific Soft Tissue Sarcomas

Vascular Sarcomas

Vascular sarcomas are tumors that originate from or differentiate toward the endothelium with varying malignant potential. Although epithelioid hemangioendotheliomas (EHEs) have an intermediate malignant potential and indolent clinical course, angiosarcomas, at the other end of the spectrum, have a highly malignant biologic behavior with early propensity for distant metastasis and dismal outcomes. These tumors also differ in their response to chemotherapy and targeted therapy and, therefore, are discussed separately below.

EHEs are considered to be of intermediate malignant potential with development of metastasis and recurrence. They typically are associated with a blood vessel, usually a medium-sized or large vein. EHE most commonly occurs in the soft tissues, but liver, lung,

and bone may be sites of primary involvement. In more than 42% of patients with hepatic EHE, symptoms are often absent, and the lesions are discovered incidentally. Some patients experience constitutional symptoms such as fatigue, anorexia, nausea, and poor exercise tolerance. Most cases of EHE affecting soft tissues are localized, whereas multifocality is more common with EHE involving liver or lung, and these patients develop metastatic disease during the course of their illness. Multifocal or metastatic disease does not equate to mortality, and many patients can survive long term with metastatic disease. Sixty-three percent of patients with liver EHE and fewer than half of patients with metastatic EHE of soft tissues die from their disease.

Localized EHE of soft tissue should be treated with surgical resection with adequate margins. After resection, these tumors can recur locally in about 12% of patients.[53] Preoperative radiation therapy should be considered in patients in whom good margins are unlikely, and postoperative radiation therapy should be considered in cases in which the margins are positive and no preoperative radiation was administered. Localized EHE does not require the use of chemotherapy or targeted therapies.

Metastatic EHE of soft tissue may be followed without therapy until there is evidence of progressive disease on serial imaging over a 3-month period. When systemic therapy is needed, conventional chemotherapy and antiangiogenic therapy may be considered. Systemic therapy options include gemcitabine, taxanes, and doxorubicin. Targeted therapy with bevacizumab (PR, 29%; stable disease, 57%; and progressive disease, 14%),[54] and sorafenib (30.7% without progression at 9 months)[55] has been reported to have utility in patients with metastatic EHE.

Angiosarcomas are highly malignant tumors with endothelial differentiation with a propensity for recurrence and distant metastasis. These tumors are extremely rare, representing fewer than 2% of all sarcomas, and can develop de novo or in the setting of prior radiation therapy or chronic lymphedema. Because of their endothelial location, these tumors are particularly well poised for early dissemination and development of metastasis. Angiosarcoma has a propensity for cutaneous involvement, and 60% of cases have skin or soft tissue involvement. Other sites of visceral involvement include spleen, liver, lung, pleura, heart, and gastrointestinal (GI) tract. Clinical behavior and response to therapy can vary from one site to another, with cardiac angiosarcomas carrying the worst prognosis.

Even when these tumors are nonmetastatic, multifocality is often present locally, resulting in high recurrence rates. Therefore, it is critical to approach localized disease with a multidisciplinary approach that combines chemotherapy, radiation, and surgery to produce better outcomes.[56] At our institution, we prefer to treat these patients with neoadjuvant chemotherapy followed by surgery and radiation. Chemotherapy can use either doxorubicin- or taxane-based approaches, both of which have excellent outcomes, and the choice of the regimen depends on the primary location of disease, histologic subtype, performance status of the patient, and potential for toxicity. For cutaneous angiosarcoma, taxanes are as good as doxorubicin-based approaches, but for visceral angiosarcoma, doxorubicin-based approaches may have better activity.

Patients with metastatic disease can be treated with single-agent or multiagent chemotherapy. Monotherapy with doxorubicin (response rate, 29%–33%; PFS, 3–5 months) and paclitaxel (response rate, 18%–89%; PFS, 4–5 months) appears to have significant activity in patients with angiosarcomas.[57–59] Based on a retrospective study of 117 patients with metastatic angiosarcoma, weekly paclitaxel (response rate, 53%) may have comparable efficacy to doxorubicin as a single agent in patients with cutaneous angiosarcoma.[59] Doxorubicin may have advantages over paclitaxel in visceral angiosarcomas. Gemcitabine also appears to have single-agent activity (response rate, 64%; PFS, 7 months),[60] but this drug is more commonly used in combination with taxanes.

The most commonly used combination therapies in angiosarcoma are doxorubicin–ifosfamide and gemcitabine–docetaxel. The doxorubicin–ifosfamide combination is preferred for visceral angiosarcomas and has better durability than any other treatment for angiosarcoma, with a median PFS of 5.4 months.[57] The gemcitabine–docetaxel combination appears to have good activity both in the visceral and cutaneous angiosarcomas.

Antiangiogenic therapies with activity in angiosarcomas include bevacizumab (PR, 9%; stable disease, 48%; median PFS, 12 weeks),[54] sunitinib,[61] and sorafenib (CR, 3%; PR, 11%; stable disease, 57%; median PFS, 3.2 months).[62] Although responses with targeted therapies appear to be low compared with conventional chemotherapy, this may be a result of using an unselected study population for treatment.

Leiomyosarcoma

LMS is a common STS subtype and can anywhere in the body. The site of origin and grade are important prognostic factors and also guide treatment. Patients with vascular-origin LMS have a worse prognosis than those with nonvascular LMS. Additionally, patients with uterine LMS tend to fare better than those with extrauterine LMS, although this may be in part due to a higher rate of complete resection in uterine LMS.[63] LMS is responsive to multiple chemotherapeutic

agents used in STS but has been shown to be less responsive to ifosfamide-containing regimens than single-agent doxorubicin.[64] A recent retrospective study conducted by the EORTC sought to identify the optimal treatment for patients with advanced LMS comparing doxorubicin–dacarbazine, doxorubicin–ifosfamide, and single-agent doxorubicin as first-line treatment.[38] Doxorubicin–dacarbazine was associated with the highest objective response rate compared with doxorubicin–ifosfamide and single-agent doxorubicin (30.9% vs 19.5% and 25.6% respectively) and showed favorable PFS. Gemcitabine is also active in the treatment of LMS. A subtype-specific phase II trial of gemcitabine versus gemcitabine in combination with docetaxel in metastatic or relapsed LMS[65] showed significant response rates with both single-agent gemcitabine and the combination (19% vs 24%, respectively) in patients with uterine LMS. In the nonuterine LMS subgroup, combination therapy resulted in higher objective response rates (14% vs 5%) and prolonged PFS (6.3 vs 3.8 months). Options for third-line therapy include trabectedin or pazopanib. Hormonal treatment may be considered for patients with uterine LMS but is typically reserved for patients with ER/PR+, low-volume, indolent disease given its limited activity. In the largest retrospective study of aromatase inhibitors in uterine LMS, response rates included PR in 9% and stable disease in 32%. Patients with hormone receptor–positive disease demonstrated better PFS.[66] The treatment algorithm for advanced LMS should take into account the site of origin (uterine vs extrauterine) and patient-specific factors (see Fig. 50–1).

Liposarcoma

Liposarcomas represent the second most common STS. There are several histologic subtypes of liposarcoma with unique clinical and biological features. Myxoid liposarcoma represents the most common subtype of liposarcoma. Other subtypes include well-differentiated, dedifferentiated, and pleomorphic liposarcoma. Myxoid liposarcomas often occur in the third through fifth decades of life, generally develop in the extremities, and harbor a balanced translocation $t^{12;16}$(q13;p11) resulting in the oncoprotein FUS-DDIT3, which is considered pathognomonic for the disease.[67,68] Although regarded a low-grade tumor, local recurrence and distant metastasis occur in about 30% of patients. Sites of metastasis include the lungs and soft tissue regions such as the axilla, the retroperitoneum, the pleural lining, the pericardium, and occasionally the spine. A variant of myxoid liposarcoma, round cell liposarcoma, is considered to be a more aggressive. An increase in round cell percentage correlates to metastasis and poor survival in myxoid liposarcomas.[67] Treatment options for myxoid liposarcoma depend on its size, location, and presence of adverse prognostic features such as the presence of round cell changes. Surgery and radiation are the mainstays of treatment; however, given the chemosensitive nature of myxoid liposarcoma, neoadjuvant or adjuvant chemotherapy is considered for patients with large or borderline resectable tumors as well as those at high risk of metastatic disease recurrence. Reports from MDACC using doxorubicin-based chemotherapy yield response rates of 44%. Trabectedin has been shown to be active in myxoid liposarcoma across multiple trials.[41,69] Aside from binding to the minor groove of DNA and forming covalent adducts and displacement of transcription factors, this agent is thought to promote differentiation of myxoid liposarcoma lipoblasts.

Surgery is the mainstay of treatment for patients with well-differentiated and dedifferentiated liposarcoma; however, recurrence rates are high, especially in the retroperitoneum. Benefit from chemotherapy has been reported to be minimal, with objective response rates of approximately 12%.[70] In a recent review of 89 patients with dedifferentiated liposarcoma of the retroperitoneum treated at MDACC, response rates were higher (23% by RECIST) with a clinical benefit rate (PR + stable disease >6 months) of 37%, suggesting a potential role for chemotherapy in select patients with unresectable or borderline resectable disease.[71] Doxorubicin-based regimens are typically preferred as first-line treatment, with gemcitabine–docetaxel, trabectedin, and eribulin also having activity in advanced or metastatic liposarcoma (see Fig. 50–1).

Alveolar Soft Parts Sarcoma

ASPS is a rare STS subtype predominantly affecting adolescents and young adults and accounting for fewer than 1% of all STS. Although the disease course is indolent with a prolonged natural history, ASPSs have a high rate of metastasis and a median OS of approximately 90 months. Although lung metastases are most common, ASPS can also metastasize to the brain, an otherwise uncommon site for sarcoma. In a review of our institutional experience with ASPS, 65% of patients presented with stage IV disease. Among those with localized disease at presentation, 5-year OS was 88%, whereas those who presented with metastatic disease had a median OS of 40 months and 5-year OS of 20%.[72] Despite its propensity for metastasis, ASPS is resistant to conventional chemotherapy. Highly vascular, these tumors are characterized by an unbalanced translocation t(X;17)(p11:q25), resulting in the ASPL-TFE3 fusion protein and overexpression of *MET*, leading to angiogenesis. Tyrosine kinase receptor inhibitors with activity against the vascular endothelial growth factor receptors such as cediranib[73] and sunitinib[74] have demonstrated activity against

several phase II studies with response rates exceeding 30% and with control rates of greater than 80% at 6 months. Interestingly, ASPS has been shown to be responsive to immune checkpoint inhibitors. We were the first to demonstrate activity of nivolumab and ipilimumab in ASPS.[75] Additionally, a phase II study of axitinib in combination with pembrolizumab demonstrated activity against ASPS with a response rate of 54.5% and a median PFS at 3 months of 72.7%.[76] Although the immune microenvironment has yet to be comprehensively defined for this rare form of sarcoma, several studies suggest the presence of programmed cell death protein 1–expressing tumor infiltrating lymphocytes, molecular evidence of mismatch-repair deficiencies, and possible immunogenicity associated with the breakpoint of the fusion protein.[77] Despite this evidence of activity, clinical trials are still ongoing, and there is yet to be an approval by the FDA for the use of immune checkpoint inhibitors in the treatment of patients with advanced or metastatic ASPS. As such, ASPS patients requiring medical management of their advanced or metastatic disease should be considered for clinical trials.

Tenosynovial Giant Cell Tumor and Pigmented Villonodular Synovitis

Tenosynovial giant cell tumor (TGCT), previously called pigmented villonodular synovitis, is characterized by hypervascular proliferative synovium with an accumulation of polyclonal macrophages, hemosiderin deposition (detectable on imaging), and multinucleated giant cells. Consequently, joint destruction by inflammatory infiltrates results in pain, swelling, and limitation of movement. Most commonly, TGCT involves a single joint such as the knee or ankle but can occur anywhere that synovium is present. Surgically resectable disease, especially in the frontline setting, should be managed using surgery as the mainstay of treatment. Patients who develop recurrent disease or present with diffuse-type disease that is not surgically resectable without considerable morbidity should be considered for targeted therapy. TGCT harbors a clonal population of cells that have the *CSF1-COL6A3* translocation, which results in overproduction of CSF1 that recruits inflammatory cells into the joint. The pathogenic mechanism opens up a unique opportunity to treat these patients with unresectable disease with a CSF1R inhibitor. Pexidartinib is an orally bioavailable agent that is FDA approved for use in this rare disease. Pexidartinib produced a response rate of 39% compared with 0% in the placebo arm of ELIVEN, a randomized phase III trial comparing the activity of the drug with placebo.[78] Pexidartinib has the potential to produce rare but potentially fatal hepatotoxicity through ductopenia that requires use of this drug to be monitored closely using the Turalio Risk Evaluation and Mitigation Strategies program. It is particularly important to administer the drug on an empty stomach because dietary fat increases the absorption of the drug and increases the likelihood of hepatotoxicity. Other CSF1R inhibitors such as imatinib and emactuzumab have shown activity in TGCT and may also have a role in treatment, but their use remains investigational.

Follow-up Management

The major goals of follow-up surveillance and management should be early identification of potentially curable recurrences, identification of treatment-related complications, and patient reassurance. Surveillance of patients treated for STS is based on known prognostic factors, outcomes in individual subsets of patients, and patterns of tumor recurrence. Similarly, the screening, evaluation, and management of late effects related to chemotherapy and radiation are based on the specific regimens received and the site and dose of radiation.

For patients with low-risk T1 primary STS who have undergone treatment with curative intent and have no evidence of disease, follow-up should include a history and physical examination, cross-sectional imaging of the tumor bed to evaluate for local recurrence, and routine chest radiography for surveillance of metastatic disease.[79] For tumors of the head and neck and extremities, MRI is appropriate; for tumors of the chest, abdomen, and retroperitoneum, CT scans are appropriate. The routine use of chest CT for evaluation of metastatic disease in low-risk STS has been studied and found not to be cost effective. The NCCN guidelines recommend follow-up with annual scanning of the primary site for at least 5 years; however, often these patients are seen every 3 to 4 months in the immediate postoperative period for the first 2 years, then every 4 to 6 months for the next 2 years, and yearly thereafter.[28]

Patients with high-risk T2 (>5 cm) STS are at a greater risk for distant lung metastases. In patients with high-risk tumors who have undergone treatment with curative intent and have no evidence of gross disease, follow-up should include a history and physical examination, cross-sectional imaging of the tumor bed, and routine chest radiography or chest CT for surveillance of metastatic disease. These patients are followed in the same manner as low-risk patients, with follow-up visits with the above studies every 3 months for the first 1 to 2 years, then visits every 4 months for the next 1 to 2 years, followed by visits every 6 months for 1 to 2 years and yearly visits thereafter. As for local recurrence surveillance, the cross-sectional imaging is omitted after 5 years

because most local recurrences appear within 5 years of initial treatment.

Gastrointestinal Stromal Tumors

GISTs are the most common mesenchymal tumors of the GI tract.[80] Previously, they were often designated smooth muscle tumors of the GI tract, specifically, GI LMS, leiomyoblastoma, LMS, and leiomyomas. Investigators discovered that GISTs express the KIT (CD-117) receptor tyrosine kinase and possibly originate from the interstitial cell of Cajal, the intestinal pacemaker cell responsible for peristalsis.[81] These tumors most commonly arise in the stomach (60%–70%), followed by small intestine (20%–30%), colon and rectum (5%), and esophagus (<5%), although they can arise anywhere in the GI tract, omentum, or peritoneum. The liver, peritoneum, and bone are the most common sites of metastatic disease; however, there are reports of associated central nervous system, lymph node, lung, and other metastases.[82] The incidence of GIST is equal in men and women; it generally peaks between the fourth and sixth decades of life, and patients are more commonly of European descent. Presenting symptoms often represent the site of tumor origin but may be vague, including abdominal pain, anorexia, weight loss, and dyspepsia. GI bleed presenting as anemia or near syncope is also common.

Historically, the mainstay of treatment for GIST was surgical resection. Conventional chemotherapy or radiotherapy has not been effective in the treatment of GIST. The identification of specific oncogenic driver mutations involving *KIT* and *PDGFRA* has led to the development and approval of multiple TKIs that have greatly improved the prognosis of patients with high-risk localized and metastatic GIST. Before the availability of TKIs, median OS was approximately 18 months. In the era of TKIs, this has improved to around 5 years.[83]

Molecular profiling of patients with GIST has now become standard of care because the mutational status has important implications in regard to diagnosis, prognosis, and guiding treatment decisions. Approximately 70% to 80% of GISTs harbor a *KIT* gene mutation, with another 5% to 8% with *PDGFRA* mutations and the remaining 12% to 15% deemed wild-type GIST.[84] Wild-type GIST constitutes a heterogeneous group, with additional mutations identified in succinate dehydrogenase (*SDH*), *BRAF* V600E, and *RAS*, among others. Deletions in exon 11 are the most common *KIT* mutation and portend a more aggressive disease course with shorter OS and higher risk of recurrence. Internal tandem repeats involving exon 11, however, are associated with gastric GIST and tend to be more indolent. Exon 9 mutations have been associated with GIST of the small intestine and a clinically aggressive course. *PDGFRA* mutations can occur in multiple exons (12, 14, and 18) and are observed primarily in gastric GIST.

Imatinib mesylate, an oral TKI that selectively inhibits BCR-ABL, KIT, and PDGFR, is approved for adjuvant therapy and for unresectable or metastatic GIST. Early trials with imatinib showed objective response rates of 53% to 69% and significant improvement in 5-year OS of about 50%.[85] These trial results led to two phase III trials (EORTC 62005 and SWOG S0033) that were designed to compare imatinib at two dose levels (400 mg/day vs 800 mg/day).[86,87] In both studies, the higher-dose arm failed to show a statistically significant difference in response or OS compared with the standard dose; however, PFS was superior for exon 9 mutant patients in the higher-dose arm. GISTs with exon 11 mutations are more responsive to imatinib therapy compared with exon 9 mutations.[88] Patients with non-KIT non-PDGFRA mutated or wild-type GIST rarely show significant or sustained response to imatinib. In one study, investigators randomized patients who had control of disease at 3 years with imatinib to either continue or discontinue treatment.[89] The 2-year PFS was 80% in the continuous treatment cohort compared with 16% in the treatment interruption group. Further randomization at 3 years to either continue for 5 years or stop revealed similar results. It is therefore recommended that patients with advanced or metastatic GIST should avoid interruption and keep taking imatinib until PD or true intolerance.

Imatinib has also shown efficacy in the adjuvant setting.[90] As in the metastatic setting, the optimal duration of adjuvant imatinib therapy has not been well established. A randomized trial comparing 1 year versus 3 years of adjuvant imatinib therapy for patients with *KIT*-positive resected GIST showed benefit to longer duration of adjuvant therapy.[91] Patients receiving 36 months of adjuvant imatinib had longer recurrence-free survival (5-year recurrence-free survival, 65.6% vs 47.9%; HR, 0.46; P <.001) and improved 5-year OS (92% vs 81.7%; HR, 0.45; P =.02). A single-arm study of 5 years of adjuvant imatinib in intermediate- and high-risk GIST reported a 5-year RFS of 90% and OS of 95%.[92]

Approximately 10% of patients with GIST have primary resistance to imatinib, with higher rates seen in exon 9 mutated and wild-type GIST. Secondary resistance is often caused by new mutations in the *KIT* gene involving exon 13 or exon 17.[93] Sunitinib, a multikinase inhibitor that targets VEGF, appears to have activity in patients with primary resistance and secondary *KIT* mutations.[94,95] The overall objective response rate, however, was less than 10%. Several additional targeted therapies targeting the KIT and PDGFRA pathways have also been evaluated. Nilotinib, a second-generation TKI, was evaluated as

third-line therapy after imatinib and sunitinib and showed a low response rate of 3%.[96] Regorafenib, a multitargeted TKI, has shown better efficacy in patients after failure of both imatinib and sunitinib. In a phase II trial, an objective response rate of 12% and clinical benefit rate (PR or stable disease >16 weeks) of 79% were observed in patients.[97] The phase 3 GIST - regorafenib in progressive disease (GRID) trial randomized patients with metastatic GIST who had failed imatinib and sunitinib to either regorafenib or placebo. Median PFS was 4.8 months versus 0.9 months in favor of regorafenib, resulting in FDA approval of this agent.[98] About 5% to 6% of patients with GIST have a primary PDGFRA D842V mutation, which is known to be resistant to all the currently approved TKIs. Avapritinib is a selective and potent inhibitor of PDGFRA loop mutations that recently received FDA approval in 2020 based on an 8% CR and 82% PR with a 12-month PFS of 85%.[99]

Response evaluation in GIST uses the Choi criteria rather than the standard RECIST measures used in most other solid tumors. PET imaging may also be used and was initially noted to show treatment response at an earlier time point compared with standard CT imaging. Certain molecular events, such as apoptosis, occur early on and may partially explain the rationale behind early PET response related to imatinib.[100] Our institution also demonstrated that RECIST criteria may underestimate early tumor response seen in GIST. Patients who respond to imatinib clinically may show a decrease in tumor size, or a decrease in tumor radiodensity by CT radiography, or both. Further analysis of patients treated with imatinib at MDACC revealed that when tumor density is taken into account, sensitivity of CT imaging is comparable to PET response.[101,102] These data culminated in the development of the Choi criteria of response assessment (Table 50–3). These criteria have been prospectively validated and are considered in response assessment in current trials of GIST. It is our experience that decisions to discontinue therapy should not be based solely on CT radiography or PET imaging but instead should also take into consideration the patient's overall clinical condition.

In summary, the frontline therapy for patients with newly diagnosed, metastatic GIST is imatinib at 400 mg/day. Patients with exon 9 mutations should have therapy initiated with imatinib at 800 mg/day. Imatinib should be continued indefinitely or until progression, as defined by Choi criteria. CT imaging is used to assess response initially at 2 months and then at 3-month intervals for at least the first 2 years. At the time of progression, if tolerable, we increase the dosage of imatinib to a total of 800 mg/day. If or when this strategy fails, we proceed to second-line therapy sunitinib and subsequent third-line therapy with regorafenib. For patients with isolated or resectable metastatic disease, surgery and/or hepatic artery embolization or radiofrequency ablation is offered if feasible. For resectable GIST patients with high-risk features, such as a high mitotic count or large tumor size, adjuvant imatinib for at least 3 years should be administered to increase recurrence-free survival. The optimal duration of imatinib use in the adjuvant setting beyond 3 years remains unknown.

TABLE 50–3 Choi Response Criteria

Response	Response Definition
Complete response (CR)	Disappearance of all disease No new lesions
Partial response (PR)	A decrease in size of >10% or a decrease in CT density (HU) >15% No new lesions No obvious progression of non-measurable disease
Stable disease (SD)	Does not meet the criteria for CR, PR, or PD No symptomatic deterioration attributed to tumor progression
Progression of disease (PD)	An increase in unidimensional tumor size of >10% and did not meet criteria for PR by CT density Any new lesions, including new tumor nodules in a previous cystic tumor

CT, computed tomography; HU, Hounsfield unit.

BONE SARCOMA

Bone sarcomas are rare tumors, making up fewer than 0.2% of all cancers. In 2020, an estimated 3600 new cases of bone sarcomas were estimated to be diagnosed in the United States, and 1720 deaths from these cancers were expected.[1] The most common malignant tumor of bone is osteosarcoma followed by chondrosarcoma and then the Ewing family of tumors (EFT), which includes sarcoma and peripheral primitive neuroectodermal tumors (PNETs). UPS of bone (previously termed malignant fibrous histiocytoma), fibrosarcoma, chordoma, and giant cell tumor of bone are rare bone tumors and account for fewer than 5% of all primary malignant bone tumors. EFT tends to occur more frequently in children and adolescents, whereas osteosarcoma has a biphasic pattern of incidence that peaks in adolescents with the growth of long bones and has a second peak in older adults with tumors arising in association with Paget

TABLE 50–4 Features of Common Bone Tumors

Type	Frequency (%)	Age Distribution (years)	Gender	Common Sites	Radiologic Features	Pathologic Features
Osteosarcoma	45	10–20	M > F	Metaphysis	Sunburst calcifications	Spindle cells, osteoid matrix
UPS of bone	8	20–80	M > F	Long bones	Radiolucent with ill-defined margins	Pleomorphic spindle cells, no osteoid
Chondrosarcoma	22	20–80	M > F	Pelvis or shoulder girdles	Lobulated appearance	Lobules, chondroid matrix
Ewing or PNET	15	10–20	F > M	Diaphysis	Lytic with soft tissue component	Small round blue cells

F, female; M, male; PNET, primitive neuroectodermal tumor; UPS, undifferentiated pleomorphic sarcoma.

disease or as a secondary malignancy after therapeutic radiation. Chondrosarcomas are usually seen in adult patients after the fifth decade of life, with fewer than 5% of cases occurring in pediatric patients, in whom the tumors tend to be of a higher grade malignancy. Features of common bone tumors are listed in Table 50–4.

Clinical Presentation

The clinical presentation of any bone tumor depends on its location. Most osteosarcomas arise in the metaphyseal region of long bones, specifically the distal femur, proximal tibia, and proximal humerus. Approximately half of all osteosarcomas occur around the knee joint. Chondrosarcomas can also arise in any bone of the body; however, they generally occur in the pelvis and other flat bones. EFTs tend to occur in the diaphyseal portion of the long bones and in flat bones of the body (eg, the pelvis and scapula) but can involve any bone and occasionally arise in the soft tissue (termed *extraskeletal* or *extraosseous Ewing sarcoma*).

The most common presenting symptom is pain and swelling or a mass. Patients who have pelvic tumors may have neurologic impairment and severe pain, typically because these tumors are often not recognized until late in the disease course. In the case of EFT, patients often present with constitutional symptoms of night sweats and fevers.

Evaluation

Evaluation of suspected bone sarcoma should begin with a careful history, physical examination, and routine laboratory tests followed by imaging directed to the given complaint. The imaging of any bone tumor should begin with a plain film of the involved area. Radiography images are often helpful in the diagnosis of bone sarcomas; for example, osteosarcoma often has a "sunburst" appearance of calcification on x-ray imaging, which is virtually diagnostic (Fig. 50–3). The amount of calcification associated with osteosarcoma depends on the histologic subtype (eg, whereas osteoblastic osteosarcoma usually has very dense calcification, telangiectatic osteosarcoma is primarily lytic). Chondrosarcoma also has a distinct appearance on x-ray imaging, with destruction of the bone and endosteal scalloping of the bony cortex and a chondroid matrix, which appears lobulated (see Fig. 50–3). EFT has a typical "onion-skin" appearance on x-ray imaging (see Fig. 50–3). Additional initial imaging should include a CT scan, MRI, or both of the primary lesion to further evaluate involvement of the neurovascular structures, surrounding soft tissues, and adjacent joints and to better evaluate any associated soft tissue mass.

Biopsy of bone sarcomas is critical to the diagnosis, and careful planning is essential. When patients are diagnosed with bone sarcoma or the diagnosis is suspected, it is important to have a multidisciplinary team approach with physicians who are experienced in the treatment of patients with bone sarcomas. Core-needle biopsy has been shown to be accurate in making a diagnosis in up to 91% of cases.[103] An open biopsy should be performed only when core-needle biopsy is nondiagnostic. Current guidelines recommend either a core or open biopsy to confirm the diagnosis before any surgical procedure. When surgery is ultimately performed, care should be taken to assure that the biopsy tract is completely resected.

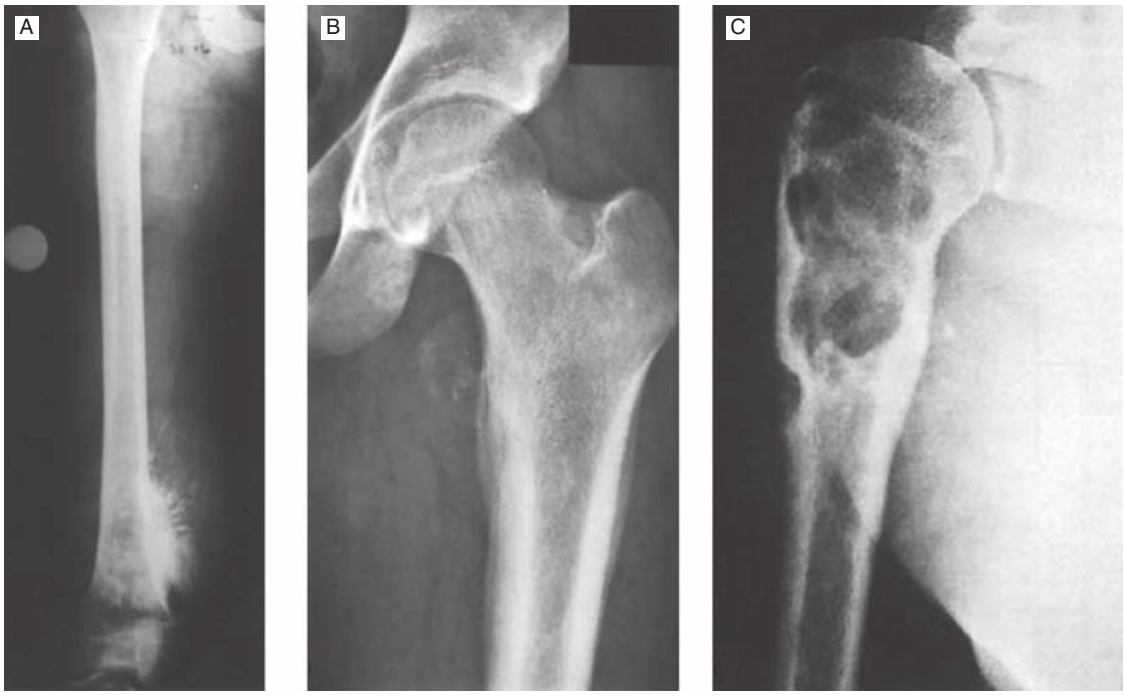

FIGURE 50–3 X-ray imaging of osteosarcoma, Ewing sarcoma, and chondrosarcoma. **A.** The typical "sunburst" appearance of osteosarcoma. **B.** The "onion-skin" appearance often seen in Ewing sarcoma. **C.** The lobulated appearance of chondrosarcoma.

Complete staging should include chest radiography, CT scan of the chest, and bone scan to evaluate for metastatic disease. Chest imaging is warranted in all patients because the most common site of metastasis from bone sarcoma is the lungs. A bone scan should be included in the workup for metastatic disease in patients with bone sarcoma to evaluate for distant bone metastases or skip metastases. For patients with EFT, an MRI of the spine should also be performed because of the risk of bone marrow metastases. We do not routinely obtain bone marrow biopsy in the staging evaluation of EFT, preferring the use of MRI because marrow involvement has been shown to highly correlate with bone metastasis.[104]

PET-CT is frequently used in the initial diagnostic evaluation, staging, and response assessment for bone sarcomas. However, fluorodeoxyglucose (FDG) uptake alone is not adequate for characterization of primary bone tumors; morphologic evaluation is key.[105] PET-CT imaging can also play an important role in response assessment because bone sarcomas do not demonstrate typical RECIST responses to chemotherapy. Multiple studies have reported the utility of PET-CT in evaluating chemotherapy response in osteosarcoma and EFTs.[106,107] In one study of osteosarcoma, a 25% to 50% reduction of SUV after 1 week of neoadjuvant chemotherapy has been shown to correlate with greater than 90% tumor necrosis on pathologic evaluation.[108] At our center, we routinely use PET-CT in the evaluation and response assessment for osteosarcoma and EFTs.

Pathology

There are multiple histologic subtypes of bone sarcoma, with the most common cytogenetic and molecular aberrations summarized in Table 50–5. Osteosarcoma can be broken down into two major categories: conventional osteosarcoma and variant osteosarcoma. Conventional osteosarcoma, which includes osteoblastic, chondroblastic, and fibroblastic subtypes, comprises approximately 60% to 75% of all osteosarcomas, whereas the 11 variants comprise the other 35% to 40%. These classifications are made based on the histologic features of the tumor, such as the amount of matrix present within the tumor and whether bone or cartilage is predominant. The classification of osteosarcoma variants often relies more on clinical features such as the site of disease (eg, jaw, skull, pelvis), the setting in which the disease presents (eg, postradiation, Paget disease, multifocal, retinoblastoma), and the morphology (eg, telangiectatic, small cell, and surface lesions such as parosteal, periosteal, and high-grade surface osteosarcoma). High-grade osteosarcomas demonstrate significant genomic instability and therefore possess complex and heterogeneous chromosomal alterations. *TP53* alterations are common and found in the vast majority of all osteosarcomas followed in frequency by

TABLE 50–5 Selected Genetic Alterations in Bone Tissue Sarcomas

Tumor	Cytogenetic Abnormality	Gene Product
Aneurysmal bone cyst	t(16;17)(q22;p13) t(1;17)(p34.3;p13) t(3;17)(q21;p13) t(9;17)(q22;p13) t(17;17)(q21;p13)	*CDH11-USP6* *THRAP3-USP6* *CNBP-USP6* *OMD-USP6* *COL1A1-USP6*
Chondrosarcoma or chondroma		*IDH1* or *IDH2* Point mutation

Fibrous dysplasia	Activating oncogenic mutations	*GNAS1*
Mesenchymal chondrosarcoma	t(8;8)(q13;q21)	*HEY1-NCOA2*
Osteosarcoma, low-grade (parosteal and intramedullary)	12q14-15 (ring chromosomes, giant marker chromosomes)	Amplification of *CDK4, MDM2, HMGA2, GLI*, and *SAS*
Osteosarcoma		Frequent *TP53* alterations; multiple genetic aberrations, including copy number alterations

PNET, primitive neuroectodermal tumor.

mutations in the tumor suppressor gene *RB1*. Copy number loss or gain in multiple chromosomes as well as amplifications in the *MDM2* gene, *CDK4*, *MYC*, and *VEGF* have been described.[109] To date, contemporary next-generation sequencing studies of osteosarcomas has yet to identify recurrent actionable molecular targets.

UPS of bone (previously termed *malignant fibrous histiocytoma of bone*) is a rare high-grade bone sarcoma accounting for fewer than 2% of all primary bone malignancies. It is similar to UPS of soft tissue histologically and can often appear to as the high-grade component of dedifferentiated chondrosarcoma. UPS is thought to be part of a spectrum of osteosarcoma in which the spindle cells do not produce apparent osteoid visible by light microscopy; however, a subset of these tumors produce osteoid in response to preoperative chemotherapy and may be subsequently reclassified as osteosarcomas.

Chondrosarcomas are malignant tumors of bone characterized by cartilaginous matrix formation. These tumors produce chondroid matrix and can arise from benign processes such as enchondromas or osteochondromas. Chondrosarcoma is characterized by the permeation of cartilage into the bone marrow. This process is considered pathognomonic for chondrosarcoma. Dedifferentiated chondrosarcoma represents a unique subset of conventional chondrosarcomas typified by a low-grade conventional chondrosarcoma juxtaposed with a high-grade soft tissue component. Several less common variants exist, including mesenchymal chondrosarcoma and clear cell chondrosarcoma. Next-generation sequencing has identified somatic mutations in isocitrate dehydrogenase 1 and 2 (*IDH1/2*) in central conventional chondrosarcomas and dedifferentiated chondrosarcomas.[110] This finding may aid in distinguishing chondrosarcoma from chondroblastic osteosarcoma and could serve as a unique therapeutic target.[111]

EFTs represent a completely separate histology and are grouped with the PNETs because of their similarities in histology, immunohistochemical staining, and molecular genetics. This family of tumors includes Ewing tumors of bone, extraosseous Ewing tumors, PNETs, and Askin tumors (PNET of the chest wall). These tumors are often referred to as "small round blue cell tumors" because, under a microscope, the cells contain scanty cytoplasm and round to oval nuclei with fine chromatin that are tightly packed together. The ESFTs possess recurrent translocations involving the *EWS* gene. The translocation $t^{11;22}$(q24;q12) *EWS-FLI-1* fusion was the first described and most common translocation. Several additional translocations have also been identified (see Table 50–5).

Bone sarcomas are classified as either high- or low-grade lesions, similar to the three-tier grading system of

STS. Grading is an important factor that helps to determine the overall stage, expected natural history, and prognosis. Finally, the pathologist should be provided with the diagnostic imaging and x-ray findings because these provide important information to assist in making a final diagnosis in bone sarcomas.

Staging and Prognosis

There are two widely accepted staging systems, that of the AJCC and that of the Musculoskeletal Tumor Society.[17,112] In a comparison of these systems, there was no significant difference between them, and neither had any notable advantage.[113] At MDACC, instead of routinely using a staging system, we prefer to emphasize prognostic factors (eg, size of the primary, location and extent of bone involvement, soft tissue involvement, histologic grade, and presence or absence of distant metastases). The prognosis of patients with bone sarcomas largely depends on the specific histology, grade, and location, as well as the presence and location of metastatic disease. In addition to the clinical and pathologic prognostic features assessed at diagnosis, pathologic treatment response assessed as the percentage of tumor necrosis after preoperative chemotherapy is the most well-established prognostic factor for patients with high-grade osteosarcoma.

Treatment

The treatment of bone sarcomas is best accomplished by a multidisciplinary team comprising medical oncologists, surgical oncologists, radiologists, pathologists, and radiation oncologists working together to provide comprehensive care. The treatment required depends on the tumor type, location, and extent of disease. Treatment algorithms for high-grade bone sarcomas and Ewing sarcoma are show in Figures 50–4 and 50–5.

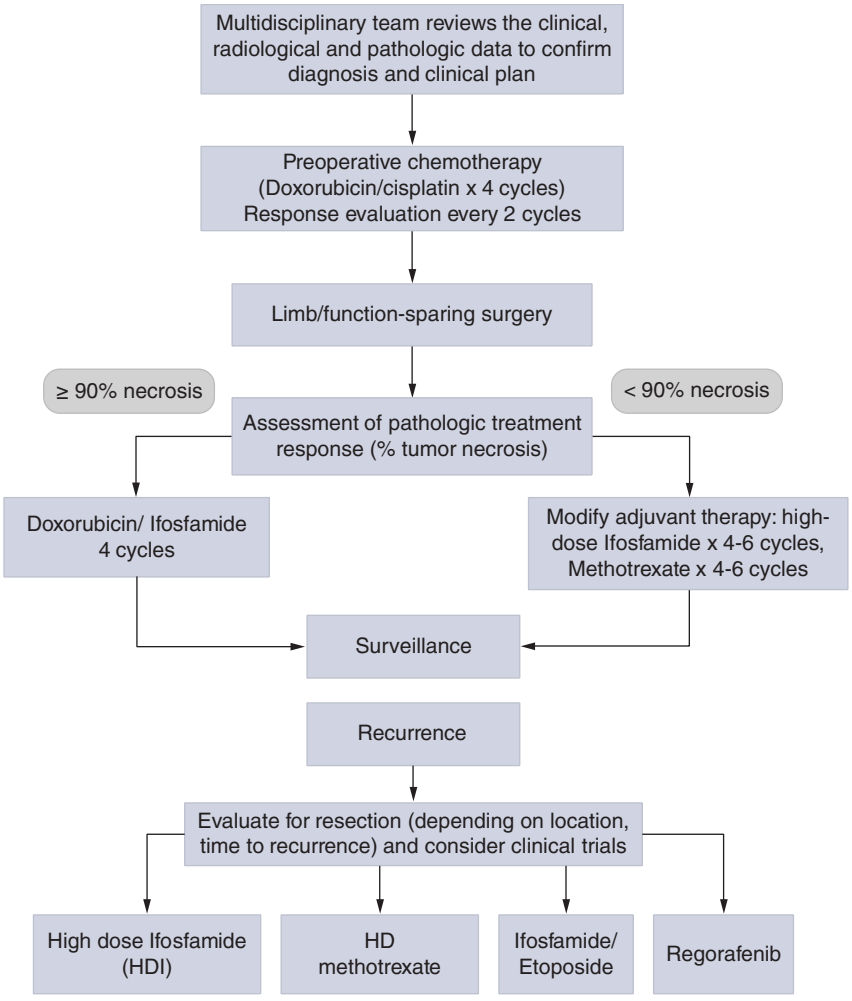

FIGURE 50–4 Treatment approach for patients with high-grade primary bone sarcomas.

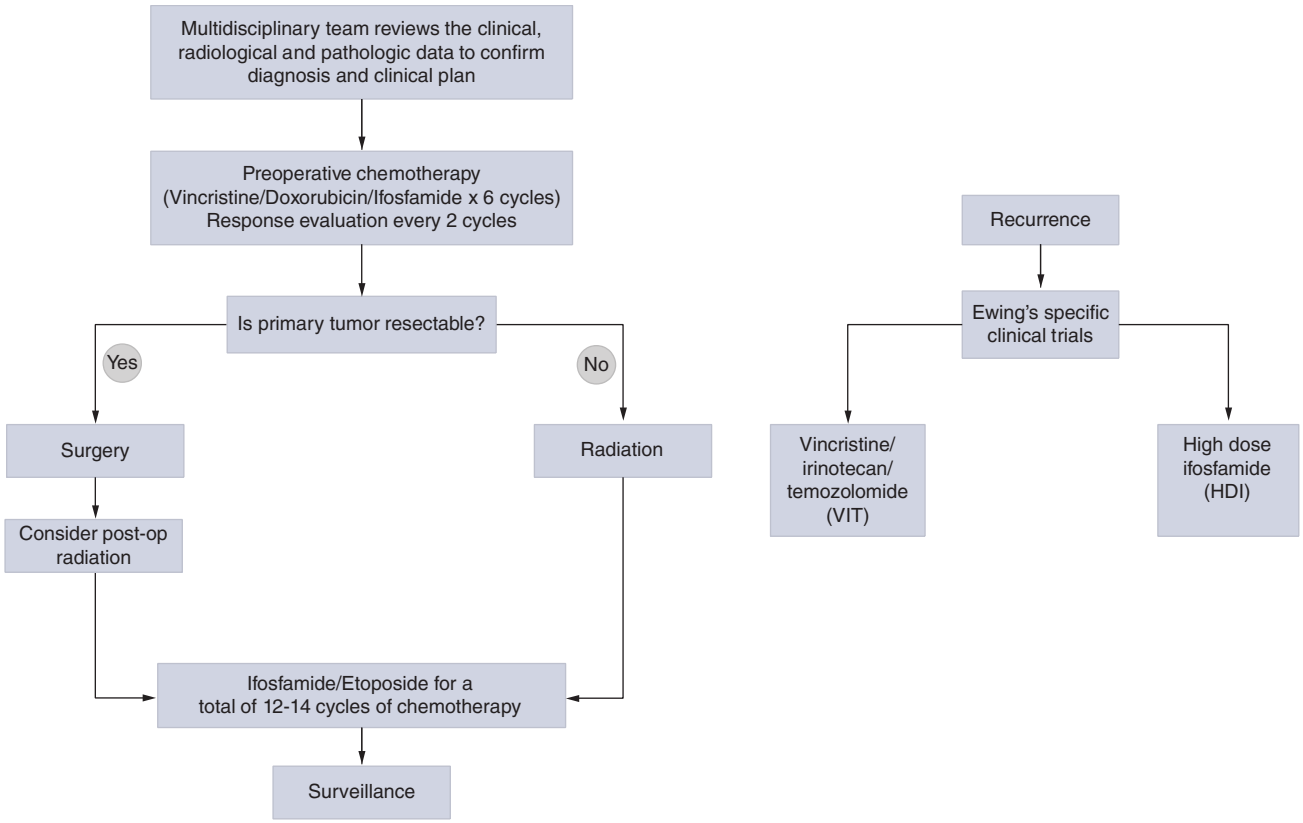

FIGURE 50–5 **Treatment approach for patients with Ewing sarcoma family tumors.**

Osteosarcoma

Osteosarcoma is the prototype of most other bone sarcomas. Chemotherapy is the mainstay of treatment for osteosarcoma, which is considered a systemic disease because most patients have micrometastatic disease at presentation. This is evidenced by the historic long-term survival rate of less than 20% in patients treated with surgery alone compared with the nearly 70% cure rate among patients with localized osteosarcoma of an extremity treated with aggressive combination chemotherapy followed by surgery.[114]

At MDACC, adult patients with conventional high-grade osteosarcoma of an extremity receive treatment consisting of preoperative chemotherapy followed by limb-sparing surgery followed by postoperative chemotherapy (see Fig. 50–4). The postoperative therapy is tailored based on the knowledge of the percent necrosis found in the pathologic specimen after surgery. This approach is based on a series of patients treated within our center in which tailored postoperative therapy demonstrated improved survival and differs from the current standard treatment of pediatric osteosarcoma.[115]

The most active agents for the treatment of patients with osteosarcoma are cisplatin, doxorubicin, ifosfamide, and high-dose methotrexate. Among pediatric patients with osteosarcoma, a combination of high-dose methotrexate, doxorubicin, and cisplatin (MAP) chemotherapy remains the standard of care within the United States. For adult patients, we use a preoperative regimen of doxorubicin (75–90 mg/m^2 as continuous infusion over 72 hours) in combination cisplatin (120 mg/m^2).[116] At resection after preoperative chemotherapy, the percentage of tumor necrosis is the single most important predictor of long-term DFS and OS. Generally, patients with 90% or greater tumor necrosis after preoperative chemotherapy have a 5-year continuous DFS of approximately 80%.[117] The 5-year continuous DFS of patients with less than 90% tumor necrosis after preoperative chemotherapy is significantly worse, ranging from 13% up to 67% depending on the postoperative chemotherapy regimen. To address this, we analyzed a consecutive series of 123 patients with osteosarcoma of the extremity treated within our center who were divided into three cohorts based on the time period in which they

were treated and the postoperative chemotherapy given. All patients received preoperative doxorubicin and cisplatin induction. Patients received the sequential addition of high-dose methotrexate (8 g/m^2) and then methotrexate plus ifosfamide postoperatively in the second and third groups depending on the time period in which they were treated. Among patients with 90% or greater tumor necrosis, relapse-free survival was not significantly different among the three groups. In patients with poor response, with less than 90% tumor necrosis, the addition of methotrexate and then methotrexate plus ifosfamide improved the 5-year relapse-free survival from 13% to 34% and 67%, respectively.[115] A recent updated analysis of adult osteosarcoma patients treated with this modified approach at MDACC confirmed the long-term survival of patients with poor response to preoperative doxorubicin and cisplatin and went on to receive postoperative therapy with high-dose ifosfamide and high-dose methotrexate.[118]

For patients who achieve 90% or greater tumor necrosis with four cycles of doxorubicin and cisplatin preoperatively, we recommend four additional cycles of doxorubicin (75 mg/m^2) combined with ifosfamide (10 g/m^2). For those with less than 90% tumor necrosis after preoperative doxorubicin and cisplatin, we favor six cycles of high-dose ifosfamide and six cycles of high-dose methotrexate given sequentially.

The role of postoperative switch therapy or intensified therapy guided by histologic response to preoperative chemotherapy remains controversial in osteosarcoma. In the European and American Osteosarcoma Studies (EURAMOS-1) study, 618 children and young adults with high-grade osteosarcoma who received preoperative methotrexate, doxorubicin, and cisplatin (MAP) with 10% or greater viable tumor at surgery were randomized one to one after surgery to receive either continuation of MAP or intensification with the addition of ifosfamide and etoposide to the same MAP backbone (MAPIE).[119] Intensification with MAPIE failed to show an advantage in terms of event-free survival (HR, 1.01) and OS (HR, 0.99) and was associated with additional toxicity at a median follow-up period of 4.5 years.

Patients with high-grade osteosarcomas of other sites are treated in a similar fashion; however, their overall outcome is worse than that of patients with extremity tumors. This may be due in part to difficulties in achieving a negative surgical margin of resection owing to anatomic constraints. Patients with low-grade and variant osteosarcomas—such as well-differentiated intramedullary osteosarcoma, parosteal osteosarcoma, and jaw osteosarcoma typically arising in the mandible, which have a lower tendency to produce distant metastases—are treated with surgical resection with negative margins alone without routine use of adjuvant chemotherapy. If surgical resection with negative margins cannot be achieved in osteosarcoma of the jaw, preoperative chemotherapy should be considered. Postoperative radiation therapy has been shown to reduce local recurrence and improve survival for patients with craniofacial and jaw osteosarcomas with positive resection margins.[120] Patients with intermediate-grade periosteal osteosarcoma should also receive preoperative chemotherapy.

UPS of bone is treated according to the same basic principles as conventional osteosarcoma. In a series of patients treated at MDACC, about 35% of patients with an initial diagnosis of UPS of bone based on biopsy were subsequently reclassified as osteosarcoma or other bone sarcomas at the time of resection after preoperative chemotherapy.[121] For patients with confirmed UPS of bone, the median OS for patients with localized disease was 5.2 years compared with 1.7 years for patients with metastatic disease at diagnosis. Importantly, among patients with localized disease, treatment with preoperative doxorubicin and cisplatin was associated with significantly better OS (HR, 0.23). The European Osteosarcoma Intergroup had similar results in studies using doxorubicin and cisplatin preoperatively and postoperatively, with 5-year PFS and OS rates of 56% and 59%, respectively.[122]

Metastatic and Recurrent Disease

Approximately 10% to 20% of patients with osteosarcoma present with metastatic disease. The lung is the most common site of metastasis in osteosarcoma; however, osteosarcoma can also metastasize to almost any bone in the body. Lymph node metastases are rare. Patients who have resectable pulmonary metastases are treated with curative intent with primary chemotherapy, as described earlier, followed by surgical resection of all lesions either at the same time or in staged operations. With this approach, patients have a 15% to 30% chance of long-term DFS and potential cure. Patients with bone or other unresectable metastasis have a poorer prognosis, with therapy usually directed at palliation.

Relapse is seen in about 30% of patients presenting with localized disease and up to 80% of patients who present with primary metastatic disease. Patients with relapsed metastatic or locally recurrent disease are approached similarly to patients with primary metastatic disease with chemotherapy or resection (or both) when possible. Surgery alone is appropriate for patients with resectable lung metastasis and a favorable disease-free interval (typically >1–2 years after initial chemotherapy). This approach yields 5-year survival rate of 25% to 40% for patients who can be rendered surgically free of disease.[123] The prognosis for patients with recurrent unresectable disease remains

exceedingly poor, and treatment is focused on disease control and palliation.[124] Several agents have activity in relapsed or refractory osteosarcoma including ifosfamide alone or in combination with etoposide (IE), gemcitabine in combination with docetaxel, and more recently, VEGF-targeted TKIs. Regorafenib, a multitargeted antiangiogenic TKI, has shown activity in metastatic osteosarcoma in two recent placebo-controlled phase 2 trials. In the French REGOBONE study, 65% of patients treated with regorafenib were progression-free at 8 weeks compared with 0% of those receiving placebo.[125] Findings from the US-led SARC024 study were comparable, with an improvement in PFS (median progression-free survival [mPFS], 3.6 months regorafenib vs 1.7 months placebo).[126] For patients with late recurrences and a favorable initial treatment response, retreatment with a combination of the initial chemotherapy (methotrexate, doxorubicin, cisplatin) can also be considered.

Chondrosarcoma

Chondrosarcomas are resistant to most chemotherapeutic agents used for the treatment of bone sarcomas. Surgical resection is the primary treatment modality, regardless of the grade of the tumor. Patients with conventional chondrosarcoma with unresectable or metastatic disease should be enrolled onto clinical trials, and genomic profiling should be considered for potential target identification. Unlike other chondrosarcoma subtypes, patients with mesenchymal chondrosarcoma and dedifferentiated chondrosarcoma should be treated with multimodality therapy.

Dedifferentiated chondrosarcoma is associated with a low-grade chondrosarcoma component as well as an area of high-grade STS, which may resemble other bone sarcomas.[127] They are associated with a much more aggressive clinical course and generally require urgent treatment to palliate tumor-related symptoms to hopefully extend survival. These tumors may respond to doxorubicin- and cisplatin-based chemotherapy and are treated in a similar manner as those with conventional osteosarcomas, although pathologic tumor necrosis at resection is frequently less than would be expected in conventional osteosarcomas. It is unclear if this measure is of the same prognostic significance as observed with osteosarcomas. Furthermore, tolerance to osteosarcoma regimens is generally less optimal compared with younger patients affected by osteosarcoma. Patients with relapsed or refractory disease should be considered for clinical trials and molecular testing. Approximately 60% of dedifferentiated chondrosarcomas harbor mutations in exon 4 of the *IDH1* gene, which makes IDH oncometabolite inhibitors an attractive option to consider.[128] Interestingly, dedifferentiated chondrosarcomas have been shown to harbor an inflamed phenotype with the presence of CD8+ T-cells and programmed cell death ligand 1 (PD-L1) expression involving the dedifferentiated portions of the tumor samples.[129] In addition, several reports suggest possible efficacy of immune checkpoint inhibitors.[130,131] Clinical trials specific to this rare malignancy are still needed to confirm this activity.

Mesenchymal chondrosarcomas are a rare variant that present in the jaw, spinal column, and ribs with lytic lesions on x-ray examination. The histology consists of a biomorphic appearance of benign to low-grade cartilaginous components with poorly differentiated small cell components.[132] The majority of these tumors harbor a unique *HEY1-NCOA2* fusion, which is thought to affect Notch signaling.[133] Patients with mesenchymal chondrosarcomas typically respond to chemotherapy; a recent series of 54 patients with localized disease treated with combination chemotherapy demonstrated a reduced risk of fracture (HR, 0.482; 95% CI, 0.213–0.996; P =.046) and death (HR, 0.445; 95% CI, 0.256–0.774; P =.004).[134] For this reason, we typically treat patients with mesenchymal chondrosarcoma in a similar fashion as those with Ewing sarcoma. In our experience, responsive tumors typically exhibit more calcification with an associated decrease in FDG avidity (when PET-CT is used for response assessment), and they are less apt to show decreases in tumor size as opposed to Ewing sarcomas, which typically exhibit dramatic volumetric response and reduction in tumor size.

Ewing Sarcoma

Like patients with osteosarcoma, those with Ewing sarcoma and the PNET family of tumors are treated primarily with chemotherapy before surgery because of the high likelihood of micrometastatic disease at the time of diagnosis. These tumors are highly chemosensitive and responsive to the following chemotherapeutic agents: doxorubicin, dactinomycin, ifosfamide, cyclophosphamide, vincristine, and etoposide. The most commonly used combinations are vincristine, doxorubicin, and cyclophosphamide (VAC); IE; and vincristine, doxorubicin, and ifosfamide (VAI). Multiple trials have shown that with these combinations of chemotherapy, survival rates greater than 50% can be achieved. At MDACC, for adult patients with EFT, we typically give vincristine (up to 2 mg) with doxorubicin (75–90 mg/m^2) and ifosfamide (10 g/m^2) as our preferred preoperative chemotherapy regimen. This is followed by surgical resection, if possible, or radiation therapy. Ewing sarcoma is very radiosensitive; often, when surgical resection is not an option or positive margins remain, consolidative radiation therapy

is used. After definitive resection, tumor necrosis is assessed, and postoperative therapy is modified as needed (see Fig. 50–5). In adults with Ewing sarcoma, this approach has yielded favorable outcomes compared with historic control participants.[135] Treatment with VAI was associated with a radiologic response in 84% of patients. Five-year OS was highest for patients with localized disease (68% vs 10%) and those with favorable tumor necrosis after neoadjuvant VAI (5-year OS, 84% for those with ≥95% tumor necrosis vs 53% for those with <95% tumor necrosis). A separate retrospective review of 66 patients from our institution treated with chemotherapy and R0 resection similarly identified histologic response (necrosis ≤95%), radiographic response by RECIST, and metastasis to be independent predictors of outcome.[136]

Metastatic and Recurrent Disease

Patients with metastatic or recurrent Ewing sarcoma are treated in a similar manner as metastatic or recurrent disease in osteosarcoma with chemotherapy being a mainstay of treatment. Patients who have lung metastasis at the time of presentation are treated as outlined earlier with chemotherapy, surgery, and/or radiation with curative intent. Patients with recurrent or metastatic disease after primary therapy are treated on the basis of their disease-free interval, location, and extent of disease. Given its rarity and limited therapeutic options available, we prefer treatment on Ewing sarcoma–specific clinical trials when available. If there is a long disease-free interval (>12 months), retreatment with previous chemotherapeutic regimens, preferably at higher-dose intensity (eg, high-dose ifosfamide), is reasonable. For patients with a shorter interval between therapy and recurrence or metastasis, second-line options include vincristine, irinotecan, and temozolomide or cyclophosphamide with topotecan. Recent studies have evaluated the activity of VEGF-targeted TKIs with varying activity, including pazopanib, regorafenib,[137] and cabozantinib.[138]

Giant Cell Tumor of Bone

Giant cell tumor of bone a rare primary bone malignancy of osteoblastic lineage that often contains osteoclast-like giant cells surrounded by stromal cells. The stromal cells are considered to be the neoplastic cells for this disease that recruit a population of non-neoplastic multinucleated giant cells.[139] This tumor generally involves the ends of long bones, including the distal femur, proximal tibia, and distal radius. Although considered benign, these tumors have a propensity for local recurrence, and approximately 3% metastasize to the lung parenchymal tissue. These tumors may result in pain, swelling, or decreased range of motion. Giant cell tumors appear as lytic, eccentrically located lesions in the epiphyses of a long bone on x-ray imaging. The primary treatment of giant cell tumors of bone consists of surgical intervention, either wide excision or intralesional curettage and cementation. Radiation therapy can be used as primary treatment or after surgery and has been shown to improve local control and DFS but has also been associated with an increased risk of malignant transformation.[140] When the primary location precludes surgical resection because of morbidity or patients develop distant metastatic disease, consideration is given to systemic therapy). Denosumab, an antibody to the receptor activator of nuclear factor kappa-B (RANK) ligand, which inhibits osteoclastic function and increases calcification, has been shown to improve pain in patients with recurrent or metastatic giant cell tumor. In a phase II study of denosumab in unresectable or recurrent giant cell tumor, treatment with denosumab resulted in tumor response in 86% of evaluable patients (defined as elimination of >90% of giant cells or no radiographic progression of target lesion for ≤25 weeks).[141] These results led to an FDA approval of denosumab for treatment of patients with giant cell tumor of bone in adults or skeletally mature adolescents who have unresectable disease or in whom surgery may result in significant morbidity. More recently, denosumab has been used as a neoadjuvant with one open-label phase 2 trial of 222 patients demonstrating native joint preservation in 96% of patients who were planned to have a joint or prosthesis replacement and 86% of patients who were originally planned to have a joint resection or joint fusion.[142] For patients with unresectable disease, we currently use denosumab as a frontline option, though there are still circumstance when we consider embolization or cryoablation on a case-by-case basis.

Follow-up Management

Regular and long-term follow-up is essential for patients with bone sarcoma. Patients are followed at MDACC with radiographs and physical examination every 3 months for the first 2 years, every 4 months for the next 2 years, every 6 months for the next 2 years, and then yearly thereafter. Surveillance includes high-quality chest imaging with either chest radiography or chest CT in high-risk patients, plain films of the primary tumor site to evaluate for recurrence and stability of any prosthesis, and routine laboratory studies. Bone scans, PET-CT scans, or both are useful in patients with specific symptoms or history of bony metastasis but are otherwise not routinely used for surveillance. Monitoring should also include an assessment of the potential late effects of chemotherapy, including anthracycline-induced cardiomyopathy, nephrotoxicity, neuropathy, and secondary malignancies.

MD ANDERSON PRACTICE TIPS

- Successful treatment of patients with soft tissue and bone sarcomas relies on multidisciplinary care, including radiology, pathology, medical, surgical, orthopedic, and radiation oncology. Treatment in experienced large-volume sarcoma centers has been associated with improved outcomes and should be considered when feasible.
- We recommend the use of neoadjuvant or adjuvant chemotherapy with doxorubicin and ifosfamide in patients with high-risk soft tissue sarcoma of the extremity, with the specific risks and benefits assessed for each individual patient.
- Within our center, treatment of stage III soft tissue sarcoma consists of neoadjuvant chemotherapy with doxorubicin and ifosfamide followed by preoperative radiation and surgical resection.
- Anthracyclines in combination with ifosfamide remain the standard frontline therapy for most patients with soft tissue sarcoma. Second-line chemotherapy regimens should be selected based on the histologic subtype and patient-specific factors.
- Treatment of bone sarcomas in adults presents additional challenges compared with the pediatric population. For adults with localized osteosarcoma, we favor neoadjuvant chemotherapy with doxorubicin and cisplatin. Postoperative adjuvant chemotherapy is tailored to histologic response based on percent tumor necrosis. For adults with Ewing sarcoma, we use WAI as frontline therapy.
- Surgical resection should be considered for patients with oligometastatic disease. Aggressive surgical management of pulmonary metastases is associated with improved survival in both soft tissue and bone sarcomas, particularly among patients with a prolonged disease-free interval.

51 Endocrine Malignancies

Ha Nguyen
Mouhammed Amir Habra

KEY CONCEPTS

- Thyroid carcinoma is the most common endocrine malignancy. Recent advances in molecular profiling identified actionable mutations, leading to the availability of multiple FDA-approved drugs. The current treatments target angiogenesis (sorafenib and lenvatinib) or can be mutation specific (larotrectinib targeting *NTRK* gene fusion and selpercatinib targeting *RET* gene fusions).
- Anaplastic thyroid carcinoma (ATC) has very poor prognosis, but the clinical outcomes appear to be improving with a multidisciplinary approach utilizing targeted therapy, immunotherapy, radiotherapy, and surgery when feasible.
- In cases with suspected parathyroid carcinoma, comprehensive surgery by an experienced team remains the mainstay of therapy, although the role of adjuvant radiation and targeted therapy remains unclear.
- Genetic counseling and testing is needed in all cases of pheochromocytoma/paraganglioma, even in the absence of family history of these tumors
- The management of metastatic pheochromocytoma/paraganglioma should be in the context of a multidisciplinary and experienced team. Resection of the primary tumor when feasible is associated with improved outcome. Iobenguane I 131 is FDA approved for patients with metastatic pheochromocytoma/paraganglioma that retain metaiodobenzylguanidine avidity, whereas traditional cytotoxic chemotherapy can be offered to select patients with rapidly progressing disease, especially in the presence of excess catecholamines. The role of targeted therapy is evolving, and extreme care must be exerted when using these drugs in patients with metastatic pheochromocytoma because they could exacerbate preexisting hypertension.
- The combined use of mitotane with cytotoxic chemotherapy (etoposide, doxorubicin, cisplatin) is associated with a suboptimal response rate of 23% and represents the first-line systemic therapy in advanced adrenocortical carcinoma. Single-agent immune checkpoint inhibitors are associated with lower response rates based on small clinical trials.

THYROID CANCER

Introduction

Thyroid cancer is the most common endocrine malignancy. The incidence of thyroid cancer in the United States has slightly declined over the past 5 years and in 2020, approximately 52,890 new cases of thyroid carcinoma were estimated to be diagnosed in the United States, accounting for 3% of all new malignancies, with women accounting for almost 76% of all cases.[1] Thyroid cancer occurs less frequently in children compared with adults, with a peak incidence of around 50 years. Despite this, overall long-term survival remains favorable. Histologic types (Table 51–1) include those that derive from the follicular epithelial cells (papillary and follicular), which account for the majority of thyroid cancers, and from the parafollicular C cells (medullary). Other thyroid tumors, including primary lymphomas of the thyroid, which are usually metastases from other primary sites, are also rarely encountered.

EVALUATION OF SOLITARY THYROID NODULES

Introduction

Thyroid cancer usually presents as a nodule identified on physical examination or discovered incidentally on imaging studies performed for unrelated reasons.

Table 51–1 Types of Thyroid Cancer

Type	Frequency	Prognosis (10-year Overall Survival)
Originating From Follicular Cells		
Papillary	80%	93%
Follicular	11%	85%
Hürthle cell	3%	76%
Anaplastic (undifferentiated)	2%	14%
Originating From C Cells		
Medullary	4%	75%

Data from Hundahl SA, Fleming ID, Fremgen AM, Menck HR. A National Cancer Data Base report on 53,856 cases of thyroid carcinoma treated in the U.S., 1985-1995. *Cancer*. 1998;83(12):2638-2648.

However, most thyroid nodules are benign, with about 10% to 15% found to be malignant on biopsy.[2] The main diagnostic challenge is accurately differentiating benign from malignant disease to ensure appropriate definitive therapy and avoid unnecessary treatments.

Diagnosis

Clinically palpable nodules are found in approximately 5% of the population. With widespread use of different imaging modalities, thyroid nodules are reported to appear in up to 60% of the population.[3] Benign and malignant nodules are almost always clinically indistinguishable. Features indicating increased likelihood of carcinoma are summarized in Table 51–2. Initial evaluation and treatment of patients presenting with thyroid nodules is detailed in Fig. 51–1.

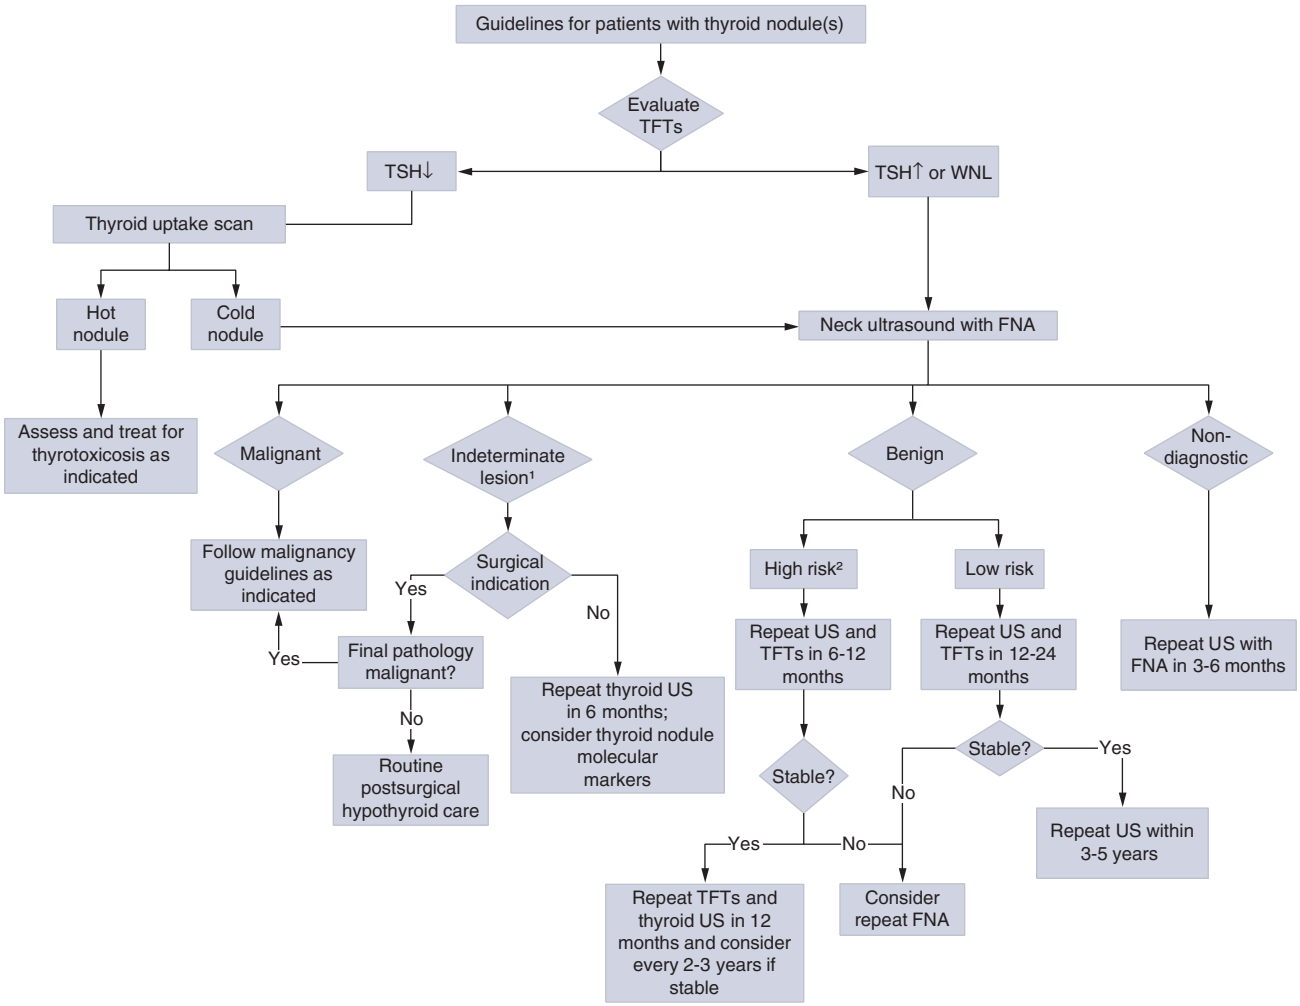
Thyroid ultrasonography (US) with fine-needle aspiration (FNA) and cytologic examination is the modality of choice for evaluating nodules with suspicious characteristics. Papillary, medullary, and anaplastic carcinomas can be readily diagnosed by FNA or biopsy, but distinguishing benign from malignant follicular lesions proves to be more difficult. Histologic examination showing capsular or vascular invasion is necessary to classify a lesion as malignant. Because follicular adenoma and carcinoma cannot be differentiated cytologically, they are grouped as "indeterminate or suspicious follicular neoplasms." The rate of carcinoma for suspicious follicular neoplasms is about 20%. The incidence of malignancy increases with larger nodule size, male sex, and increasing age. Testing for molecular markers should be considered for patients with indeterminate or suspicious follicular neoplasm on cytology.[4,5] Five percent to 10% of the time, the FNA will yield "inadequate diagnostic material," and this necessitates repeat aspiration. The majority (85%–95%) of thyroid nodules are benign. Radionuclide scans usually show malignant lesions as hypofunctioning or "cold," although 85% of "cold" nodules are still benign.

Table 51–2 Clinical Features Associated with Increased Risk of Malignancy

Age <20 years
Presence of cervical lymphadenopathy
History of radiation to the head and neck during childhood
Family history of medullary thyroid cancer or MEN types 2A and 2B
Hard, fixed nodule
Recent nodule growth
Hoarseness of voice (indicating invasion of recurrent laryngeal nerve)

MEN, multiple endocrine neoplasia.

DIFFERENTIATED THYROID CANCER



Introduction

Differentiated thyroid cancer (DTC) includes papillary, follicular, and poorly differentiated histology types and comprises about 90% of all thyroid cancers. The factors associated with increased risk of thyroid carcinoma are summarized in Table 51–3.

Traditionally, exposure to ionizing radiation, family history, and genetic syndromes have been the main risks associated with DTC.[6] In addition, a meta-analysis of 21 observational studies suggests an association with obesity (adjusted relative risk [RR] 1.33; 95% CI 1.24–1.42).[7] On average, thyroid tumors can be recognized 10 years after radiation exposure, but can be seen for as long as 30 years. Malignancy occurs in up to 30% of cases with head or neck irradiation. Exposure to external sources of radiation after the Chernobyl nuclear accident led to a three- to 75-fold increase in the incidence of papillary thyroid carcinoma (PTC) in fallout regions, especially in younger children.[6] Familial PTC is reported in 5% of all patients with PTC and may portend a more aggressive disease course. In addition, DTC has also been associated with other tumors, particularly breast and renal cancers.[8]

Pathogenesis

Understanding the follicular cell tumorigenesis pathways is central to the development of novel therapies to treat thyroid cancer. The MAPK pathway is the main oncogenic propagator of PTC. *BRAF* and *RAS* genes in this pathway normally code for growth and function in normal and tumor cells. Chromosomal rearrangements of the gene encoding the transmembrane

tyrosine kinase receptors RET and TRK have been implicated as an early step in the development of these tumors. Mutations in either *BRAF* (40%–60%) or *RAS* (10%–15%) or *RET/PTC* rearrangements (10%–15%) are present in most DTCs (Fig. 51–2).[9]

Activating *RET* mutations may be the result of ionizing radiation and were the most common mutations found in the Chernobyl radiation-induced thyroid carcinomas.[10] *BRAF* mutation has been implicated in more aggressive disease and greater mortality from PTC.[11]In addition, when present in combination with *BRAF*, a recent novel driver, telomerase reverse transcriptase (*TERT*) mutation, which is implicated in advanced thyroid cancer, results in the most aggressive PTC with the highest recurrence rate.[12] Of follicular thyroid cancers, 30% are driven by Pax8-peroxisome

proliferator-activating receptor (*PPAR*)-γ rearrangements, and 10% to 15% are driven by *RAS* mutations.[9]

Thyroid tumor growth is dependent on angiogenesis, which is important for tumor cell growth, promotion, and development of metastases.[13] Vascular endothelial growth factor (VEGF), an important proangiogenic factor, binds to VEGF receptors. This then activates MAP-kinase signaling and promotes further tumor growth. VEGF receptors play a contributory role in the development and progression of thyroid cancer.

Diagnosis

Thyroid cancer is subdivided into well-differentiated neoplasms characterized by slow growth and high curability and a small group of poorly differentiated tumors with poor outcome. There are four major subtypes of thyroid cancer, which are based on morphology and biological behavior. This classification is advantageous because it relates morphology to methods of treatment and prognosis.

Histologic characteristics of conventional PTCs include numerous papillae lined by cuboidal to low columnar follicular cells with enlarged irregular nuclei with longitudinal grooves, intranuclear cytoplasmic pseudo-inclusions, and solitary or multiple marginally placed micronucleoli (Fig. 51–3). Follicular variants of PTC and other PTC variants are also recognized. Follicular tumors, although frequently encapsulated, can exhibit vascular and capsular invasion microscopically; it is this invasion that, when identified histopathologically, distinguishes benign neoplasms from malignant follicular neoplasms (Fig. 51–4). Hürthle cell carcinomas are considered a subtype of follicular cancer. Tall cell variants, columnar cell variants, Hürthle cell variant, and insular type are histologic subtypes that may portend a worse prognosis.

Staging

The TNM (tumor, node, metastasis) method may be most useful for prediction of disease-free survival and is generally used in our institution. Tumor size and presence of extrathyroidal invasion carry prognostic importance and thus should consistently be included in the pathologist's synoptic report. Anaplastic thyroid carcinoma (ATC) by convention is always stage IV (Tables 51–4 and 51–5).

Management

Surgical Management

Preoperative US of the entire neck (not just of the thyroid) is indicated to help identify the presence of nodal metastases and help the surgeon perform the

Table 51–4 Staging of Thyroid Carcinoma

Primary Tumor (T)	
Note: all categories may be subdivided into (a) solitary tumor and (b) multifocal tumor (the largest determines the classification).	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1a	Tumor ≤1cm in greatest dimension limited to the thyroid
T1b	Tumor >1 cm but ≤2 cm in greatest dimension limited to the thyroid
T2	Tumor >2 cm but ≤4 cm in greatest dimension limited to the thyroid
T3a	Tumor >4 cm limited to the thyroid
T3b	Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumor of any size
T4a	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
T4b	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0a	One or more cytologically or histologically confirmed benign lymph nodes
N0b	No radiologic or clinical evidence of locoregional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis to level VI or VII (pretracheal, paratracheal, or prelaryngeal/Delphian, or upper mediastinal) lymph nodes. This can be unilateral or bilateral disease.
N1b	Metastasis to unilateral, bilateral, or contralateral cervical neck lymph nodes (levels I, II, III, IV, or V) or retropharyngeal lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

appropriate surgery. Total thyroidectomy was traditionally the standard of care in the majority of thyroid cancer cases. However, there is increasing evidence that thyroid lobectomy could be a reasonable option in certain group of patients with low-risk papillary or follicular carcinomas such as those younger than 45 years of age, those with intrathyroidal unifocal tumor, those with tumor smaller than 4 cm, and those with absence of nodal disease and no evidence of extrathyroidal extension.[14] Several studies have demonstrated excellent long-term clinical outcomes in properly selected patients eligible for thyroid lobectomy.[15,16] The rate of recurrent disease was less than 5%, readily detectable with long-term surveillance, and when properly treated, did not affect overall outcome (Fig. 51–5).[17]

Total thyroidectomy remains the treatment of choice in patients with higher risk of recurrence or death including primary tumor larger than 4 cm, presence of extrathyroidal extension, and regional or distant metastasis. However, patients with tumors between 1 and 4 cm with risk factors such as familial DTC, prior radiation therapy to the neck area, age older than 45 years, and presence of contralateral thyroid nodules may be considered to undergo total thyroidectomy to facilitate postoperative radioactive iodine (RAI) treatment or surveillance. Prophylactic central neck dissection remains controversial and is not always indicated. However, neck dissection should be performed on patients with identifiable nodal disease, because their presence affects recurrence. Calcium and parathyroid hormone levels should be monitored postoperatively because of the risk of hypoparathyroidism from either vascular damage intraoperatively or inadvertent removal.

Postoperative Iodine-131 Therapy (Radioactive Iodine Treatment)

Iodine-131 (^{131}I) is used as adjuvant therapy for thyroid carcinoma; iodine is preferentially taken up and

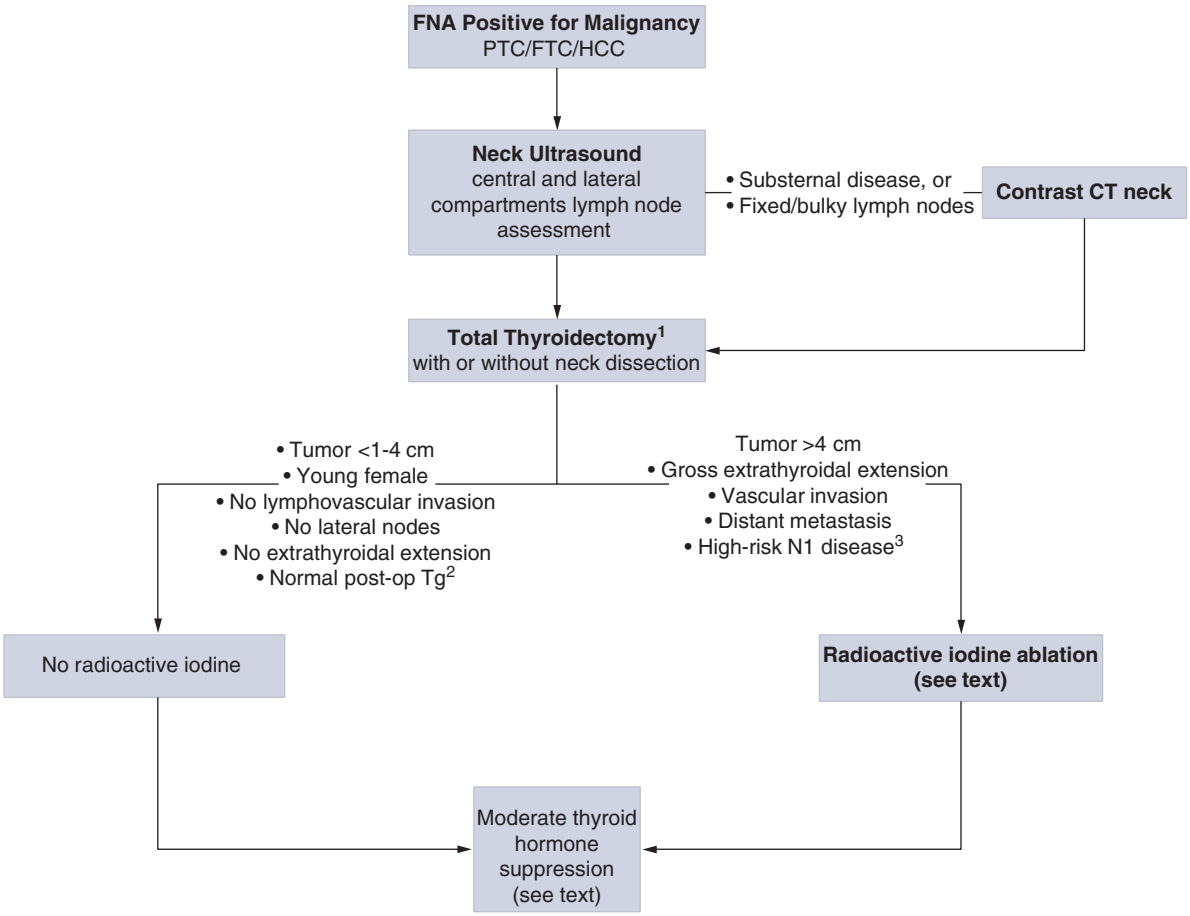

Table 51–5 Stage Grouping for Thyroid Carcinoma

Separate stage groupings are recommended for papillary or follicular, medullary, and anaplastic (undifferentiated) carcinomas.			
Papillary or Follicular (<55 Years)			
Stage I	Any T	Any N	M0
Stage II	Any T	Any N	M1
Papillary or Follicular (≥55 Years)			
Stage I	T1/T2	N0/NX	M0
Stage II	T1/T2	N1	M0
Stage II	T3a/T3b	Any N	M0
Stage III	T4a	Any N	M0
Stage IVA	T4b	Any N	M0
Stage IVB	Any T	Any N	M1
Medullary Carcinoma			
Stage I	T1	N0	M0
Stage II	T2–T3	N0	M0
Stage III	T1/T2/T3	N1a	M0
Stage IVA	T4a	Any N	M0
	T1/T2/T3	N1b	M0
Stage IVB	T4b	Any N	M0
Stage IVC	Any T	Any N	M1
Anaplastic Carcinoma			
All anaplastic carcinomas are stage IV.			
Stage IVA	T1–T3a	N0/NX	M0

trapped by the thyroid follicular cells as well as malignant counterparts. Iodine-131 destroys cells of follicular origin by first becoming concentrated in the cell where β rays are released, and the high-energy electrons spewed induce radiation cytotoxicity; simultaneously, γ rays are released that allow for detection of the emission by a camera. Therefore, postoperative examination with RAI scanning allows the identification of residual regional or distant foci of disease, and RAI can be used therapeutically to ablate such tumor deposits. The rationale for using ^{131}I as adjuvant therapy is as follows: (1) it destroys any residual microscopic foci of disease, (2) it increases specificity of subsequent ^{131}I scanning for detection of recurrent or metastatic disease by elimination of uptake by residual normal tissue, and (3) it improves the value of measurements of serum thyroglobulin (Tg) as a serum marker; hence, any elevation in Tg would be representative of recurrent or metastatic disease and not residual normal thyroid tissue. Combined retrospective data suggest that RAI ablation reduces long-term, disease-specific mortality in patients with primary tumors 4 cm in diameter or larger, those with multicentric disease, or those in whom there is evidence of soft tissue invasion at presentation.[18] Low-risk patients (Fig. 51–5) may not benefit from RAI, and selective use is advocated in these patients. The use of postoperative Tg measured 1 to 2 months after surgery is a useful tool to gauge residual or metastatic disease. Undetectable stimulated or unstimulated Tg indicates a very low likelihood of residual disease. Suppressed Tg levels lower than 0.2 ng/mL or stimulated Tg levels lower than 1 ng/mL are indicative for excellent response.[14] However, the decision to administer ^{131}I should not rely solely on the level of Tg.

Postoperatively, patients who require ^{131}I therapy may continue to take a thyroid supplement if recombinant human thyrotropin (rhTSH) is used or

[1]Consider lobectomy for small tumors <4 cm; no history of radiation; no gross extrathyroidal extension; no cervical lymph node disease; age <4; no family history.
[2]Nonstimulated Tg <5 ng/mL or stimulated Tg <10 ng/mL and negative Tg antibodies.
[3]High-risk N1 disease: >10 involved nodes if all are less than 5 mm; >5 involved nodes if most are 5-15 mm; or any single lymph node more than 15 mm.

Selective use of RAI for ablation and adjuvant therapy after total thyroidectomy for differentiated thyroid cancer: a practical approach to clinical decision making. *Oral Oncol*. 2013;49(7):676-683.

undergo thyroid hormone withdrawal in preparation for treatment.. During this time, patients should avoid iodine-rich food. Urinary iodine concentrations can be checked to assess total-body iodine content before RAI therapy. For maximum RAI uptake, thyroid-stimulating hormone (TSH) should be allowed to rise to more than 30 μIU/mL because this facilitates uptake of iodine by follicular cells. Increased iodine stores decrease RAI uptake. For patients in whom a preoperative contrast computed tomography (CT) was done, RAI therapy should be avoided for at least 2 months. A pretreatment scan using a 2- to 5-mCi ^{123}I or ^{131}I RAI scan for localization of uptake before ablation is recommended but not mandatory. Twenty-four to 96 hours after dosing, a whole-body scan showing less than 5% uptake is presumed to be normal residual tissue. An uptake of more than 5% indicates excessive thyroid tissue and warrants consideration for further surgical resection. The dose of RAI is determined by extent of residual disease: 30–100 mCi for adjuvant ablation, approximately 150 mCi for nodal disease, and 200 mCi or more for metastatic disease outside the lungs.[14] However, it is important to know that the routinely used ^{131}I doses are not administered from high-quality evidence. A post-treatment scan is performed to assess for further uptake of RAI that was not previously seen on the pretreatment scan (ie, regional or distant metastases). The post-treatment scan is a more sensitive technique to detect metastatic disease, because the ability to demonstrate RAI-avid lesions is directly proportional to the amount of RAI given (Fig. 51–6).

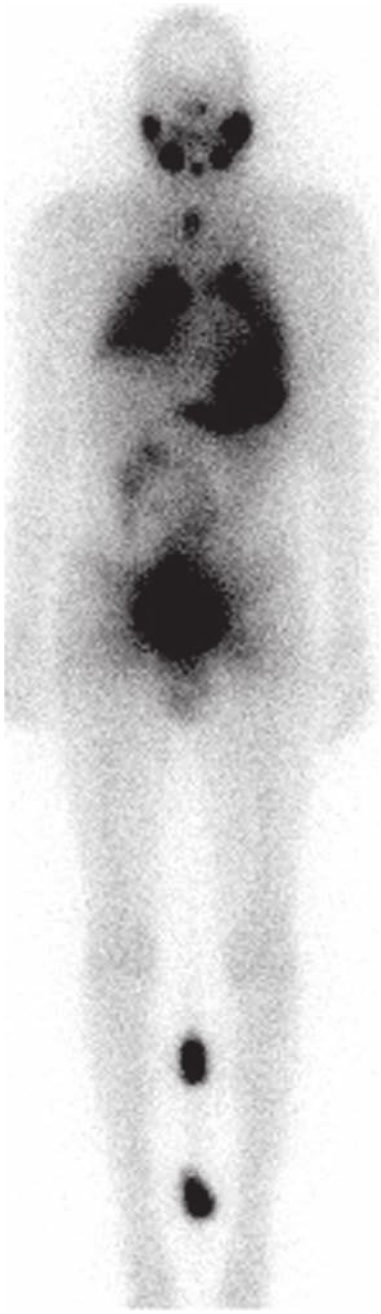

FIGURE 51–6 Whole-body scan with iodine-131 (^{131}I) showing multiple metastatic deposits in the neck and lungs, with physiologic uptake in the salivary gland, stomach, intestines, and bladder.

Short-term complications, although rare, include radiation thyroiditis, neck edema, sialadenitis, and tumor hemorrhage. These occur more often in the presence of bulky disease. Long-term complications, which increase with cumulative doses, include xerostomia, nasolacrimal duct obstruction, pulmonary fibrosis (if pulmonary metastasis is present and treated at high doses), and secondary malignancies such as acute myelogenous leukemia.[19] There are no reports of congenital abnormalities in children conceived after RAI treatment; however, most physicians recommend waiting for 6 months before conceiving. Radioactive iodine should not be given to pregnant women because of the potential teratogenic effects for the fetus's growth and thyroid development; all women of childbearing age must have a negative pregnancy test before receiving treatment.

Thyroid Hormone Therapy

Thyroid hormone replacement targeting TSH suppression has been shown to increase disease-free survival two- to threefold, especially in high-risk patients. It minimizes potential TSH-stimulated growth of thyroid cancer cells. Over-suppression of TSH to undetectable levels can present morbid consequences including osteopenia, atrial fibrillation, and possible cardiac hypertrophy. Moderate TSH suppression (subnormal but not undetectable) during follow-up was associated with better outcomes in all stages, including in patients with distant metastatic disease. For high-risk patients, moderate TSH suppression continued for the first 3 years after initial diagnosis may be indicated.

External Beam Radiotherapy

External beam radiotherapy (EBRT) plays a role in the treatment of PTC in certain subgroups of patients. Our institutional review of postoperative conformal EBRT in high-risk patients with DTC showed durable locoregional control in those with residual microscopic disease after initial surgery. However, patients with gross residual disease had significantly worse outcomes.[20] EBRT can be considered in aerodigestive invasion as adjuvant therapy after surgery.[14] Radiotherapy can also be a palliative local therapeutic option in RAI–nonavid, locally advanced or distant metastatic disease.

Management After Initial Therapy

Imaging

After initial therapy, patients with DTC need lifelong monitoring using both clinical and radiographic data. In high-risk patients, follow-up RAI scan 12 months after initial RAI ablation should be considered for reassessment of disease burden. The TSH should be allowed to increase to a value higher than 30 μIU/mL by either withdrawal of thyroid hormone or using rhTSH. Thyrotropin alfa, an rhTSH, administered as two injections on 2 consecutive days, may be used in lieu of standard thyroid hormone withdrawal to increase thyrotropin concentrations and for adequate stimulation of both RAI uptake for scanning and serum Tg concentrations. The use of rhTSH is of particular benefit for the patient in whom endogenous TSH levels cannot rise because

of hypopituitarism or in whom the clinician prefers to avoid prolonged hypothyroidism and its resultant complications caused by concurrent medical problems. Radioiodine scanning beyond this first follow-up scan needs to be individualized and is no longer routine for all patients with thyroid cancer, including high-risk patients.

Ultrasonography of the neck (thyroid bed and cervical neck compartments) with FNA of suspicious accessible lesions is used 6 to 12 months postoperatively as part of routine follow-up.

Other non–RAI imaging techniques include CT of the neck and chest, chest radiographs, fluorodeoxyglucose–positron emission tomography (FDG-PET) or PET, and magnetic resonance imaging (MRI). MRI and CT of the neck play important roles in the detection of recurrent disease; they are not as sensitive as US but are much less operator dependent. Chest CT shows both micronodular and macronodular pulmonary metastases. Fluorodeoxyglucose-PET/CT imaging is useful in patients with a Tg higher than 10 ng/mL who have negative RAI imaging but is not routinely used in follow-up of other patients with thyroid cancer.[14] Patients with DTC with little to no iodine activity generally have higher glucose metabolism and positivity on FDG-PET scans. Lack of iodine uptake denotes tumor dedifferentiation. Although PET is sensitive in detecting metastatic disease, it is not specific for thyroid cancer, and caution should be exercised when evaluating recurrent disease (Fig. 51–7). The use of CT imaging in conjunction with FDG-PET improves the sensitivity for small subcentimeter metastatic disease seen with DTC.

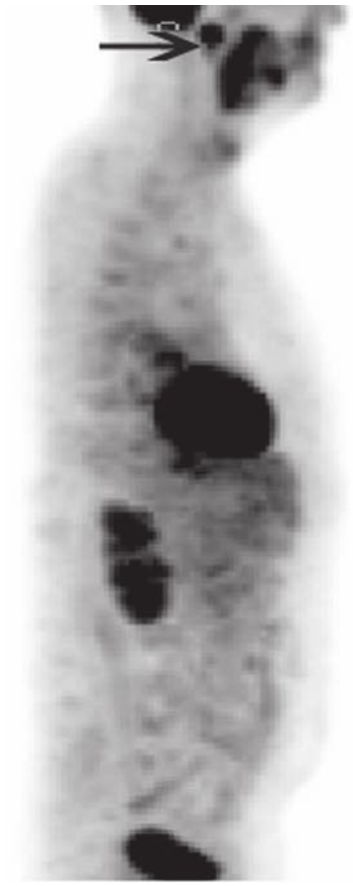

FIGURE 51–7 Positron emission tomography (PET) scan showing posterior pharyngeal metastatic papillary thyroid carcinoma. Thyroglobulin level was 35 ng/mL, and radioiodine whole-body scan was negative for disease.

Monitoring Serum Thyroglobulin

Thyroglobulin is a unique protein synthesized only by the thyroid follicular cells (both benign and differentiated malignant tissue) and, therefore, is a good biochemical test to assess for the presence of residual, recurrent, or metastatic disease. Dedifferentiated tumors lose the ability to secrete Tg, and it may not be used as a tumor marker. After total thyroidectomy with or without RAI ablation, the Tg falls to its nadir usually within 3 months but may take as long as 2 years. Subsequent Tg measurements (stimulated or unstimulated) are used to monitor for disease recurrence and should be repeated in the same laboratory to avoid erroneous misinterpretations of interassay variability. Simultaneously Tg and Tg antibody (TgAb) should always be measured together because TgAb can falsely lower the Tg concentrations in immunometric assays. These antibodies, which are present in approximately 25% of patients, interfere with the assay's ability to bind to Tg. Thyroglobulin measurements by radioimmunoassay or liquid chromatography tandem mass spectrometry are more resistant to interference by TgAb and are used when antibody presence is detected. The median time to TgAb disappearance after total thyroidectomy and RAI ablation is about 3 years.[21] Therefore, increases in TgAb after the nadir has been reached should alert the clinician to the possibility of recurrent disease. Although in general the diagnostic accuracy of serum Tg is higher after TSH stimulation than during thyroxine treatment, an unstimulated Tg measured by second-generation assays may be used to follow up patient treatment with stimulated Tg of less than 2 ng/mL with no evidence of recurrent disease on imaging.[22]

Metastatic Disease

Distant metastases are evident in about 15% of patients with DTC. Half of these patients have notable metastases at the time of initial presentation.[9] The most common sites of metastasis, in decreasing order of frequency, are the lungs, bones, and other soft tissues (Figs. 51–8A, B, and 51–9). Older patients have a higher

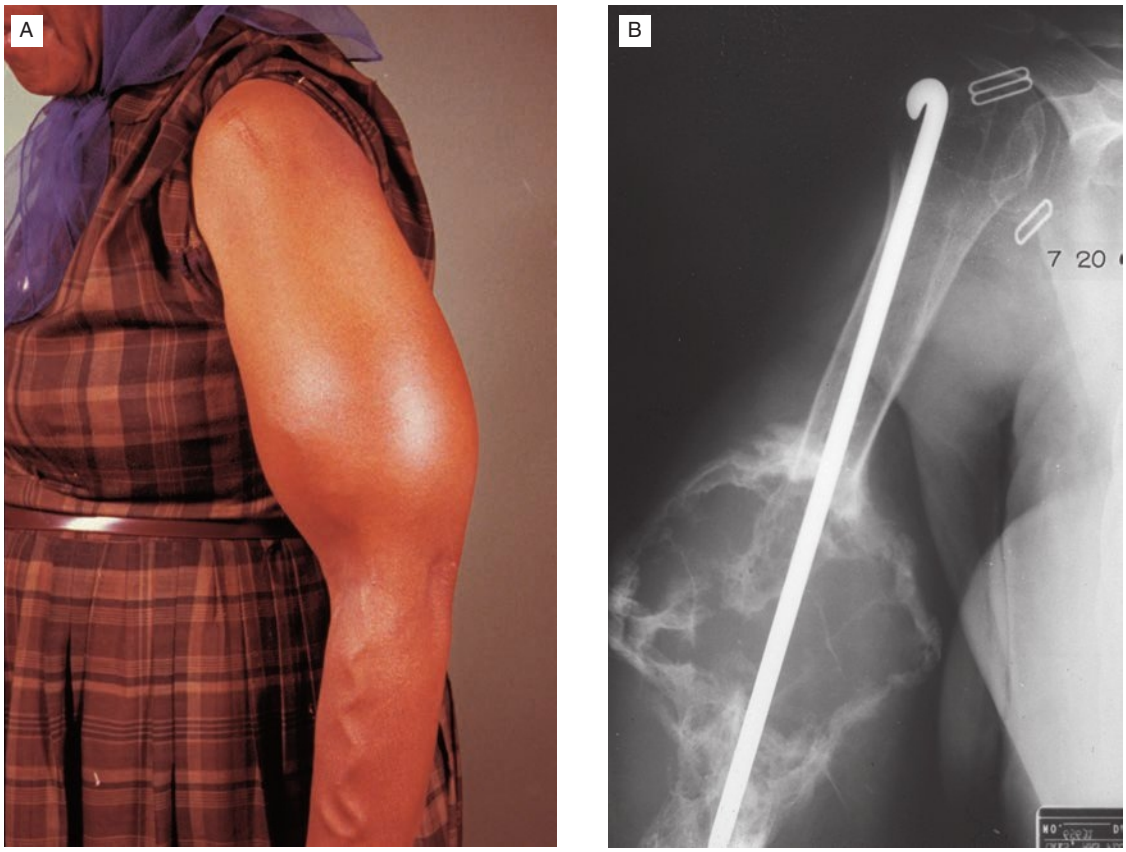

FIGURE 51–8 **A.** A woman with metastatic follicular thyroid carcinoma of the left humerus. **B.** Radiograph of metastatic follicular thyroid carcinoma of the left humerus in the same patient.

FIGURE 51–9 Patient with multiple metastatic deposits of papillary thyroid carcinoma to the skin.

risk for distant metastases. For resectable locoregional and isolated metastasis, surgery is preferred.

In those with iodine-avid unresectable disease or distant metastasis, ^{131}I treatment should be recommended, and higher doses (150–200 mCi) are typically used. Although this treatment may be repeated over time, caution and careful monitoring for side effects should be exercised. Moderate TSH suppression should also be continued in these patients. Metastases at different sites require management by multimodality approaches. Bone lesions may be surgically resected or treated with ^{131}I treatment or EBRT.[23] In follicular thyroid carcinoma, where the lesions are highly vascular, arterial embolization has been used anecdotally with successful reduction in pain at our institution. In addition, intravenous bisphosphonates (pamidronate or zoledronic acid) and denosumab are prescribed for painful bony metastases with some success. Experience at our institution also showed improved median survival for patients with one or more brain metastases after surgical resection. Stereotactic radiosurgery is also an option. We suggest a multidisciplinary approach and discussion with the surgeon, radiation oncologist, and endocrinologist about the risks and benefits of each modality in the management of metastatic disease.

Systemic Therapy

In patients with progressive metastatic disease that does not respond to standard therapy, long-term overall survival is less than 10%. For this subset of patients,

the understanding of the molecular model for thyroid cancer and the discovery of targeted therapies have led to a new era of treatment.[9] Consequently, two tyrosine kinase inhibitors (TKIs), sorafenib (2013) and lenvatinib(2015), have been approved by the FDA for the treatment of locally recurrent or metastatic, progressive DTC that is refractory to RAI treatment. Previously recommended cytotoxic therapies with agents such as doxorubicin have had poor outcomes with significant toxicities. TKIs target intercellular signaling pathways (MAPK pathway in the tumor cells) but also play a role in the surrounding tumor vasculature.[9] Trials evaluating the efficacy of the approved drugs have shown better progression-free survival (PFS) than in the placebo groups (5 months with sorafenib and 14.7 months with lenvatinib).[24,25] Lenvatinib had an overall response rate of 64.8% versus 1.5% in the placebo group (odds ratio [OR] 28.87, 95% CI 12.46–66.86). However, it is important to note the deleterious effects of these drugs, most commonly hypertension, gastrointestinal effects such as diarrhea, altered taste and stomatitis, palmar-plantar erythrodysesthesia syndrome (hand and foot syndrome), and weight loss. Recently, gene-specific therapies have received FDA approval for thyroid cancers harboring certain genetic mutations: larotrectinib (neurotrophic receptor tyrosine kinase [*NTRK*] gene fusion) (November 2018), dabrafenib and trametinib (*BRAF* V600E mutation in ATC) (May 2018), and selpercatinib (*RET* gene alterations) (May 2020).[26–28]

Indications for therapy include patients with progressive or symptomatic unresectable disease that is refractory to ^{131}I treatment. Patients with asymptomatic stable or very slowly progressive disease on thyroid hormone suppression therapy may be closely monitored. Before initiation of therapy, a comprehensive evaluation to ascertain appropriate selection of patients should be conducted. This should include a candid discussion with the patient and family about the benefits and risks of these agents. Furthermore, because of the life-threatening adverse effects of these drugs, only clinicians who are well versed in the use of these agents should initiate and monitor these patients. We have previously published an adverse event monitoring tool used at our institution to guide clinicians when starting patients on these agents.[29]

Differentiated Thyroid Carcinoma in Children

As in adults, PTC followed by follicular thyroid cancer occur most frequently in children. Exposure to radiation is the major risk factor. It is not unusual for children with PTC to present with multifocal disease with lymph node involvement, extrathyroidal extension, and pulmonary metastasis.[30] Despite this, children have high cure rates overall, with a 10-year survival rate of almost 100%. Those diagnosed before the age of 10 years, however, seem to have a higher risk of recurrence and death. The treatment of thyroid cancer in children mirrors that of adults. Total thyroidectomy (rarely lobectomy) with nodal dissection done at a high-volume center experienced with higher complication rates is recommended.[30] Postoperative universal RAI therapy is no longer advocated, and careful selection based on risk of recurrence, residual or distant disease remaining after surgery, and Tg levels is used to determine the need for therapy. Moderate TSH suppression (0.1–0.5 μIU/mL) with relaxation when there is no evidence of recurrent disease is suggested. Lifelong surveillance is essential in monitoring children for recurrent disease because recurrence may occur 20 to 30 years later. For the few children with progressive RAI-refractory DTC, referral to a center with pediatric endocrine neoplasia expertise for consideration for systemic therapy is recommended.

MEDULLARY THYROID CARCINOMA

Introduction

Medullary thyroid carcinomas (MTCs) are derived from C cells (calcitonin-secreting cells) that are part of the neural crest origin (see Table 51–1). The majority (75%) of patients with MTC have sporadic disease. The other 25 % have an inherited form that occurs as an autosomal dominant trait as part of the multiple endocrine neoplasia (MEN) clinical syndromes, MEN type 2A or type 2B, or familial MTC. In MEN 2A, MTC occurs in association with pheochromocytoma and multigland parathyroid tumors; MTC is usually the first manifested disease of the three components of this syndrome. In MEN 2B, MTC occurs in association with pheochromocytoma and mucosal neuromas (Figs. 51–10A, B) or neurofibromas and marfanoid habitus. Familial MTC is a variant of MEN 2A, where only MTC is clinically evident. Sporadic MTC in most patients presents in the fifth or sixth decade of life, with a male-to-female ratio of 1.4:1.[31]

Clinical Features and Diagnosis

The most common clinical presentation of sporadic MTC is a solitary thyroid mass found incidentally during routine examination. Other symptoms such as secretory diarrhea and facial flushing may also be seen with hormone overproduction. Fine-needle aspiration should be performed for suspicious nodules and once MTC is suspected, calcium, calcitonin, and carcinoembryonic antigen (CEA) levels should be obtained, as well as a screening for pheochromocytoma and a thorough

FIGURE 51–10 **A. Patient with multiple endocrine neoplasia (MEN) type 2B, with typical thickening of the palpebrum. Note also the ganglioneuroma on the left superior eyelid. B. Multiple ganglioneuromas on the tongue of a patient with MEN type 2B.**

history and physical examination done. Because about 6% of patients with sporadic MTC carry a germline *RET* mutation, genetic counseling and testing are offered to all patients with newly diagnosed apparent sporadic disease.[32] If pheochromocytoma is confirmed, appropriate control of catecholamine hypersecretion and removal should precede thyroid surgery.

Medullary thyroid cancer occurs as a solid mass or cluster of C-cell hyperplasia interspersed between

FIGURE 51–11 **Gross specimen of thyroid gland containing medullary thyroid carcinoma.**

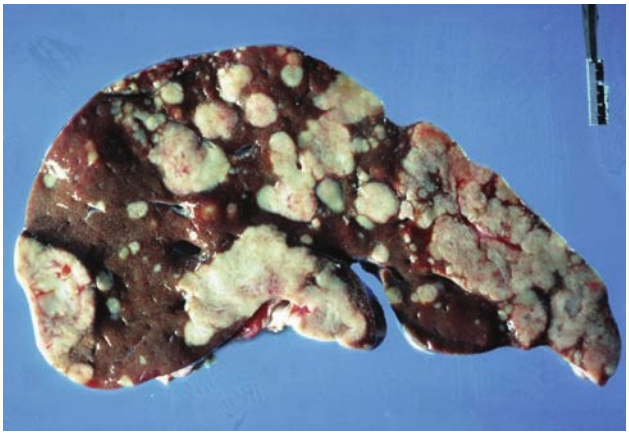

FIGURE 51–12 **Gross specimen of liver containing metastatic lesions of medullary thyroid carcinoma.**

normal thyroid follicles and can be visualized with calcitonin immunostaining (Fig. 51–11). It appears as variable amounts of fibrosis as well as deposits of amyloid in 60% to 80% of tumors. Notably, even the smallest visible tumors can be associated with metastases.

Metastases to cervical and mediastinal lymph nodes are found in about 50% of patients at the time of initial presentation. Distant metastases to the lungs, liver, bones, and adrenal glands most commonly occur late in the course of the disease (Fig. 51–12).

Inherited Medullary Thyroid Cancer

Inherited syndromes of MTC are all transmitted in an autosomal dominant form. In kindred with inherited MTC, prospective family screening is essential because of the 90% to 95% penetrance of the disease.[33] In these cases, MTC is usually present by the third to fourth decade of life. The mutation is detected in *RET* and can be identified in 98% of affected family members with

appropriate screening. Patients with MEN 2B tend to exhibit more locally aggressive MTC.[33] Screening with *RET* testing is recommended at less than 6 months of age for familial MTC, and MEN 2A screening is recommended by 5 years of age.[31]

Analysis of the *RET* gene should include the most common sites of mutation, exons 10 and 11 (C609, C611, C618, C620, C630, and C634) and RET codon mutations in exons 13, 14, 15, and 16.[34] With the substantial decrease in the expense of genetic sequencing in the last few years, some laboratories may sequence the entire RET coding region as the first step in screening. Appropriate genetic counseling must be a part of the initial evaluation, including the possibilities of errors in testing, the potential for discrimination, and changes that may occur in quality of life.

Management

Surgery

In MTC, there is a high propensity for bilateral disease in both the sporadic and familial forms, and therefore, the usual treatment is total thyroidectomy with central neck compartment dissection in all patients. In unilateral sporadic disease, if the primary tumor is greater than 1 cm or central compartment disease is present, strong consideration should be given to ipsilateral modified radical neck or mediastinal dissections, or both.[35] Bilateral neck dissections are usually performed in many institutions, including our own. Hypoparathyroidism and recurrent laryngeal nerve damage are the most frequently encountered complications in both children and adults. We recommend referral to centers with high volume and experienced surgeons to decrease these complications.

For carriers of a hereditary *RET* mutation, current guidelines recommend prophylactic total thyroidectomy at a certain age cut-off based on the risk of aggressive MTC disease in relationship with specific *RET* mutation. The ATA 2015 MTC guideline classified mutations M918T, C634F/G/R/S/W/Y, and A883F as highest-risk/high-risk mutations and others as moderate risk.[34] Of note, in many patients, C-cell hyperplasia and/or MTC is already present histologically at the time of surgery. There is also significant variability between families with similar mutations in terms of presentation, aggressiveness, and age of onset. Therefore, the timing of total thyroidectomy should involve a detailed and individualized discussion in addition to the available genotype-phenotype correlation data. As of this writing, total thyroidectomy is recommended in patients with MEN2B in the first year of life. Children with MEN2A carrying high-risk RET mutations should have total thyroidectomy by the age of 5 years. MEN2A moderate-risk RET mutations carriers may choose to have prophylactic total thyroidectomy during childhood or when the calcitonin level is elevated.

There is no role for thyroid hormone suppression therapy; hence, the goal should be to maintain the TSH and free thyroxine (T_4) concentrations within normal levels. There is also no role of RAI therapy in the treatment of MTC, and therefore, thyroid hormone replacement may be started immediately after surgery.

External Beam Radiotherapy

External beam radiotherapy should be considered for patients who are at high risk for locoregional recurrence, because of the improved relapse-free rate.[36] In general, 20 fractions totaling 40 Gy are given to the cervical, supraclavicular, and upper mediastinal lymph nodes over 4 weeks; subsequent booster doses of 10 Gy are then given to the thyroid bed, especially if there was gross residual disease.[35] External beam radiotherapy can also be given to treat painful skeletal metastases.

Monitoring and Follow-Up

Biochemical testing with serum calcitonin and CEA is used in the routine follow-up of patients with MTC. About 3 months postoperatively, these markers should be within the normal ranges (a nadir of 6 months has been reported). Patients with palpable recurrent/residual disease, in general, will have calcitonin levels of at least 10 pg/mL except for tumors that are dedifferentiated and no longer secrete calcitonin (these tumors usually secrete CEA). Monitoring calcitonin and CEA levels every 3 to 6 months to determine doubling times is helpful in assessing disease progression and pace of growth. Values of serum calcitonin higher than 100 pg/mL suggest residual neck disease or distant metastases, particularly in the liver, and these patients should be aggressively assessed clinically and radiographically.[35] Because of MTC's propensity to metastasize to the neck, mediastinum, liver, and bone, diagnostic imaging should include US of the neck, CT of the chest, MRI of the liver, and MRI of the spine. FDG- PET/CT and gallium-68 dotatate PET/CT can also be used in selected cases.[37]

Recurrent or Persistent Disease

Patients with stable and asymptomatic recurrent disease can be monitored closely without therapy. Once the disease is progressive, symptomatic treatment is recommended. For those with locoregional disease without metastases, surgery is preferred. Similar to metastatic DTC, treatment of individual metastatic sites causing symptoms or problems can be addressed individually (see earlier Differentiated

Thyroid Carcinoma section). As with DTC, the FDA has approved two TKIs, vandetanib (2011) and cabozantinib (2012), for progressive metastatic MTC. In May 2020, RET-specific inhibitor selpercatinib received FDA approval for RET-altered thyroid cancer, including MTC, after it showed durable efficacy with low-grade toxic effects in patients with and without previous vandetanib or cabozantinib treatment.[28] Initiation of these therapies should be done by clinicians who are well versed in using these agents and are able to monitor these patients closely.

ANAPLASTIC THYROID CARCINOMA

Introduction

ATC is a locally and systemically aggressive undifferentiated tumor with a disease-specific mortality rate approaching 100%. More than 90% of patients are over the age of 50 years, and more females than males are affected.

Diagnosis

ATC most commonly presents as rapid growth of a thyroid or neck mass. A history of longstanding thyroid enlargement is noted in about 80% of the patients. Fine-needle aspiration or surgical biopsy can usually establish the diagnosis. Preoperative imaging (CT of brain to pelvis including FDG-PET) to assess the extent of disease and planning for surgery and/or radiation therapy is recommended but should not delay therapy. Vocal cord paralysis is common in patients with ATC and should be assessed. ATC frequently arises from preexisting well-differentiated thyroid carcinoma, which supports the opinion that some ATCs develop by dedifferentiation from well-differentiated DTC (Fig. 51–13). Immunohistochemical staining for Tg, TTF1, and paired box protein Pax 8 (PAX8) should be used to aid in identifying better-differentiated sections.[38] However, because undifferentiated carcinoma cells lose their ability to synthesize Tg, Tg immunoreactivity in ATCs may be absent.

Therapy

Treatment is generally palliative in nature because ATC is rarely cured and almost always fatal. Death occurs from upper airway obstruction and suffocation in half of patients and complications of therapy or distant metastases in the others. A multidisciplinary thyroid cancer team approach is needed in the management of disease in these patients. The potential risks and benefits of all treatment modalities including palliative care should be discussed with the patient and family. Prognosis historically was dismal, with a median survival of 3 to 5 months and one-year survival of 20%.[39] Better survival rates were seen only in patients with well-localized anaplastic tumors. Favorable prognostic features seem to be: age younger than 60 years, tumor size less than 5 cm, extent of surgery, radiotherapy, chemotherapy, coexisting DTC, and absence of distant metastases.[40] Over the past decade, overall survival in ATC seems to be improving because of the availability of actionable mutations that can be targeted with small-molecule kinase inhibitors that are often combined with surgery, radiation, and immunotherapy through a multidisciplinary approach.[41]

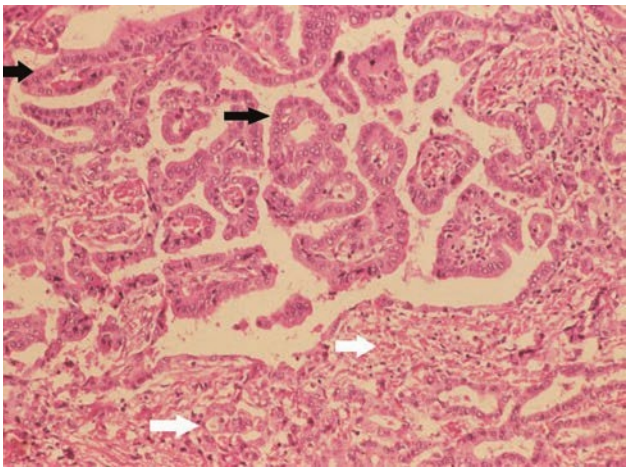

FIGURE 51–13 **Hematoxylin and eosin staining of thyroid illustrating papillary thyroid carcinoma (*black arrows*) in transition to anaplastic thyroid carcinoma (*white arrows*).**

For primary lesions with no distant metastases for which effective resection can be safely achieved, surgery is recommended as first-line treatment followed by adjuvant conformal radiotherapy with or without chemotherapy. In the presence of distant metastases, primary tumor resection should be considered to avoid invasion of surrounding structures. For unresectable lesions, neoadjuvant conformal radiotherapy with or without chemotherapy used to be considered first because this may render the tumor resectable.[38] Patients with poor performance status were often offered palliative doses of radiotherapy if tolerable. Recent advances in precision oncology have brought some impressive changes in the treatment paradigm of ATCs. The combination of dabrafenib (BRAF inhibitor) and trametinib (MEK inhibitor) has shown strong clinical activity as well as tolerability in patients with *BRAF* V600E–mutant ATC. In a phase 2, open-label trial including 16 ATC patients who had undergone surgery, radiation, and systemic therapy, confirmed overall response rate to dabrafenib + trametinib was 69% with 12-month estimates of median duration of

response, PFS, and overall survival were 90%, 79%, and 80%, respectively.[27] In May 2018, this combination was granted the first FDA-approved treatment for patients with ATC. Immunotherapy may also play a role in the treatment of this aggressive cancer. Pembrolizumab as salvage therapy added at the time of progression on TKI has shown some benefits in a subset of patients.[42] Further research to explore other targeted therapies aiming at other driver mutations in ATC and a combination with immunotherapy is warranted. This novel molecular-based treatment together with a multidisciplinary approach appears to be associated with a higher survival rate, according to a large retrospective study from MDACC that included 479 patients with ATC over the span of 20 years. This has opened a new era in the treatment of ATCs, one of the most aggressive and lethal human cancers.[41]

PARATHYROID CARCINOMA

Introduction

Parathyroid carcinoma is a rare endocrine malignancy, with a prevalence of 0.005% of all cancers.[43] The etiology of parathyroid carcinoma remains largely unknown. No well-recognized risk factors have been identified. Predisposing factors identified with some cases are outlined in Table 51–6. Parathyroid carcinoma also occurs sporadically or as part of a genetic syndrome. Patients with parathyroid carcinoma are about a decade younger than patients with benign hyperparathyroidism. The disease occurs with similar frequency in both sexes.

Clinical Features

Hypercalcemia is common and ranges from mild to severe and may manifest with peripheral target organ complications such as kidney stones and osteoporosis. Parathyroid hormone levels are generally five times greater than normal, and patients may present with a discrete neck mass. However, parathyroid cancer is an uncommon cause of primary hyperparathyroidism. The presence of severe hypercalcemia (>12 mg/dL), extremely elevated parathyroid hormone, and a palpable neck mass should raise the suspicion for parathyroid carcinoma.[44]

Table 51–6 Risk Factors and Syndromes Associated with Parathyroid Carcinoma

Predisposing Factors
Prior diagnosis of thyroid cancer
Prior hyperfunctioning parathyroid gland
Secondary and tertiary hyperparathyroidism resulting from chronic renal failure and dialysis
Radiation exposure to the head and neck region
Genetic Syndromes
Multiple endocrine neoplasia type 1
Familial isolated hyperparathyroidism
Hereditary hyperparathyroidism–jaw tumor syndrome

Diagnosis

The presence of personal or family history of associated conditions and the constellation of clinical features described earlier significantly increase the likelihood of parathyroid cancer. Confirming the diagnosis before histologic confirmation remains challenging. Imaging modalities routinely used to aid diagnosis include parathyroid US and technetium-99m sestamibi. Chest CT and bone scintigraphy may also be useful for initial staging.[45] Fine-needle aspiration is not routinely recommended because of the risk of seeding the tumor and lack of sufficient sample to make a definitive diagnosis. Screening for mutations in the *CDC73* gene, which encodes parafibromin, a protein that inhibits its mitogenic function, is considered an integral part of the diagnostic workup of patients with sporadic or familial parathyroid cancer. Patients with familial hyperparathyroidism are also considered at high risk for *CDC73* mutation and should also be screened. Recent studies have provided useful data regarding genetic background in parathyroid carcinoma. The most common mutations reported were in the PI3K and TP53 pathways. Some other genetic alterations in the *KDM*, *TSC*, *RB1*, *NF1*, *KDR*, and *PTEN* genes have also been found.[46,47]

Pathology

Histopathologic diagnosis following the World Health Organization criteria is defined by the presence of capsular invasion and soft tissue invasion or histologic evidence of vascular invasion with or without invasion of vital organs or presence of locoregional or distant metastasis. The classic histopathologic criteria initially described by Schantz and Castleman, including the presence of a trabecular or lobular pattern, mitotic figures, thick fibrous bands, and capsular or blood vessel invasion, are also still used today (Fig. 51–14).[48]

However, in some cases, the histopathologic diagnosis remains challenging, and some highly differentiated tumors without distinct nuclear atypia or classic histopathologic criteria are initially considered to be adenomas but are later reclassified when recurrence or metastases appear. Immunohistochemical staining for parafibromin may increase the diagnostic accuracy,

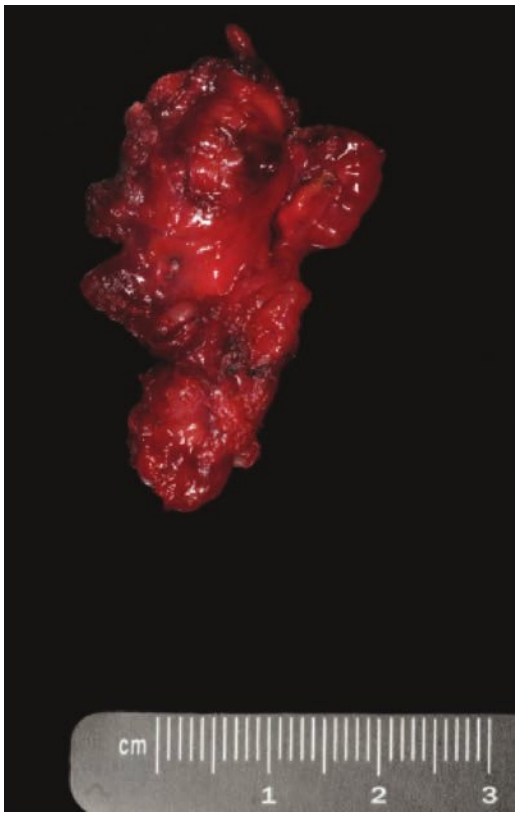

FIGURE 51–14 **Parathyroid gland carcinoma.**

and although not widely used, we have used this at our institution for various cases. Mutations in the *CDC73* gene are seen not only in the majority of patients with hyperparathyroidism–jaw tumor syndrome but also in cases of sporadic and familial parathyroid cancer.[49,50] Fifteen percent of the parathyroid tumors associated with hyperparathyroidism–jaw tumor syndrome are carcinomas.[51] On the contrary, mutations in *MEN1* seldom result in parathyroid carcinoma. To improve the accuracy of diagnosis of malignant parathyroid disease, pathologic specimens of suspected cases should be reviewed by experienced pathologists. As of this writing, we are exploring the role of molecular profiling of parathyroid cancer in prognostication and also to identify targetable mutations that could result in novel targeted therapies.

There no universally agreed upon staging criteria for parathyroid carcinoma.

The 5-year survival rate has improved over the years to approximately 85%, and the 10-year survival rate is approximately 50%.[42] Death usually results from hypercalcemia and its associated complications.

Management

Because of its rarity and unpredictable clinical course, a multidisciplinary approach to caring for the patient with parathyroid carcinoma that involves the endocrinologist, surgeon, oncologist, and radiotherapist offers the best chance for cure.

Preoperative suspicion and intraoperative identification of malignancy and appropriate initial surgery are critical to the choice of therapy for parathyroid carcinoma. Comprehensive resection of the tumor along with the ipsilateral lobe of the thyroid and abnormal or involved adjacent tissues (the so-called "en bloc" resection) is indicated.[52] Every effort should be made to maintain the integrity of the capsule to prevent seeding of tumor, because this will contribute to recurrence. Because this tumor does not typically metastasize to lymph nodes, routine lymph node dissection is not indicated unless involved by tumor. For recurrences, a wide excision of locally recurrent tumor and an aggressive surgical resection of metastases whenever possible are recommended. Although these repeat operations are not always curative, they usually offer palliation for the marked hypercalcemia (the cause of true morbidity in these patients) for a considerable although variable period. Nevertheless, surgical resection, where possible, remains the most effective treatment for both primary and recurrent disease.

Radiotherapy has not become the standard of care in patients with parathyroid carcinoma because it is difficult to prove its efficacy with such small numbers of patients being treated in reported series.[53] It may be considered in select patients at high risk of local relapse (those with gross or local invasion or tumor spillage intraoperatively) or those left with gross disease.

Chemotherapeutic agents with TKIs have shown some success in a few cases with radiographic and hormonal control. Case reports of patients with advanced parathyroid carcinoma achieving hormonal control and stable disease with sorafenib, cabozantinib, vandetanib and everolimus, temozolomide have been reported.[54] The exact mechanism of how TKIs were somewhat beneficial in selected patients is unclear. However, it could be from anti-angiogenic properties as well as bone resorption inhibition, which could be beneficial in parathyroid carcinoma with refractory hypercalcemia. Although selection bias was likely present, these cases suggest a possible role of targeted therapy in advanced parathyroid carcinoma, and further research is much needed.

Morbidity and mortality are generally caused by the effects of unremitting hypercalcemia rather than tumor growth. Medical treatments, especially in patients with unresectable disease, such as bisphosphonates, denosumab, or calcimimetics, offer only temporary and palliative control of hypercalcemia. Lifetime surveillance of serum calcium and parathyroid hormone levels is essential because of the protracted and unpredictable course of malignant parathyroid disease.

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Introduction

The term *pheochromocytoma* refers to a neoplasm derived from chromaffin cells. Although the majority of these tumors occur in the adrenal medulla, about 15% to 20% of cases arise from sympathetic or parasympathetic ganglia and are known as paragangliomas. Pheochromocytomas and paragangliomas are rare, with an estimated incidence of 0.95 per 100,000 person-years,[55] and they have a slight female predominance (54%).[56] Although pheochromocytoma is a possible cause of secondary hypertension, it represents less than 1% of cases. Nonetheless, it is important to consider this diagnosis in the proper clinical setting because it is potentially curable. Furthermore, failure to treat or improper treatment can lead to serious complications or death (Fig. 51–15).

The "rule of 10" is a classic teaching in regard to pheochromocytoma. This rule states that among pheochromocytomas, 10% are bilateral, 10% are extra-adrenal, 10% are familial, and 10% are malignant. However, this does not capture our current understanding. Data now suggest that nearly 25% of apparently sporadic pheochromocytomas are hereditary and associated with germline mutations such as *RET*, *VHL*, *SDHD*, and *SDHB*.[57] These are patients who were thought to have sporadic disease but have a higher risk of bilateral disease, malignancy, or extra-adrenal disease on the basis of their germline mutation.

Clinical Features

The presentation of pheochromocytomas and paragangliomas ranges from incidental discovery to cardiovascular shock and death. A classic presentation is described as spells of the five Ps: pressure (hypertension), pain (headache), palpitations, perspiration, and pallor. Although none of these signs and symptoms is universally present, it is reasonable to screen patients with hypertension and symptomatology suggestive of hyperadrenergic episodes. The spells can last from minutes to hours and may be triggered by exercise, stress, micturition, Valsalva maneuver, or anesthesia induction (Table 51–7).

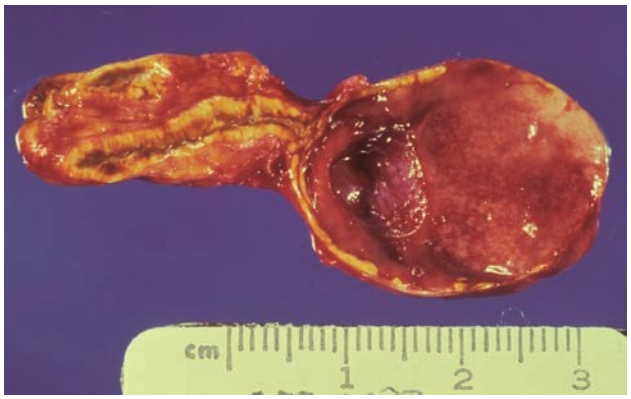

FIGURE 51–15 Adrenal gland with pheochromocytoma.

Table 51–7 Signs and Symptoms of Pheochromocytoma (List Not All Inclusive)

Hypertension	Anxiety
Headache	Constipation
Sweating	Nausea
Palpitations	Insulin resistance
Pallor	Orthostasis
Flushing	Weight loss

Additional findings include hyperglycemia (caused by suppression of insulin release), orthostasis/volume depletion (caused by vasoconstriction), and constipation/abdominal distention (a result of inhibition of gut motility). Rarely, there is cosecretion of other hormones resulting in distinct endocrine syndromes. These include vasoactive intestinal peptide causing Verner-Morrison syndrome, adrenocorticotropic hormone (ACTH) causing Cushing syndrome, growth hormone–releasing hormone causing acromegaly, and parathyroid hormone–related protein causing hypercalcemia (Figs. 51–16 and 51–17).[58]

Diagnosis

Laboratory

Biochemical testing is the cornerstone of diagnosis. Plasma-free metanephrines and 24-hour urine fractionated metanephrines are the two most commonly used laboratory tests to diagnose pheochromocytoma or paraganglioma. The high sensitivity and specificity of these tests are the main reasons they are preferred over alternatives such as plasma or urinary catecholamines, urinary total metanephrines, or urinary vanillylmandelic acid. Of course, note should be taken of any drugs or other factors that may cause false-positive results (Table 51–8).[59]

Even in patients without signs or symptoms of pheochromocytoma or paraganglioma, testing is suggested in the following situations: (1) features or family history suggestive of syndromes associated with pheochromocytoma listed in Table 51–9; (2) personal history of pheochromocytoma; or (3) adrenal incidentalomas.

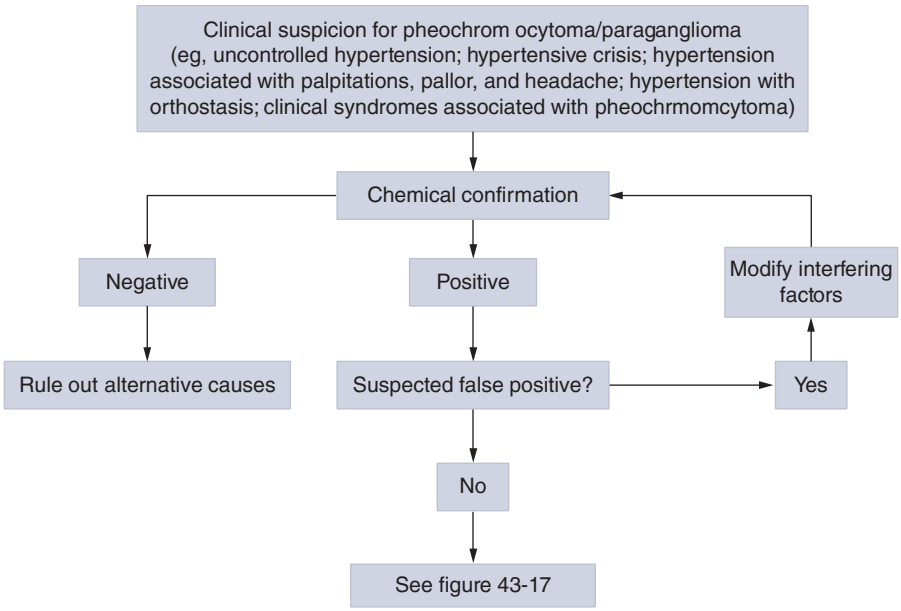

FIGURE 51–16 Biochemical confirmation of pheochromocytoma or paraganglioma.

Imaging

Imaging is not recommended for screening in the absence of biochemical evidence of pheochromocytoma or paraganglioma. However, once biochemical confirmation of the diagnosis is obtained, the next step is localization with imaging studies. Because the majority of pheochromocytomas and paragangliomas are located in the adrenal gland or elsewhere in the abdomen, cross-sectional imaging (CT or MRI) of the abdomen with attention to the adrenal glands has the highest yield. If an adrenal mass is not seen, the paraspinous region and urinary bladder should be carefully examined. Less commonly, extra-adrenal tumors may be located in the chest or the head and neck region.

There are certain imaging characteristics considered suggestive of pheochromocytoma or paraganglioma. Although helpful when present, their absence cannot be used to exclude the possibility that a mass is a pheochromocytoma or paraganglioma. On CT scan, they are usually heterogeneous with a density of greater than 10 Hounsfield units (HU) and delayed washout of contrast. On MRI, they are also usually heterogeneous and hyperintense on T2-weighted images with no dropout of signal on opposed phase imaging.[60] Functional imaging, such as meta-iodobenzylguanidine (MIBG) scintigraphy or PET scan, may be useful when cross-sectional imaging is nonlocalizing despite a high clinical suspicion. Because these tests are more often used to complement cross-sectional imaging when there is suspicion of metastases, they will be discussed in the section on malignant pheochromocytomas and paraganglioma (Figs. 51–18 and 51–19).

Genetics

Because pheochromocytoma and paraganglioma are associated with multiple familial syndromes (the majority of which are inherited in an autosomal dominant fashion), it is important to consider genetic testing. Features associated with familial cases include young age at diagnosis, positive family history, bilateral or multiple adrenal pheochromocytomas, and any paraganglioma. The syndromes in which pheochromocytomas or paragangliomas are seen include MEN type 2, familial paraganglioma syndromes, neurofibromatosis type 1, von Hippel–Lindau syndrome, Carney triad, and Carney-Stratakis syndrome (see Table 51–9).[61]

Although some clinicians recommend genetic testing only in patients with features suggesting a familial syndrome, others advocate more widespread testing because of a reported incidence of somatic mutations in more than 20% of patients with apparently sporadic disease. Genetic testing should be performed on all patients with pheochromocytoma or paraganglioma regardless of family history. In any case, patients should always meet with a knowledgeable genetic counselor to discuss the risks and benefits before and after any familial testing. When a decision is made to test, it is recommended that genetic testing be performed taking into account the most likely diagnoses rather than checking all mutations at once.

Therapy

Medical

Although surgery is the treatment of choice for pheochromocytoma or paraganglioma, patients must be

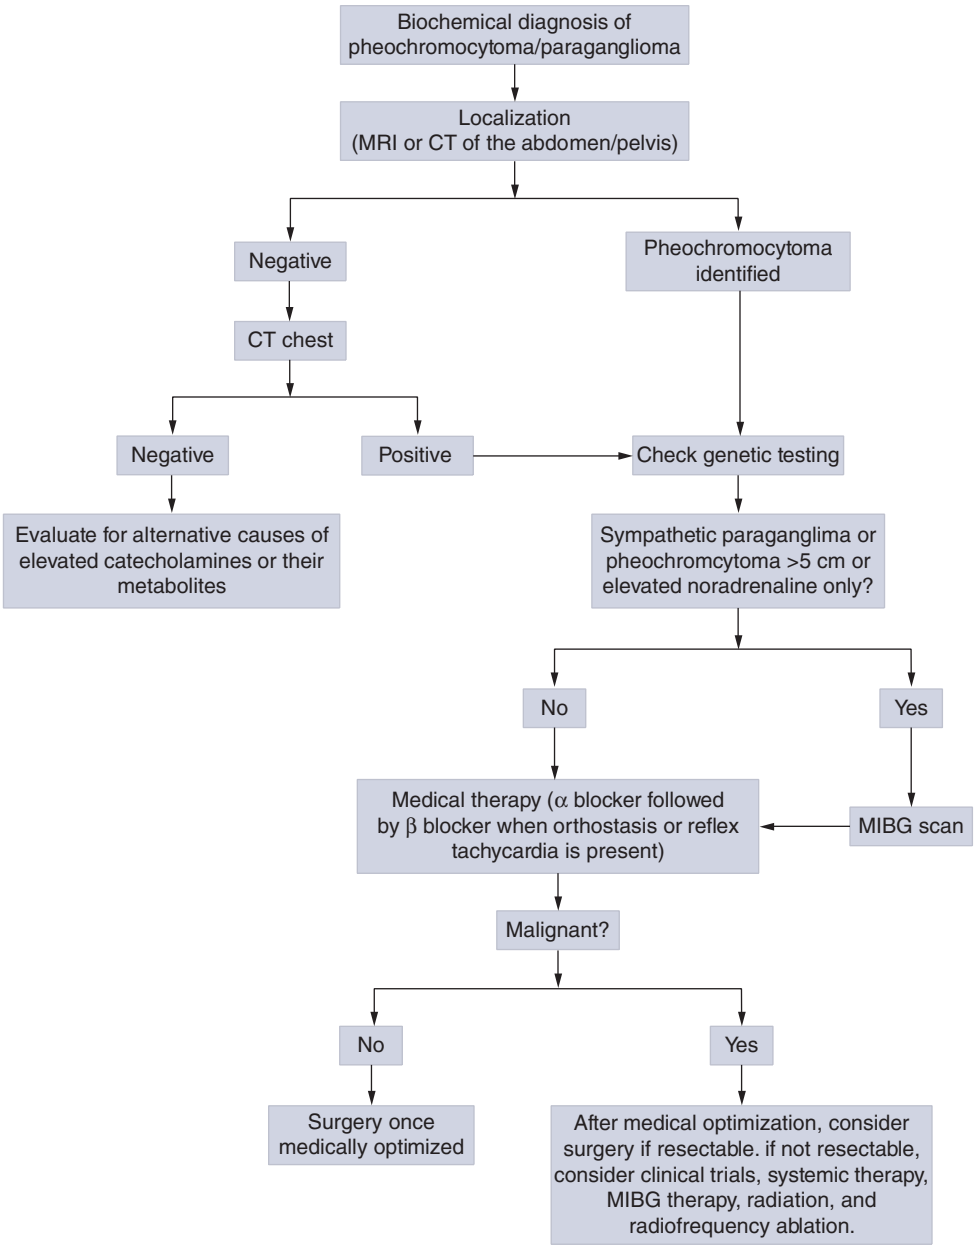

FIGURE 51–17 **Algorithm for clinical approach to pheochromocytoma or paraganglioma after biochemical confirmation. CT, computed tomography; MIBG, meta-iodobenzylguanidine; MRI, magnetic resonance imaging.**

medically optimized before surgery to reduce the risk of perioperative mortality. Preparation for surgery includes management of hypertension along with volume expansion. The first step is initiating α blockade with either a nonspecific α-blocker (phenoxybenzamine) or a selective α-1 blocker (eg, doxazosin, prazosin, or terazosin).[62] The dose is titrated until adequate control of hypertension is achieved without inducing severe orthostatic hypotension. Once the patient starts to develop orthostasis or reflex tachycardia, β blockade should be initiated. A high-sodium diet starting at the same time as α blockade is helpful for some patients to promote volume expansion. Medical optimization before surgery may be accomplished in 1 to 2 weeks. However, each patient is unique, and preparation may take longer for some patients.

It is of utmost importance to avoid β-blockers before achieving adequate α blockade because lone β blockade leaves α receptors unopposed and open for activation by circulating catecholamines. This situation could potentially promote a hypertensive crisis. Although it is not currently the standard of care, calcium channel blockers have also been effective in the preoperative management of these patients.

The computed tomography (CT) scan (*left*) and CT angiogram (*right*) show a 1.6-cm pheochromocytoma in the medial limb of the right adrenal gland (*white arrowheads*) and a 4.6-cm pheochromocytoma in the left adrenal gland (*white arrows*).

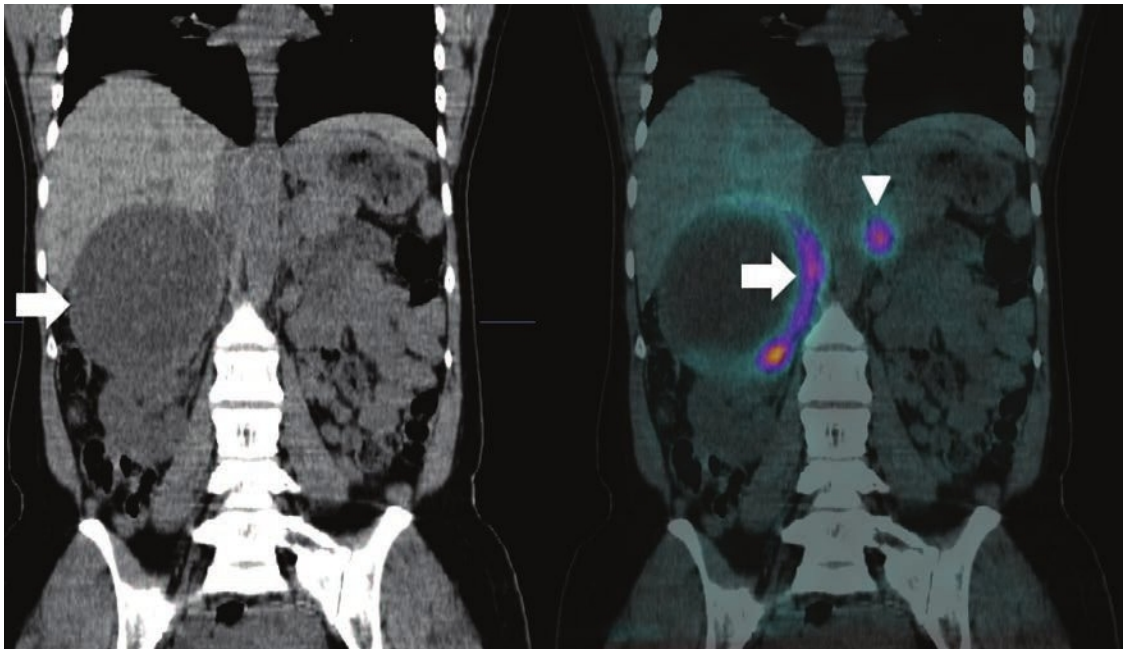

FIGURE 51–19 This is a patient with bilateral adrenal pheochromocytomas. These images are coronal views from a single photon emission computed tomography on the left and a meta-iodobenzylguanidine scan on the right. They show increased uptake in the periphery of a cystic right-sided adrenal pheochromocytoma (*white arrows*) as well as a smaller left-sided adrenal pheochromocytoma (*white arrowhead*).

Surgical

Surgical resection after appropriate medical therapy is the primary mode of treatment for benign pheochromocytoma or paraganglioma. For smaller tumors, minimally invasive surgeries can reduce blood loss and hospital length of stay. As a result, the preferred procedures are laparoscopic or posterior retroperitoneoscopic adrenalectomy. However, in some cases, a larger tumor or a lack of local surgical experience with these techniques may make an open procedure preferable.

Close hemodynamic monitoring with pre- and intraoperative volume repletion is important to avoid hypotension after tumor resection. Short-acting intravenous vasodilators (eg, nitroprusside, nitroglycerine, phentolamine) may be needed intraoperatively to

decrease the risk of precipitating a hypertensive crisis during tumor manipulation. Intravenous fluids should contain dextrose because patients are prone to hypoglycemia as a result of rebound insulin secretion after the precipitous drop in catecholamine levels after successful tumor resection. In patients who have pheochromocytoma associated with a germline mutation or bilateral adrenal disease, cortical-sparing adrenalectomy is the procedure of choice to minimize the risk of lifelong adrenal insufficiency. However, these patients require long-term follow-up because recurrence may develop many years after their primary surgery, and some may develop adrenal insufficiency despite a cortical-sparing technique.[63]

METASTATIC PHEOCHROMOCYTOMA

Introduction

Unfortunately, there are no reliable clinical or pathologic features of the primary tumor that have been shown to consistently identify malignant pheochromocytoma or paraganglioma. As a result, the diagnosis can only be made after the discovery of metastatic disease. The most common sites of metastasis are the axial skeleton, followed by the liver, lymph nodes, lungs, and peritoneum.[64] Although a generally quoted statistic is that 10% of pheochromocytomas are malignant, the risk of metastatic pheochromocytoma/paraganglioma is much higher and approaching 35% in all patients and close to 70% in patients with germline *SDHB* mutation.[65]

In a large retrospective review, it was found that almost half of patients with metastatic pheochromocytoma or paraganglioma are diagnosed with metachronous metastases (ie, they were thought to have benign disease until they were later found to have metastatic disease). This review identified tumor size (>5 cm) and site of primary tumor (infra-diaphragmatic para-aortic paraganglia or the mediastinum) as being associated with a higher incidence of malignancy. However, there were no criteria that reliably excluded the possibility of malignancy, and newly noted metastatic disease can be found up to 20 years after resection of an apparently benign pheochromocytoma. It is for these reasons that lifelong surveillance of patients with seemingly benign pheochromocytoma or paraganglioma is always recommended.[66]

Diagnosis

Because the diagnosis is made based on identification of metastatic disease, a combination of laboratory testing, imaging, and pathologic confirmation is generally relied upon. Typical staging studies include cross-sectional imaging (ie, CT or MRI) of the chest, abdomen, and pelvis. In the setting of malignant pheochromocytoma or paraganglioma, functional studies may be used to complement cross-sectional imaging. For example, MIBG scintigraphy has been used since 1981 to localize pheochromocytoma. Its usefulness is based on the fact that MIBG structurally resembles norepinephrine and is stored in the catecholamine-storage vesicles. For patients in whom dedifferentiation has occurred, as well as patients with an *SDHB* mutation, PET scans using FDG or Ga-dotatate have been a useful adjunct to cross-sectional imaging. Furthermore, 6-[^{18}F]fluorodopamine PET scanning may have a role in the future but is not widely available (Fig. 51–20).[67,68]

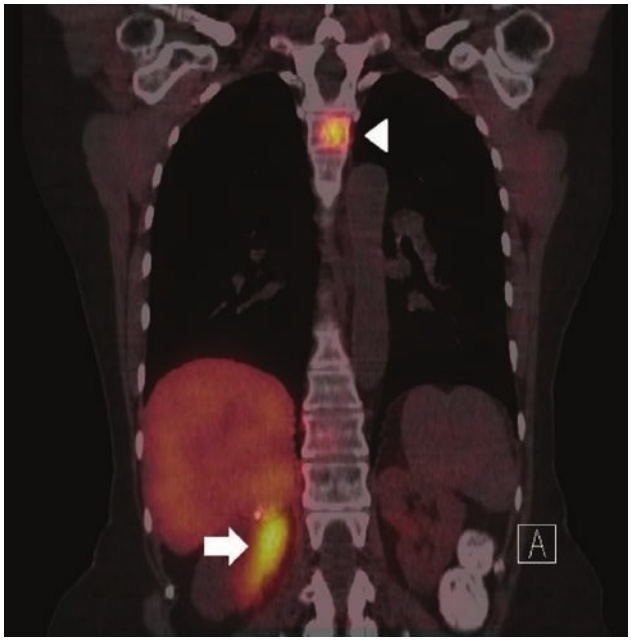

FIGURE 51–20 Meta-iodobenzylguanidine scan showing uptake in recurrent malignant pheochromocytoma in the right adrenal bed (*white arrow*), as well as metastatic disease in the T2 vertebral body (*white arrowhead*).

Given the rarity of this entity, mostly retrospective data exist regarding prognosis. In a meta-analysis, the 10-year mortality rate was 29%, with male patients and those presenting with synchronous metastases having a worse prognosis.[69] The American Joint Committee on Cancer's 8th edition of cancer staging used the TNM (T = primary tumor size, N = lymph node involvement, M = distant metastasis) staging system in metastatic pheochromocytoma/paraganglioma. In this system, tumors larger than 5 cm are associated with a worse prognosis compared with primary tumor smaller than 5 cm. Other important prognostic features include extra-adrenal location and the location of distant metastases.[70]

Therapy

Medical/Surgical

Medical therapy is recommended following the same process as for benign tumors. For patients whose disease is potentially curable, surgery via an open approach is the preferred strategy. In patients for whom surgical cure is not feasible, palliative surgery has been associated with improved survival and is recommended to assist with the control of catecholamine excess or for the prevention of complications related to the location of the disease.[71] Because skeletal metastases are commonly seen, it is important to consider antiresorptive therapy to reduce the risk of skeletal-related events and associated morbidity.

Radiation and Radiofrequency Ablation

If there is evidence of MIBG avidity, radiolabeled therapy can be used as a carrier for ^{131}I delivery as targeted therapy. Traditional MIBG has been associated with tumor response rates of about 30% and hormonal response in about 40% of treated patients.[72] Ultratrace iobenguane I-131 is produced using a solid-phase resin to reduce the percentage of unlabeled MIBG. Iobenguane I-131 is now FDA approved for patients 12 year and older with metastatic pheochromocytoma/paraganglioma that retain MIBG avidity. A multicenter, phase 2 trial reported the outcomes of 68 patients who received at least one iobenguane I-131 dose (~18.5 GBq) intravenously. More than 90% of evaluable patients had a partial response or stable disease within the first year and 25% had durable reduction in their antihypertensive therapy. Nausea, fatigue, and myelosuppression were the most common adverse events.[73]

Considering the neuroendocrine origin of pheochromocytoma/paraganglioma, somatostatin receptor expression is seen in the majority of these cases. The data about the efficacy of peptide receptor radionuclide therapy targeting somatostatin receptor in metastatic pheochromocytoma/paraganglioma are emerging. In 20 consecutive patients with metastatic pheochromocytoma/paraganglioma and high somatostatin receptor expression, ^{177}Lu-dotatate was associated with partial tumor response and blood pressure improvement in 29% and 57% of patients, respectively.[74]

External beam radiation therapy can also be used for symptomatic relief of metastases not amenable to surgical resection. Retrospective studies have demonstrated improvement in symptoms but no dramatic response of the tumor on imaging.[75] Radiofrequency ablation (RFA) has also been attempted in a limited number of patients with metastatic pheochromocytoma and can be considered as part of the treatment armamentarium.[76]

Chemotherapy

Traditional cytotoxic chemotherapy has been used with some success, though the survival benefit is unclear. The regimens most often used are CVD (cyclophosphamide, vincristine, and dacarbazine) and CVAD (cyclophosphamide, vincristine, doxorubicin, and dacarbazine). In a meta-analysis that included four studies (total 50 patients) with metastatic pheochromocytoma/paraganglioma, CVD chemotherapy was associated with complete response in 4%, partial response in 37%, and stable disease in 14% of treated patients and improvement of catecholamine excess in 54% of patients.[77]

Although initial reports using a multikinase inhibitor (sunitinib) suggested partial short-term responses in a very small number of patients, data regarding the long-term efficacy and validation of these findings are still lacking.[78] The data are more limited with other tyrosine kinas inhibitors. Pazopanib use in metastatic pheochromocytoma/paraganglioma was associated with significant toxicity and lack of efficacy based on a reported phase 2 study that enrolled six evaluable patients. In this small cohort, four patients had disease progression, one had grade 4 cardiomyopathy, and one withdrew from the study.[79] Cabozantinib is another multitarget kinase inhibitor and its efficacy in metastatic pheochromocytoma/paraganglioma is being studied in an ongoing phase 2 trial (NCT02302833).

Immunotherapy

Over the past decade, immune checkpoint inhibitors have transformed cancer care, and these drugs are now approved to treat a plethora of solid and hematologic malignancies. However, the role of immunotherapy in metastatic pheochromocytoma/paraganglioma is not yet defined. In a recently published phase 2 study, 11 patients with metastatic pheochromocytoma/paraganglioma received pembrolizumab 200 mg intravenously every 3 weeks. Only one patient had partial response and the clinical benefit rate was estimated to be around 73%.[80]

ADRENOCORTICAL CARCINOMA

Introduction

Adrenocortical carcinoma (ACC) is a rare malignancy with significant morbidity and mortality. A review of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database found the majority of patients (87%) were White and diagnosis occurred at an average age of 51 years. A bimodal distribution of incidence was seen in the first and fourth

Table 51–10 Clinical Syndromes Associated with Hormonally Functional Adrenocortical Carcinoma

Clinical Syndrome	Suggestive Clinical Features	Suggested Laboratory Workup
Cushing syndrome	Obesity, moon facies, purple striae, cervical fat pads, easy bruising, myopathy, hypertension, diabetes mellitus	Plasma electrolytes, plasma glucose, adrenocorticotropic hormone (ACTH), cortisol, 24-h urine-free cortisol
Virilizing syndrome	Hirsutism, clitoromegaly, temporal balding, increased muscle mass, amenorrhea, male precocious puberty, advanced bone age in children	Dehydroepiandrosterone sulfate (DHEAS), testosterone, 17-OH progesterone
Feminizing syndrome	Gynecomastia, loss of libido	Estradiol, prolactin, testosterone
Hyperaldosteronism	Hypertension, hypokalemia	Plasma renin activity, plasma aldosterone concentration, plasma electrolytes, 18-OH corticosterone
Mixed syndromes	Combinations of features above	Testing as appropriate based on clinical features

Data from Ayala-Ramirez M, Jasim S, Feng L, et al. Adrenocortical carcinoma: clinical outcomes and prognosis of 330 patients at a tertiary care center. *Eur J Endocrinol*. 2013;169(6):891-899.

decades of life. The age-adjusted annual incidence was 0.72 per million in the United States, and there was a slight female predominance (54%).[81]

A review of 330 patients seen at our institution found that 42% of cases were hormonally productive, but there have been studies reporting numbers as high as two-thirds of cases. The majority of cases (55%) were associated with hypercortisolemia, and smaller numbers were associated with hyperaldosteronism or hyperandrogenism. Furthermore, the production of multiple hormones was present in almost 20% of these patients.[82] The various syndromes seen with functioning adrenal cancers are presented in Table 51–10. ACC can be hormonally silent and discovered incidentally on imaging studies or may present with nonspecific symptoms such as back pain, abdominal discomfort, indigestion, or site-specific symptoms based on the location of metastatic disease.

Diagnosis

Laboratory

In addition to the evaluation of general laboratory tests, evaluation of hormonal levels should include serum cortisol, ACTH, 11-deoxycortisol, plasma renin activity, plasma aldosterone concentration, total testosterone (in women), dehydroepiandrosterone sulfate, and estradiol (in men and postmenopausal women). Further workup may be needed, including an overnight 1-mg dexamethasone suppression test or 24-hour urine-free cortisol test to evaluate cortisol production. In addition, urinary or plasma-free metanephrines must be assessed in every patient with an adrenal mass at baseline to rule out functioning pheochromocytoma (Fig. 51–21).

Imaging

Cross-sectional body imaging (CT or MRI) of the chest, abdomen, and pelvis is generally the first step in staging. On CT, ACC is usually a large, heterogeneous mass with attenuation values greater than 10 HU showing heterogeneous contrast enhancement, poor contrast washout, and necrosis. Special attention should be devoted to assessment for metastatic disease in the lungs, liver, bones, and regional lymph nodes. The MRI appearance of ACC is also heterogeneous and hyperintense on T2-weighted images. As seen on CT, contrast enhancement on MRI is heterogeneous with poor washout. Of note, MRI is particularly useful in assessing for tumor invasion of the inferior vena cava. Although FDG-PET scan is a sensitive tool for detecting malignant tissue, its low specificity limits its usefulness. However, FDG-PET can play an important role in the identification of metastatic disease in the setting of known ACC (Figs. 51–22 and 51–23).[83]

Pathology

The Weiss scoring system consists of nine pathologic criteria to aid in the diagnosis of ACC (Fig. 51–24). The criteria include: (1) mitotic rate greater than 5 mitoses per 50 high-power fields in the most active areas of the tumor, (2) atypical mitoses, (3) nuclear grade 3 or 4 tumor (Fuhrman method), (4) clear cells comprising 25% or less of the tumor, (5) tumor necrosis, (6) diffuse (solid) architecture in more than one-third of the tumor, (7) venous invasion, (8) invasion of sinusoidal structures, and (9) capsular invasion. The presence of three or more of these nine features is highly suggestive of ACC.[84] The staging of ACC is detailed in Table 51–11. Ki-67 expression is useful in assessing prognosis and

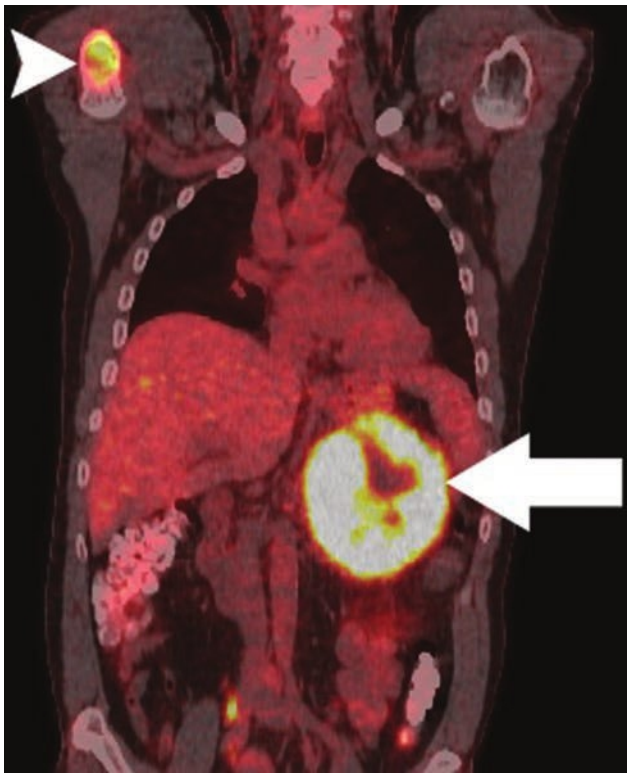

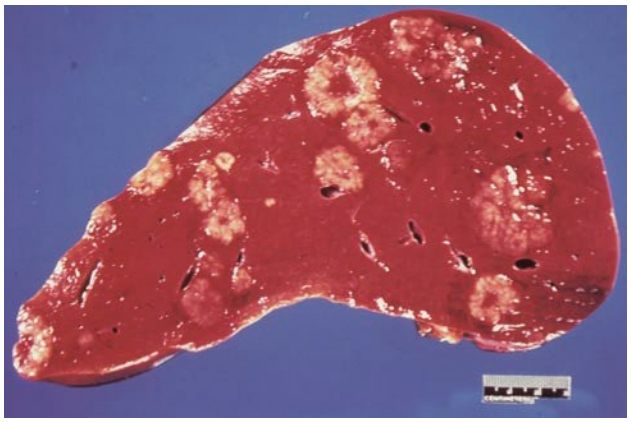

FIGURE 51–23 Fluorodeoxyglucose (FDG) positron emission tomography (PET) scan (coronal view) of a patient with adrenocortical carcinoma (ACC) showing FDG-avid left adrenal mass (*white arrow*) with bone metastases (*arrowhead*).

XFIGURE 51–24 Liver metastases from adrenocortical carcinoma.

should be part of the routine pathologic assessment of ACC; cases with Ki67 higher than 10% tend to have a worse prognosis, with a shortened time to recurrence after surgical resection and shorter survival compared with ACC cases with a lower Ki67 percentage.[85]

In general, FNA of suspected ACC is not recommended because of the risk of seeding the needle track with tumor. However, FNA may be considered after pheochromocytoma has been ruled out in the context of hormonally silent tumor with metastases before embarking on definitive therapy.

Table 51–11 Staging for Adrenocortical Carcinoma

Stage	ENSAT/AJCC 8th Edition
I	Primary tumor ≤5 cm with no nodal or distant metastasis
II	Primary tumor >5 cm with no extra-adrenal spread
III	Primary tumor not invasive but lymph node metastasis present *or* Primary tumor locally invasive or invading adjacent organs but without distant metastasis (lymph node metastasis may be present)
IV	Distant metastasis present (no other requirements)

AJCC, American Joint Committee on Cancer; ENSAT, European Network for the Study of Adrenal Tumors.

Genetics

An association has been observed between ACC and Li-Fraumeni syndrome, Lynch syndrome, and Beckwith-Wiedemann syndrome. Very rarely has ACC been seen in association with MEN1, familial adenomatous polyposis, neurofibromatosis type 1, and Carney complex.[86] As a result, it is important to review family history and to consider referral to genetic counseling in young patients diagnosed with ACC (Table 51–12).

Prognosis

ACC carries high rates of morbidity and mortality. A review of the National Cancer Institute's SEER database found a 1-year cause-specific mortality rate of 58% and a 5-year rate of 88%.[81] However, long-term survival is possible in these patients if complete resection with tumor-free margins can be achieved. At our institution, the 5-year survival rate has been found to be 38%, with a median overall survival of 3.21 years for all patients. As is seen in many other cancers, survival is inversely correlated with disease stage at diagnosis. For example, those with stage I disease had a mean survival of 24.1 years compared with 0.89 years for those with stage IV disease.[81]

Therapy

Surgical

Complete surgical resection is the most important treatment for ACC and offers the best chance for

Table 51–12 Genetic Syndromes Associated with Adrenocortical Carcinoma

Syndrome	Gene(s)	Inheritance	Common Clinical Findings
Li-Fraumeni syndrome	*TP53*	Autosomal dominant	Sarcoma, breast cancer, leukemia, brain tumors, radiation-induced cancers
Beckwith-Wiedemann syndrome	Multiple	Majority of cases are sporadic	Macrosomia, macroglossia, cleft palate, omphalocele, advanced bone age, Wilms tumor, hepatoblastoma
MEN1	*MENIN*	Autosomal dominant	Parathyroid adenoma, pituitary adenoma, pancreatic islet cell tumors, carcinoid, angiofibromas, collagenomas
Familial adenomatous polyposis	*APC*	Autosomal dominant	Colon polyps/cancer, pancreatic cancer, thyroid cancer, medulloblastomas, osteomas
Lynch syndrome	*MLH1, MLH2, MSH6, PMS2*	Autosomal dominant	Colorectal cancer, endometrial cancer, ovarian cancer, glioma, gastric cancer
Carney complex	*PRKAR1A*	Autosomal dominant	Primary pigmented nodular adrenocortical disease, lentigines, testicular cancer (Sertoli cell), thyroid cancer, pancreatic cancer, atrial myxoma
Congenital adrenal hyperplasia	*CYP21A2*	Autosomal recessive	Ambiguous genitalia, precocious puberty, infertility, hirsutism, electrolyte abnormalities

Data from Else T, Kim AC, Sabolch A, et al. Adrenocortical carcinoma. *Endocr Rev*. 2014;35(2):282-326; Libe R, Arlt W, Louiset E, et al. A case of androgen-secreting adrenal carcinoma with non-classical congenital adrenal hyperplasia. *Indian J Endocrinol Metab*. 2013;17(suppl 1):S243-S245.

prolonged disease-free survival. If ACC is suspected, laparoscopic adrenalectomy is not recommended because it can result in early locoregional recurrence and peritoneal carcinomatosis. Furthermore, it may decrease the ability to achieve tumor-free margins (R0) or adequate lymph node dissection.[87] Tumor encasement of the celiac axis, aorta, or proximal superior mesenteric artery may make the tumor unresectable. In contrast, the presence of tumor thrombus in the inferior vena cava or renal vein, or tumor invasion of the pancreas, spleen, or kidney, is not a contraindication for complete resection in selected patients. Although there is limited evidence of benefit from resection of the primary tumor in the presence of metastatic disease, there may still be a role for resection of the primary tumor and all visible metastases in an otherwise young, healthy patient, especially in cases of symptomatic, hormonally active tumors.

In corticosteroid-producing ACC, there is speculation that preoperative blockade of steroid production using agents such as ketoconazole or metyrapone may reduce postoperative morbidity. In these cases, the contralateral adrenal gland is usually atrophic, and patients may require peri- and postoperative corticosteroid replacement. In fact, relative adrenal insufficiency may last for months after successful resection.

Chemotherapy

In 1949, it was found that oral administration of the insecticide dichlorodiphenyltrichloroethane (DDT) to dogs caused selective necrosis of zona fasciculata and zona reticularis of the adrenal cortex. Since 1960, a DDT analog known as mitotane has been used to treat ACC. Mitotane is fat soluble and requires on average 3 to 4 months to achieve therapeutic serum levels (target 14–20 mg/L).[88] Mitotane is approved to treat metastatic/unresectable ACC but is often used in adjuvant setting based on retrospective data and expert guidelines.[89,90] In addition to adrenal toxicity, mitotane also increases corticosteroid-binding globulin and enhances steroid clearance. As a result, there are increased glucocorticoid requirements during mitotane therapy, and failure to adequately replace glucocorticoids can result in adrenal crisis. Other potential side effects include hypothyroidism, male hypogonadism, ovarian cysts, dyslipidemia, elevated liver enzymes, and, rarely, hematuria. Our starting mitotane dose is 1.5 g/day and the dose increases within 1 week to 4.5 g/day. Subsequently, mitotane use requires periodic measurement of mitotane serum levels (every 3–4 weeks initially, then every 2–3 months after achieving therapeutic levels). When the mitotane level reaches 20 mg/L or higher, or in patients with adverse events, we often reduce the dose by 25% to 50% and occasionally hold therapy temporarily. After achieving therapeutic level, most patients require much lower maintenance dose (1–2 g/day) to remain within therapeutic range. In addition to monitoring mitotane level, mitotane therapy requires careful clinical and biochemical assessment to manage unwanted adverse side effects (Fig. 51–25).[91]

In terms of other chemotherapeutic agents, an international phase 3 study (FIRM-ACT) compared mitotane plus EDP (etoposide, doxorubicin, cisplatin)

FIGURE 51–25 Chest radiographs of a patient with metastatic ACC. These images demonstrate the multiple bilateral lung metastases before mitotane (*left*) and remarkable improvement after mitotane use (*right*).

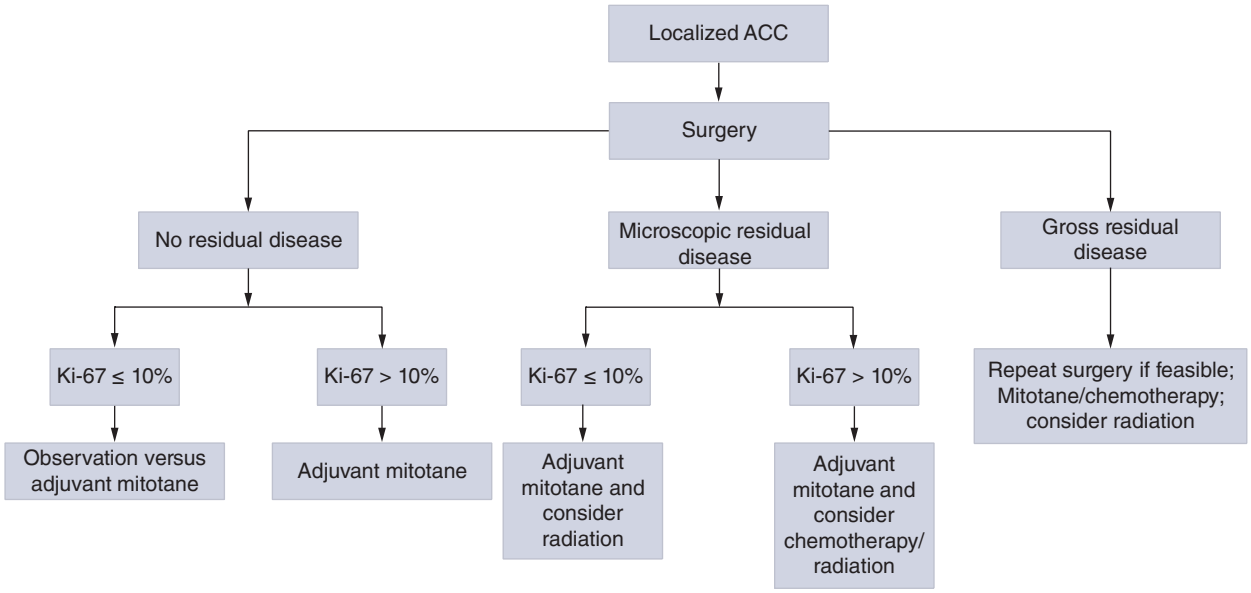

FIGURE 51–26 Management of localized adrenocortical carcinoma (ACC).

with mitotane plus streptozotocin. In this study, it was found that mitotane-EDP showed better tumor response compared with mitotane-streptozocin (23% vs 9%) and better PFS (5.3 vs 2.1 months).[92] Our current practice in managing ACC is summarized in Figs. 51–26 and 51–27. Beyond mitotane-EDP, there is no proven second-line chemotherapy regimen, and multiple treatments such as gemcitabine-capecitabine, temozolomine, and others did not prove to be reasonably effective.

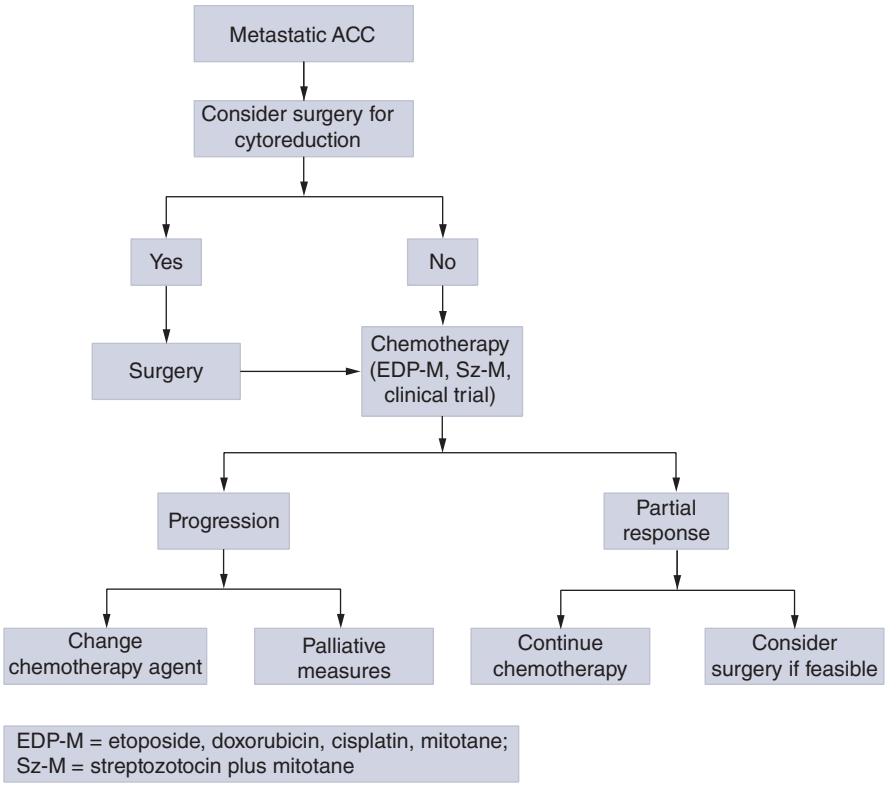

FIGURE 51–27 **Management of metastatic adrenocortical carcinoma (ACC).**

Targeted therapies are also a fertile area for clinical investigation. Potential candidates include insulin-like growth factor-1R inhibitors, epidermal growth factor receptor inhibitors, multitarget TKIs, mammalian target of rapamycin inhibitors, and Wnt signaling pathway inhibitors.[93] Enrollment in clinical trials for the use of investigational agents is favored to help answer important clinical questions regarding safety and efficacy.

Immunotherapy

The role of immunotherapy in ACC is evolving. Multiple studies reported the early experience with immune checkpoint inhibitors in advanced ACC. Avelumab (programmed cell death ligand 1 inhibitor), nivolumab (programmed cell death protein 1 inhibitor), and pembrolizumab (programmed cell death protein 1 inhibitor) were studied in patients with ACC.

Although few participants had prolonged disease control, the efficacy rates were generally low and ranged from 6% to 23%.[94] The combined use of TKIs (lenvatinib) with immunotherapy (pembrolizumab) has been reported in a small group of patients, and some patients had sustained response to therapy after failing to respond to multiple lines of therapy including prior use of immunotherapy alone.[95] It is very important to explore the combined use of immune checkpoint inhibitors with other available treatments (mitotane, cytotoxic chemotherapy, multikinase inhibitors) to improve the current status of ACC therapy.

Radiation and Radiofrequency Ablation

ACC is generally considered a radioresistant tumor, and adjuvant radiation may not reduce the risk of recurrence or increase overall survival, although recent retrospective data suggested survival benefit of adjuvant radiation therapy in patients who had positive resection margins after surgery.[96] More commonly, radiation treatment is used in selected patients with metastatic ACC for palliation of symptomatic metastasis. Percutaneous image-guided RFA has also been attempted in the setting of unresectable primary or metastatic ACC. This procedure may be useful for short-term, local control of small adrenal tumors, but further data are needed to elucidate the long-term efficacy and potential impact on survival.

MD ANDERSON PRACTICE TIPS

- Tumor profiling has transformed the management of patients with differentiated thyroid carcinoma. Patients with actionable mutation can be enrolled in clinical trials or use approved targeted therapy. The role of immunotherapy is evolving and often used in combination with targeted therapy
- The use of targeted therapy in patients with metastatic thyroid carcinoma must be guided by objective evidence of disease progression and not by circulating tumor markers alone.
- A multimodality approach in ATC has transformed the management and improved the outcomes of this disease. Tumor profiling to identify actionable mutations (mainly BRAF) can open the door to using BRAF/MEK inhibitors in combination with other therapies such as surgery, radiation, and immunotherapy.
- Aggressive control of hypertension is critical in patients with metastatic pheochromocytoma/paraganglioma before the use of radiopharmaceutical therapy. It is also very important to control blood pressure before the use of anti-angiogenic therapy.
- A laparoscopic approach is discouraged when managing disease in patients with suspected ACC. Open resection is associated with a higher chance to achieve complete resection with pathologically negative margins compared with the laparoscopic approach. The risk of peritoneal carcinomatosis is also higher with laparoscopic resection compared with open resection
- In patients with borderline resectable ACC, the use of neoadjuvant chemotherapy (mitotane + platinum-based chemotherapy) can facilitate surgical resection and is associated with improved outcome.

52 The Acquired Immunodeficiency Syndrome–Related Cancers

Adan Rios
Fredrick B. Hagemeister

KEY CONCEPTS

- One million, two-hundred thousand people in the United States (0.3%) were living with HIV in 2018; however, more than 36,000 new infections occurred, and an estimated 1 in 7 (14%) of those with the diagnosis were not aware of it. Forty-five percent of those with new diagnoses identified as Black or Latino. According to World Health Organization (WHO) statistics from 2018, the prevalence globally has not statistically changed among adults 15 to 49 years of age since 2014, and the prevalence is as high as 21% in sub-Saharan Africa (Botswana).
- Classically, Burkitt and aggressive B-cell lymphomas have been AIDS-defining malignancies. Although not originally described as HIV-related, other categories of lymphomas are now identified in the WHO classification as occurring in patients with HIV seropositivity include peripheral T-cell, marginal zone, and Hodgkin lymphoma (HL) subtypes, as well as primary effusion and plasmablastic lymphomas, and others. Cervical carcinoma is the only AIDS-defining cancer; however, other cancers increased in patients with HIV seropositivity include lung cancers and anal carcinomas in men.
- In the post–highly active antiretroviral therapy (HAART) era, there has been a reduction in the incidence of various lymphoma subtypes, including primary central nervous system (CNS) and systemic high-grade B-cell lymphomas, and Kaposi sarcoma (KS), but other lymphoma subtypes have not decreased, including Hodgkin and Burkitt lymphomas.
- Human herpesvirus 8 is responsible for KS, and, as in patients without HIV seropositivity, Epstein-Barr virus (EBV) in some patients with aggressive B-cell and Burkitt lymphomas and human papillomavirus in cervical carcinoma. Other agents associated with these cancers are unknown.
- Patients with advanced HL (stages III–IV) and known HIV disease should receive brentuximab vedotin plus adriamycin/vinblastine/dacarbazine chemotherapy. Limited-stage disease may be treated with therapy as for patients who are seronegative.
- Without the availability of randomized studies, EPOCH-R, tailored to disease extent with number of cycles of therapy adjusted to early positron emission tomography (PET) results, is the preferred regimen for treatment of patients with high-grade lymphomas; this combination is also recommended for those with Burkitt lymphomas, and those with other aggressive lymphoproliferative disorders.

THE CHANGING INCIDENCE OF MALIGNANCIES IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS DISEASE

The relationship between malignancies and AIDS changed in 1996 when highly active antiretroviral therapy (HAART) was introduced in industrial nations. Thanks to the United Nations and other philanthropy programs, HAART has also been successfully introduced into a number of developing nations.[1] Africa, the pandemic epicenter, is the exception, because of the epidemic magnitude on that continent and its significant political and social turmoil. Before 1996, epidemiologists noted specific malignancies afflicting patients with AIDS, with a risk proportional to host immune status. Before HAART, patients with AIDS could be separated into two groups: patients with an opportunistic infection as their first manifestation of AIDS (60%) and those with a malignancy as its mode of presentation (40%).[2]

Of those with an AIDS-related malignancy, up to 90% would have Kaposi sarcoma (KS) and the rest non-Hodgkin lymphomas (NHLs), including primary central nervous system lymphoma (PCNSL) and systemic diffuse large B-cell lymphoma (DLBCL). Despite an increase in human papilloma virus (HPV)–related invasive cervical cancers in women with high-grade uterine cervical dysplasia, recent findings of a lack of clear association between cervical cancer and HIV-related immunosuppression question the validity of including cervical cancer among AIDS-defining or associated malignancies.[3] After HAART, previously obvious relationships between AIDS and some malignancies have been challenged. An example is HIV-related Burkitt lymphoma, initially associated with AIDS-induced immunosuppression. Investigators have found that HAART improvement of immunity is associated with significant reductions in KS, PCNSL, and systemic DLBCL, but this is not the case with Burkitt lymphoma. Together with invasive cervical cancer, the incidence of Burkitt lymphoma has remained stable across the pre- and post-HAART eras, increasing its proportional frequency. Epithelial dysplasia and squamous cell carcinomas of the anal canal, rectum, and oral cavity are also observed in men infected by HIV. There has been a post-HAART era increase in HL (Epstein-Barr virus [EBV] related), lung cancer, nonmelanoma skin cancer, cancer of the anus, and cancer of the liver, which has remained similar during the early and late HAART periods and which are known as non–AIDS-defining cancer (NADCs). This category carries implications related to the complex relationship between immunity, aging, chronic antigenic stimulation, and viral oncogenesis. This increase of NADCs has changed malignancies as a cause of death in HIV-infected patients from fewer than 10% of all deaths to as high as 28% post-HAART.[4] Overall, the excess risk of a malignancy in HIV disease is observed mostly in cancers with an established or suspected infectious cause.[5]

In this chapter, we first discuss HIV and its effect on the immune system. We then concentrate on malignancies associated with AIDS immunosuppression. We include a discussion of malignancies (Burkitt lymphoma and HPV-related cancers) not directly associated with HIV immunosuppression occurring with a high enough incidence in HIV-infected patients to merit study.

HIV DISEASE

Historical Significance of the Virus

The AIDS pandemic came into the medical world in 1980 with the publication in the Centers for Disease Control and Prevention's (CDC) journal *Morbidity and Mortality Weekly Report* of a series of patients afflicted by de novo opportunistic infections, mostly *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) pneumonia and cytomegalovirus infections.[6] At about that time, these conditions were known to occur in immunodeficient patients. It was followed by a report of KS in 26 homosexual men thought to be immunologically healthy. The number of similar cases increased exponentially throughout the United States and Europe, with reports from other parts of the world confirming a new pandemic with an epicenter in sub-Saharan Africa. The high number of cases with similar clinical presentations gave way to a new syndrome, the acquired immunodeficiency syndrome, or AIDS. Twenty-five years later, much is known and much is to be learned about the cause of the syndrome, HIV, and its complications, including opportunistic infections and malignancies.[7]

HIV disease is caused by infection of a human subject with a retrovirus, human immunodeficiency virus. The virus is only transmitted through blood or unprotected sexual contact, causing a progressive destruction of the immune system with occurrence of opportunistic infections and malignancies. When an opportunistic infection or a malignancy occurs, it signals a significant degree of immunodeficiency. The association of opportunistic infections and immune suppression is well established in the medical literature and clinical practice. The relationship between immune surveillance dysfunction and development of malignancies has also been described in the medical literature. In the early 1970s, kidney transplantation programs in Canada reported an increased incidence of malignancies in patients treated with the immunosuppressant azathioprine.[8] Similar reports indicated that pharmacologically immune-suppressed patients had increases of several folds of magnitude of certain types of cancers and opportunistic infections.

Typically, they had KS or lymphoproliferative malignancies, although other types of malignancies were also reported. In a sense, these patients had chemically-induced AIDS, whereas HIV patients have biologically-induced AIDS.

Origin of the Disease

Human immunodeficiency virus was discovered in 1983,[9] dispelling much of the mystery surrounding AIDS. The syndrome in humans is caused by a retrovirus, HIV, a lentivirus (Latin *lentus*, meaning "slow," + virus), endemic in African primates, which entered the human population as a result of a cross-species transmission, or zoonosis. Two types of HIV have infected humans: HIV-1 and HIV-2. The HIV-1 virus originated from chimpanzees infected by a retrovirus, the SIVcpz

(the chimpanzee simian immunodeficiency virus), and HIV-2 originated from sooty mangabey monkeys endemically infected by another retrovirus, SIVsm. SIVcpz is the product of recombination in chimpanzees of two monkey retroviruses preyed upon by chimpanzees: the SIVrcm and the SIVgsn (the red capped mangabeys, *Cerocebus torquatus*, and the great spot-nosed monkeys, *Cercopithecus nictitans*, respectively). These viruses do not cause disease in their natural hosts and were named simian immunodeficiency viruses, or SIV, after their genetic and structural similarities with HIV. Both HIV types (1 and 2) are phylogenetically classified in groups and clades; HIV-1 has three groups: M (major), N (non-M, non-O), and O (outlier), with a possible group P ("pending" the identification of further human cases). The predominant group M comprises 12 clades A–L, and HIV-2 has eight clades, A–H. The HIV-1 and HIV-2 clades can recombine giving origin to genetically complex viral quasispecies. Transmission from animals to humans occurs when infected animals enter in contact with humans as a result of hunting and butchering (SIVcpz from chimpanzees) or through contact with infected animals used as domestic pets (sooty mangabey monkeys).[10]

The HIV-2 virus is endemic and contained in coastal West Africa. The HIV-1 virus is endemic in west equatorial Africa, with several clades from the group M responsible for the majority of worldwide infections. In the Western world, HIV-1B is responsible for more than 90% of infections, whereas in Africa, subtypes A, C, D, and G, and in Asia, subtype C and the circulating recombinant forms (CRFs) 01 and 02 can be found. The disease is diagnosed by detecting serum anti-HIV antibodies using an enzyme-linked immunosorbent assay (ELISA) test. The initial result can be corroborated by a repeated ELISA test (saying "with another ELISA test" implies a different type of ELISA) or by a Western blot blood test. The amount of replicating virus can be measured by quantitative polymerase chain reaction (PCR) or via signal amplification such as branch-DNA HIV viral load test.[11]

Status of the Pandemic and Its Effects on the Immune System

HIV and AIDS are responsible for a human tragedy of incalculable proportions. Since the pandemic's beginnings, there have been more than 30 million deaths and more than 70 million persons infected, including those who have died. The estimated rate of new infections is 5000 new infections per day. Most of these new infections occur in developing nations, affecting many women and children. The most frequent modes of transmission are unprotected sex and intravenous (IV) drug use. The main epicenter of the pandemic continues to be sub-Saharan Africa, with new epicenters in the former Soviet Union, China, India, and Latin America. In the United States, minority groups such as Hispanics and Blacks, as well as younger generations of gay men, are disproportionately affected by HIV.[12]

HIV is an enveloped diploid RNA virus (two RNA ribbons per particle), each with an armamentarium of enzymes essential for the virus life cycle. The viral particle membrane is composed of human leukocyte antigen (HLA) groups, other cell surface membrane proteins, and the viral protein gp120 in a trimer form. Among the enzymes within the viral particle are reverse transcriptase, integrase, and proteases. Eighty percent of transmitted mucosal HIV infections are established by a single transmitted/founder (T/F) variant, or T/F virus. The other 20% are transmitted by two to five variants (ie, IV drug users). These T/F viruses have specific phenotypic characteristics, including enhanced infectivity, higher envelope content, more efficient binding of dendritic cells, and relative resistance to interferon (IFN)-α.[13] Once HIV enters a susceptible host, the viral envelope spikes (gp120 trimers) bind to receptors (CD4) and coreceptors (CCR-5) of cells of the immune system, entering through a membrane fusion. The particle content is released into the cytoplasm, and viral RNA is transcribed into DNA. This viral DNA is then randomly integrated into the genome of the infected cell. Through a complex process of transcription activators and as a result of the frequent replication cycles of the immune system's cells, new viral particles are generated. These new particles are released through budding and lysis, continuing to infect new susceptible cells with this process, occurring at an unusually fast pace. Infection with HIV is characterized in simian models of AIDS and in man by a rapid destruction of memory cells of the gut-associated lymphoid tissue (GALT). This process occurs in days to a few weeks in animal models and in weeks in man. GALT harbors the majority of body lymphocytes compared with the 2% to 5% of lymphocytes located in the peripheral circulation.

The result of GALT's destruction, together with the activation of B cells and inhibition of the immune system function by HIV viral gene products such as the vif protein, which inhibits the APOBEC3 gene family, implicated in the control of HIV infection including the production of neutralizing antibodies, induces a severe immune dysfunction and depletion. (This is an important piece of information that addresses the mechanistic question of why we have such a difficult time developing neutralizing antibody against HIV).[14] Once HIV is integrated into the genome of the susceptible cells, there is a gradual destruction of the immune system, leading to a progressive status of immunodeficiency, with development of opportunistic infections and tumors. This early senescence of the immune system is implicated in changes at a molecular

level, resulting in loss of control of oncogenic viruses, and is associated with the malignant transformations observed in AIDS.

AIDS-DEFINING MALIGNANCIES

Kaposi Sarcoma

Epidemiology

KS was described by Dr Moritz Kaposi in 1872 as an indolent dermatologic disease characterized by the appearance of purplish nodules or plaques, particularly in the lower extremities of older men of Eastern European, Mediterranean, or Jewish descent (classical KS). Canadian investigators were one of the first to note in the 1970s that KS occurred in renal transplant patients exposed to immunosuppressant regimens (ie, azathioprine; transplant or iatrogenic KS). Their observations included reports of remissions when immunosuppressant regimens were temporarily discontinued, suggesting a relationship between immunodeficiency and the malignancies. They also noted a high incidence of NHL. In the 1960s, British investigators reported an aggressive lymphadenopathic form of KS confined to equatorial Africa (African KS). This form occurred in younger patients with aggressive involvement of lymph nodes and appearance of nodules and plaques of the lower extremities that rapidly became ulcerated. With the CDC's *Morbidity and Mortality Weekly Report* of 26 gay men with KS, the disease became one of the hallmarks of the AIDS epidemic (epidemic or AIDS-related KS).

In contrast to the classical form, the AIDS-related KS lesions appear with an aggressive pattern of distribution that includes the trunk, arms, and face in addition to the lower extremities.[15] Before antiretroviral therapies, patients died of a combination of tumor progression and opportunistic infections. Despite HAART, KS continues to be a prevalent cancer among HIV-infected patients, although HAART has significantly changed the incidence of the disease.

From 1990 to 1995, the incidence of KS in the United States was 1838.9 cases per 100,000 person-years in contrast to 334.6 cases per 100,000 person-years from 1996 to 2002. It is currently considered to have an incidence in the United States of six cases per 1 million people. In the United States and Europe, AIDS-related KS has been almost exclusively diagnosed in homosexual men, suggesting that its prevalence may vary among different categories of AIDS patients. In Africa, where human herpesvirus 8 (HHV-8), or KS herpesvirus (KSHV), is endemic, the male-to-female ratio of AIDS-related KS in some countries is 2:1, almost the same ratio observed in transplant- or iatrogenic-related KS. Thus, in the presence of profound immune suppression, factors that made the disease more prevalent in males than in females before the AIDS pandemic appear to be of little relevance. What is clear is that the incidence of AIDS-related KS is related to the degree of the immune suppression of the infected hosts, with most afflicted patients having CD4+ cell counts of 200 CD4+ cells/μL or less.

The Viral Etiology of Kaposi Sarcoma

The etiologic agent of all forms of KS is HHV-8, also called KSHV.[16] Early in the pandemic, other viruses or agents were implicated as the cause of AIDS-related KS, including cytomegalovirus. In 1994, sequences of a new herpeslike virus were isolated from the lesions of an AIDS-related KS patient. Using a subtractive PCR technique called representative differential analysis, investigators found sequences isolated from KS lesions homologous but not identical to other known herpesviruses, and thus it was named HHV-8, because it became the eighth known herpesvirus. Not all patients infected with HHV-8 develop KS; however, viral DNA and seroconversion can be detected in patients before the development of KS, confirming the role of HHV-8 as the cause of all forms of KS and the relationship of its pathogenesis to immunosuppression, in addition to other cofactors.

HHV-8 belongs to the γ-herpesvirus subfamily and the subgroup γ-2 or rhadinovirus (from the Latin term *rhadino*, referring to the tendency of the viral genome to break apart when it is isolated) and is the first human virus of this subfamily to be identified. The detection of the infection relies on the presence of antibodies against viral antigens using immunofluorescence assays based on the use of B lymphocytes as the antigen source or ELISA with recombinant immunogenic proteins or peptides of HHV-8. The infection seroprevalence mirrors the geographic distribution of AIDS-related KS, with the highest infection rates in central African countries (80%), rates of 25% to 50% among homosexual men in the Western world, and an intermediate level in the Mediterranean regions. The adult general population of blood donors in North America and Europe has an HHV-8 seroprevalence ranging from 0% to 8%. In addition to being the etiologic agent of AIDS-related KS, HHV-8 has been associated with two other lymphoproliferative disorders: primary effusion lymphoma (PEL, a subset of body cavity–based lymphomas [Fig. 52–1], subsequently called PELs) and multicentric Castleman disease (MCD).[16]

Pathogenesis of Kaposi Sarcoma

Human herpesvirus 8 incorporates a significant number of host genes such as cyclin D and growth factor interleukin (IL)-6.[17] These genes participate in

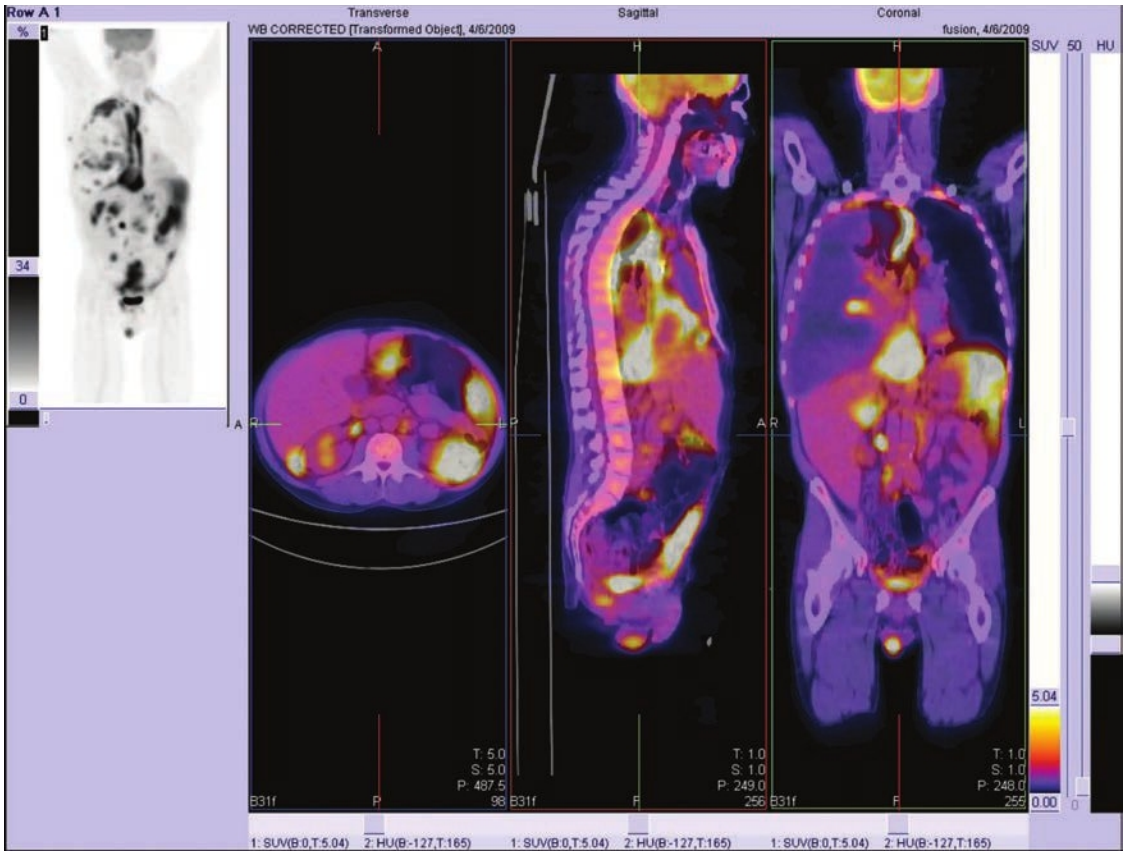

FIGURE 52–1 **Scan in a patient with primary effusion lymphoma (PEL) showing multiple sites of increased fluorodeoxyglucose activity and a large right pleural effusion.**

the replication, survival, and transformation of the infected tumor cells. The viral K1 gene kaposin and viral G protein-coupled receptor (vGPCR) have transformation potential. The viral K1 gene kaposin and viral G protein-coupled receptor (vGPCR0) have transformation potential. Others deregulate cell growth and lead to transformation including viral IL-6, viral IL-10, viral cc-class chemokines, and viral FLICE-inhibitory protein (vFLIP). The expression of the different key genes is related to the latency and lytic cycles of HHV-8. During the latency phase, genes such as *LANA-1* (latency-associated nuclear antigen 1), in addition to the maintenance of latency, inactivate p53, inhibiting apoptosis. In addition, a viral cyclin prevents cell cycle arrest by cyclin-dependent kinases, pRB and vFLIP, avoiding the activation of the Fas death receptor pathway. During the lytic phase, homologues of replication genes including the K1 kaposin gene, a Bcl-2 homologue, a viral G protein–coupled receptor gene (*vGPCRP*), a viral homologue of IL (IL-6), and viral macrophages and IFN regulatory factors become active. Some of these genes have immunosuppression functions, such as the inhibition by vFLIP including cytotoxicity of T-cells against HHV-8–infected cells and the inhibition of HHV-8 class 2 major histocompatibility complex (MHC)-mediated T-cell activation by K1.[18] Finally, other viral proteins such as K3 and K5 downregulate the presentation of MHC class 1 molecules on the cell surface.

Pathology of Kaposi Sarcoma

The histology of KS is characterized by the abundance of spindle cells in a matrix of neovascular formation and a rich background of mononuclear inflammatory cells and collagen. Vascular spaces are dilated and contain extravasated erythrocytes. Involvement of the reticular dermis, reflected by patchy lesions and the involvement of all the layers of the skin, clinically presents as nodular or plaque lesions that can coalesce, interfering with the lymphatic circulation, and are histologically and clinically associated with surrounding hemorrhage and subcutaneous edema. The spindle KS cells are rich in endothelial factor VIII. Recent microarray studies have demonstrated that the origin of the KS cell is from a virally transformed lymphatic endothelial cell. KS spindle cells express angiogenic/inflammatory cytokines and growth factors, including vascular endothelial growth factor, basic fibroblast growth factor, IL-1, and IL-6, among others. Kaposi sarcoma cells

also overexpress receptors for cytokines, suggesting growth through autocrine or paracrine mechanisms. They also proliferate in response to IL-1, IFN-γ, IL-6, and tumor necrosis factor, which are abundantly present in the serum of patients with poorly controlled HIV infection, and matrix metalloproteinases, enzymes involved in the destruction of extracellular matrix proteins required for angiogenesis and metastasis. In AIDS-related KS, Tat (the transactivator of transcription protein) stimulates KS spindle and endothelial cell replication, promoting an increase in the concentrations of basic fibroblast growth factor. This, in turn, upregulates the integrins α5β3 receptors for fibronectin and vitronectin, which are highly expressed in AIDS-related KS.

Clinical Features of Kaposi Sarcoma

Most patients with AIDS-related KS have CD4+ cell counts of 200 CD4+ cells/μL of blood, with an increased number and aggressiveness of lesions in those who are more severely immunosuppressed. There are periods of exacerbation alternated with quiescence related to oscillations of the patient's immunity. KS rarely invades the central nervous system (CNS). This is of biological interest because many other human malignancies are characterized by the invasion of the CNS.[19] The distribution of skin lesions in patients with AIDS-related KS often follows the Langer's folds of the skin. The occurrence of lesions in acral regions of the body such as the tip of the nose is common. The evolution of the skin lesions correlates with the patient's immune system status. In the pre-HAART era, severe involvement of the skin of the face by raised purplish lesions was frequent. With KS progression, there is frequent involvement of the gastrointestinal tract. Lesions of the palate and gums are often the first ones to be noted, and diarrhea and occasional bleeding can suggest KS involvement of the gastrointestinal tract. In the case of involvement of the lower extremities, progressive edema with nodular and coalescing plaque lesions can cause significant discomfort and pain. Prior to HAART, this was a frequent and serious complication of KS, because "elephantiasis" secondary to the progression of KS was extremely difficult to treat. Advanced cases often involve ulceration of lesions, particularly when located in the lower extremities. Lymph node involvement is frequent, and when there is only generalized lymph node involvement, a biopsy is required for confirmation of diagnosis. In advanced cases, lung involvement is manifested by bilateral basilar infiltrates mixed with a nodular appearance; however, severe hemoptysis or gastrointestinal bleeding is infrequent. During the early years of the epidemic, a significant number of patients experienced involvement by large masses of KS in vital organs such as the liver and heart, and death was caused by progression of their KS tumors and associated opportunistic infections.

Staging and Prognostic Factors for Patients with Kaposi Sarcoma

The usual TNM system used in other solid tumors is not easily applicable to AIDS-related KS. A system based on the work of Chachoua and colleagues was proposed in 1989 by the AIDS Clinical Trial Group (Table 52–1). This staging system included the extent of tumor involvement, the immune status measured by the level of CD4+ cell count, and the presence or absence of any systemic illness (B symptoms). In addition to a complete physical examination, it also included a complete blood count, serum chemistries, HIV viral load, panendoscopy of the gastrointestinal tract, computed tomography (CT) of the abdomen and pelvis, and when indicated, the performance of bronchoscopy when pulmonary involvement by KS was suspected. Biopsies of skin or lymph nodes were

Table 52–1 TIS Staging System for AIDS-Related Kaposi Sarcoma and Risk Status

Characteristics	Good Risk (0) All of the Following	Poor Risk (1) Any of the Following
Tumor (T)	Tumor confined to skin and lymph nodes and/or minimal oral disease[a]	Tumor-associated edema or ulceration; extensive oral KS; gastrointestinal KS; KS in other non-nodal viscera
Immune system (I)[b]	CD4 cells ≥150/mm^3	CD4 cells <150/mm^3
Systemic illness (S)	No history of opportunistic infection or thrush; no B symptoms[c]; performance status ≥70 (Karnofsky)	History of opportunistic infection and/or thrush; B symptoms; performance status <70 (Karnofsky); other HIV-related illness (eg, neurologic disease, lymphoma)

[a]Minimal oral disease defined as non-nodular KS confined to the palate.
[b]I stage has less prognostic value than T or S stages in the presence of HAART.

also suggested when indicated to rule out entities that could be similar in presentation, such as bacillary angiomatosis or pyoderma gangrenosum. After HAART, the extent of disease and the presence of HIV systemic symptoms became the most important prognostic factors; however, pulmonary involvement by KS still carries a particularly poor prognosis. Correlations with levels of HIV viral load and the status of HHV-8 infection are under study in relationship to their impact on survival.[20]

Therapy of Kaposi Sarcoma

HAART brought a dramatic decrease in the incidence of AIDS-KS. HAART consists of the administration of a combination of agents with anti-HIV activity, including integrase strand transference inhibitors, which inhibit HIV reverse transcriptase and protease inhibitors. The consensus of experts in the field about frontline components of HAART is periodically published in *Guidelines for the Use of Antiretroviral Agents in HIV-1 Infected Adults and Adolescents* by the Department of Human and Health Services (available online: https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/AdultandAdolescentGL.pdf). For patients in whom KS is part of the initial diagnosis of AIDS, HAART therapy should be started irrespective of the extent of the disease. For patients with minimal tumor burden, HAART initiation constitutes frontline therapy of their AIDS-related KS. This approach can control these lesions for long periods of time, often more than 1 year and, in many instances, results in complete disappearance of KS lesions.[21] Patients with extensive disease or visceral involvement can receive specific systemic KS therapies in addition to HAART.

Radiation Therapy for Kaposi Sarcoma

Radiotherapy is useful for the treatment of minimal local disease and when the use of systemic treatment other than HAART is not indicated. It can also be used as an adjunct treatment modality for patients in whom the administration of chemotherapy leads to incomplete results, enhancing the beneficial effects of the systemic treatment. Depending on the general condition of the patient and the size of the lesions to be treated, doses range from the administration of a single fraction to fractionated doses over periods of 2 to 4 weeks. For single lesions and frail patients, the administration of a single 800-cGy dose can be used. Radiotherapy can be used for cosmetic reasons, although this should be done carefully to avoid secondary side effects such as post-radiation cataracts in the case of periorbital lesions. For larger lesions or when the therapeutic intent is cosmetic, fractionated doses between 200 and 4000 cGy are effective and carry less risk. For patients receiving systemic therapy, radiotherapy can be an adjuvant for the treatment of complicated single lesions, particularly when they are bleeding, ulcerated, or painful, or when they affect the well-being of the patient. Such is the case in patients with disseminated disease receiving systemic treatment and in whom oral lesions may affect eating because of local pain or lesion size.

Local Therapy Other Than Radiotherapy for Kaposi Sarcoma

In the modern era, the use of local therapies such as cryotherapy and laser therapy may have a role for patients with few and small lesions. The use of surgery may be appropriate in selected cases such as large skin lesions or when there are complications (bleeding OR obstruction of a hollow viscus). Other treatments, such as intralesional injection of chemotherapeutic agents, particularly of the oral cavity, and application of alitretinoin gel, have been abandoned and replaced by a more sophisticated use of radiotherapy techniques, HAART, and systemic chemotherapy.

Immunomodulators in the Therapy of Kaposi Sarcoma

After the demonstration of the activity of IFN-α in hairy cell leukemia and renal cell cancer in 1984,[22] there was an impetus to use the same doses of IFN in patients with AIDS-related KS. Low doses of IFN-α effective against hairy cell leukemia and renal cell carcinoma were ineffective against AIDS-related KS (Rios A, personal observation). A dose-response study unequivocally demonstrated the therapeutic effect of IFN-α in KS when used at doses of 20–30 MU/m.[23,24] A different situation was observed with IFN-γ. Under the angiogenic stimuli of IFN-γ, KS has the capacity to replicate, resulting in a deleterious impact on patients treated with this agent in pilot studies. As a result of these trials, recombinant IFNs α-2a (Roferon-A, Roche Laboratories) and α-2b (Intron-A, Schering-Plough) were approved for the systemic treatment of patients with AIDS-related KS. Expanded use of these agents has revealed their true activity to be in the range of 15% to 20%.

Interferon can block the synthesis of viral proteins and the budding of viral particles from infected cells in addition to other complex pleiotropic effects. Interferon actions are accompanied by significant systemic side effects including tiredness, fatigue, anorexia, hepatotoxicity, and severe myelosuppression. With the development of HAART and the use of more effective systemic chemotherapy regimens in the treatment of AIDS-related KS, the interest in the use of IFN-α in the treatment of AIDS-related KS has declined.

Other Immunomodulatory Agents

Thalidomide, a known immunomodulatory agent, has been studied in KS, with partial responses seen in 47% of patients and stable disease seen in 12%. However, its use has been limited by adverse constitutional effects. More recently, pomalidomide, a derivative of thalidomide with antiangiogenic and antiproliferative activities has shown significant activity against AIDS-related KS, with an overall response rate of 60%. The median time to response was 4 weeks and a median progression-free survival of 16.6 months.[25]

Chemotherapy for Kaposi Sarcoma

Indications for the use of systemic chemotherapy in AIDS-related KS includes extensive skin, mucocutaneous, and visceral involvement by tumor. In patients who require systemic chemotherapy, local radiotherapy is used to treat local complications in addition to systemic disease. The introduction of HAART has resulted in better and more durable responses with increased tolerability and durability than those observed before the use of HAART. Before the discovery of antiretrovirals, a variety of chemotherapeutic agents had modest to significant activity as monotherapy for KS. These agents included etoposide, vinblastine, vincristine, bleomycin, doxorubicin, vinorelbine, and epirubicin, which induced responses in 40% to 69% of patients. After HAART, ABV (doxorubicin 20 mg/m^2, bleomycin 10 U/m^2, and vincristine at maximum doses of 1–2 mg) became the first standard treatment of AIDS-related KS. It produced a response rate of 60%, with complications depending on the performance status and general condition of the patient.[26] Antiretroviral and other supportive therapies with growth factors (granulocyte-macrophage colony-stimulating factor [CSF] and granulocyte CSF [G-CSF]) paired with vigorous prophylaxis of opportunistic infections reduced the risks of treatment. Complications of ABV were the expected ones with systemic chemotherapy including the potential for cardiac toxicity induced by doxorubicin. The ABV regimen was followed by the introduction of agents considered today to be the standard of care for AIDS-related KS, including liposomal-encapsulated anthracyclines (doxorubicin and daunorubicin) and taxanes (paclitaxel). The last of these promotes apoptosis and downregulates Bcl-2 protein expression in KS cells in vitro and in KS-like lesions in mice. In addition, it has an important antimitotic effect associated with its capacity for the disruption of tubulin activity during mitosis.

The current treatment of AIDS-related KS is based on the combination of an anthracycline (liposomal doxorubicin 20 mg/m^2 or liposomal daunorubicin 40 mg/m^2 *but not both together*) with paclitaxel 25 mg/m^2 with or without bleomycin or vincristine. Escalation of the dose of liposomal doxorubicin is not recommended because of a syndrome of desquamation of the skin of the palms and soles of the feet, known as palmar-plantar erythrodysesthesia. In contrast, the dose of liposomal-encapsulated daunorubicin can be increased to up to 60 mg/m^2 or even higher for patients who tolerate lower doses. This is of particular relevance in patients with advanced disease or significant pulmonary involvement and for whom prompt control and achievement of a quick therapeutic response is of great importance (Fig. 52–2).

Future Therapies for Kaposi Sarcoma

Only patients with early disease and relatively good performance status consistently achieve durable remissions with current therapies for KS. For the remaining patients, only palliation and stabilization of disease is achieved with current treatments. For these reasons, efforts are under way to develop new therapies based on the knowledge of the pathophysiology of the disease. For example, because angiogenesis is an important component of AIDS-related KS, agents such as thalidomide and anti-VEGF agents such as bevacizumab are of great interest in the therapy of this disease, although they continue to be recommended under certain circumstances. Metalloprotease inhibitors are also of great interest, and active clinical trials are in progress. Viruses associated with the production of malignancies tend to constitutively activate the nuclear factor–κB (NF-κB) pathway, and agents that can inhibit this pathway such as bortezomib may be of some value. Inhibition of signaling cell receptors implicated in the stimulation of angiogenesis such as platelet-derived growth factor receptor and C-kit receptor by agents such as imatinib, an orally administered tyrosine kinase inhibitor, approved by the Food and Drug Administration (FDA) for treatment of chronic myeloid leukemia and gastrointestinal stromal tumor, is being investigated.

There is significant interest in the development of therapies against the latent phase of HHV-8, the most common form of HHV-8 in KS cells, which does not respond to standard antiherpetic drugs such as foscarnet and cidofovir. This area of research has led to potential development of a vaccine against HHV-8. More recently it has been demonstrated in a small number of AIDS-KS patients the upregulation of PDL-1 with weak cytoplasmic expression in 50% of the studied patients. After this finding, another group treated a heterogeneous group of nine AIDS-KS patients with checkpoint immune inhibitors and observed one complete remission and five partial responses. There were no serious adverse toxicities above grade 2. This has triggered significant interest in the potential use of PD-1 checkpoint blockade in AIDS-KS.[27,28] Despite all these new potential therapeutic developments, the impact of HAART in the incidence of

AIDS-related KS cannot be overemphasized. The development of more potent and less toxic HAART regimens and the acceptance of earlier therapeutic intervention against HIV seem to be the main paths to controlling the epidemic of AIDS-related KS.

Other Diseases Associated with Kaposi Sarcoma Herpesvirus

KSHV is the etiologic agent of PEL (discussed in the Lymphomas section), KSHV-associated MCD, and a KSHV inflammatory cytokine syndrome.[29–31] KSHV-associated multicentric disease is a B-cell lymphoproliferative disease involving multiple regions of lymphadenopathy. The spectrum of histopathologic features includes hypervascular changes and *LANA*-expressing plasmablasts. Patients with KSHV-associated MCD have systemic inflammatory symptoms with generalized lymphadenopathy, hepatosplenomegaly, cytopenias, and organ dysfunction with excessive proinflammatory hypercytokinemia, including IL-6. Treatment consists of the administration of antivirals (valganciclovir, foscarnet), rituximab, and IL-6 inhibitors. When associated with AIDS-KS, specific therapy for KS is added. KSHV inflammatory cytokine syndrome is an inflammatory syndrome clinically similar to MCD but without MCD, which tends to occur in patients with high-KS burden and portends a poor prognosis. In contrast to MCD there is no splenomegaly, and the widespread lymphadenopathy typical of MCD.

AIDS-RELATED NON-HODGKIN LYMPHOMA

Systemic Non-Hodgkin Lymphoma

Epidemiology

NHL is the second most frequent AIDS-associated malignancy. Both KS and NHL were occurring with an incidence almost linear in its relationship to the patient's immunodeficiency status.[32] In 1985, high- or intermediate-grade B-1 l NHLs were considered part of the spectrum of AIDS-related malignancies. Eighty percent of AIDS-related NHLs were systemic (peripheral) lymphomas, involving nodal or extranodal sites, with 15% to 20% originating in the PCNSL. A small

proportion (<3%) of patients with systemic AIDS-related NHL had PELs, known as body cavity lymphomas. In general, the risk of AIDS-related NHL in patients with HIV appears to be higher in those who have poor immune function with an average CD4+ cell counts of 150 CD4+ cells/μL of blood. A viral relationship is implicated in the development of AIDS-associated lymphomas. EBV contributes to the development of most of these tumors, although HHV-8 is associated with the development of PEL.[29] There is no relationship between the risk of development of AIDS-related NHL and modes of HIV transmission. The incidence of pre-HAART AIDS-related NHL was 60 to 200 times higher than in a matched HIV-seronegative population; the relative risk was higher for PCNSL. Age, nadir of CD4+ cell count, and absence of anti-HIV therapy were critical factors that predicted the development of AIDS-related NHL. In the pre-HAART era, 80% of these NHLs, including systemic and PCNSL cases, were immunoblastic variants associated with CD4+ cell count depletion and EBV infection. In the post-HAART era, there has been a 30% reduction in peripheral cases and a 70% reduction in PCNSL, indicating the impact of immune reconstitution in the incidence of immunosuppression-related lymphomas. In contrast, the incidence of Burkitt lymphoma and of centroblastic DLBCL has remained stable without significant change from the pre- to the post-HAART eras.[33] When comparing the AIDS-related lymphomas with non–AIDS-related NHL, the former tend to be of higher histologic grade, with increased frequency of B symptoms, extranodal presentations, and an increased incidence of leptomeningeal and primary CNS involvement.[34] In the post-HAART era, the WHO has expanded the categories of lymphomas that can occur in patients with HIV to include extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue type, peripheral T-cell lymphoma, and classical Hodgkin lymphoma (HL), as well as lymphomas that more specifically occur in patients with AIDS, including plasmablastic lymphomas of the oral cavity, polymorphic B-cell lymphomas (posttransplant lymphoproliferative disorder–like), and PEL.[35] Finally, the demographics of patients with AIDS-related NHL have changed in the last decade, reflecting changes in the demographics of the AIDS epidemic, with increasing incidence in Hispanic and Black patients and patients who have acquired HIV through heterosexual contact (Table 52–2).

Pathogenesis of AIDS-Related Non-Hodgkin Lymphomas

The development of NHLs in patients with HIV is similar to that of malignancies associated with other congenital or posttransplant immunodeficiency disorders.[36,37] In such conditions, most of the malignancies consist of NHL and KS. In the case of HIV, immunodeficiency and cofactors, including oncogenic viruses, chronic antigenic stimulation, and cytokine overproduction, are responsible for the development of AIDS-related NHL malignancies. In contrast to AIDS-associated KS, no one has yet found HIV sequences in tumor cells of AIDS-related NHLs,[38] although PCR analysis has revealed the presence of HIV in infiltrating T-cells. For patients with severe HIV immunodeficiency, the oncogenic nature of both EBV and HHV-8 is responsible for the development of the immunoblastic subtype of DLBCL, PCNSL, plasmablastic lymphoma of the oral cavity, and PEL. The last of these often results from coinfection with HHV-8 and EBV. These lymphomas are the result of active oncogenic viruses released from control by an effective immune surveillance.

EBV is central to the pathogenesis of AIDS-related NHLs, including those that are related to immunodeficiency and those that occur with a reconstituted immune system, such as centroblastic DLBCL and Burkitt lymphoma. The EBV genome presence is very high in immunodeficiency-associated AIDS-related NHLs (100%),[39] although it can only be detected in approximately 60% of centroblastic DLB- CLs and 30% of Burkitt lymphomas. This suggests that other factors, including other common latent or chronic viral infections, may be involved in the development of these tumors. In EBV-infected cells, the EBV virus is, for the most part, in a state of latency with brief periods of lytic activity. The malignant transformation of B cells occurs in the latent phase, requiring multiple molecular events.[40] EBV contributes to the cellular transformation process through expression of genes with oncogenic activity such as *LMP-1*, *LMP-2*, *EBNA-1*, and *EBNA-2*. There is also expression of small EBV-encoded nonpolyadenylated nuclear RNAs (EBERS), all of which participate in the oncogenic transformation phenomenon. These proteins can rescue cells from apoptosis by mimicking cell receptors such as CD40 and B-cell receptor. For example, LMP-1 (latent membrane protein-1) is capable of replacing the function of CD40 in germinal B cells, which otherwise would follow an apoptotic fate. The latency patterns of EBV gene expression have been classified as I, II, and III. Latency I is characterized by expression of EBV nuclear antigen 1 and is associated with Burkitt and PEL; latency III involves the expression of all nine EBV latent genes. The proteins expressed are highly immunogenic and thus this latency occurs in severely immunodeficient individuals and typically is associated with AIDS-DLBCL. Type II latency is an intermediate type of pattern of protein expression and is associated with HL and NK-T cell lymphomas.[41]

The Impact of Highly Active Antiretroviral Therapy on Distribution of Acquired Immunodeficiency Syndrome–Related Non-Hodgkin Lymphoma

In the post-HAART era, there has been a decline in the incidence of NHLs associated with immunodeficiency caused by AIDS. In contrast, the incidence of centroblastic DLBCL and Burkitt lymphoma appears to be similar before and after introduction of HAART. Factors influencing the pathogenesis of these diseases include an increase in regulatory cells of the immune system, associated with recovery of the immune status of the host, and effects of chronic antigenic stimulation by HIV with a resultant overproduction of cytokines. The existence of more than one pathogenic mechanism for the occurrence of AIDS-related NHLs can be inferred from the variety of genetic abnormalities displayed by the malignant cells.[42] The number and type of these genetic abnormalities vary according to the anatomic site and tumor histology. They include c-*myc* rearrangement, *bcl-6* gene rearrangement, *ras* gene mutations, and *p53* mutations/deletions.[43]

Pathology of Systemic Non-Hodgkin Lymphomas

The hallmark of AIDS-related NHL is a high-grade histology, regardless of the histologic subtype, including diffuse large cell, immunoblastic, and small noncleaved cell lymphomas and Burkitt and Burkitt-like lymphomas. The cells of PEL express CD45 and activation-associated antigens such as HLA-DR, CD30, CD38, CD71, epithelial membrane antigen, and CD 138/syndecan-1. PEL cells often lack B-cell antigens and c-*myc*

gene rearrangements and mutations and uniformly contain HHV-8 and frequently also contain EBV[42,43]). Other hematologic neoplasms, including low-grade B-cell lymphomas and lymphocytic leukemia, multiple myeloma/plasmacytomas, T-cell neoplasms, and various acute myeloid leukemias and myeloproliferative disorders, have been reported in patients with HIV infection. However, there is no evidence that the incidence of these neoplasms has increased in parallel with the AIDS epidemic.[42–48]

Clinical Features of Systemic Non-Hodgkin Lymphomas

Patients with AIDS-related NHLs usually present with advanced stages of the disease and B symptoms, including fever, weight loss, night sweats, and enlarged lymph nodes or masses. More than 60% of the patients will present with stage III or IV disease. Frequent extra nodal sites of involvement are bone marrow, CNS parenchyma and meninges, lungs, and spleen. Patients with PEL present with ascites or a pleural effusion and, less frequently, with a pericardial effusion. Masses are typically absent in the presentation of PEL, although sometimes a mass may accompany the development of the effusion (see Fig. 52–1).[49]

The staging of patients with AIDS-related NHL is similar to non–HIV-infected patients with NHL and should be reported according to the Ann Arbor system (Table 52–3). The International Prognostic Index (IPI) has been validated in pre-HAART studies, and significant changes in treatment outcomes have occurred since the initiation of HAART.[50] Complete blood count, β2-microglobulin, lactic dehydrogenase, and complete blood chemistry laboratory tests should be performed, and a radiologic staging should include magnetic resonance imaging (MRI) of the brain and positron emission tomography (PET)/CT scan. Patients in remission after two courses of treatment tend to remain in remission for the duration of induction therapy. Patients with Burkitt types of lymphoma should have a bone marrow aspiration and biopsy and a diagnostic lumbar puncture. All patients should be screened for hepatitis B, because the exacerbation of this virus by the use of rituximab or chemotherapy can be prevented by screening patients for hepatitis B surface antigen, hepatitis B core antibody, and hepatitis C. Hepatitis B surface antigen–positive patients or patients with a positive hepatitis B core antibody should have evaluation of e antigen, hepatitis B viral load by PCR, and surface antibody if one of the screening tests is positive because the rate of reactivation of hepatitis B virus with the risk of fulminant hepatitis is approximately 20% to 50%.These patients should be treated prophylactically and if there is active disease (PCR+) the treatment is not considered prophylactic but therapeutic.

Table 52–3 Ann Arbor Staging Classification for Hodgkin Lymphoma

Stage	Characteristics
I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (IE).
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site (IIE).
III	Involvement of lymph node regions on both sides of diaphragm (III) or localized involvement of an extralymphatic organ or site (IIIE) or spleen (IIIS) or both (IIISE).
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement. The organ(s) involved should be identified by a symbol: A, asymptomatic; B, fever, sweats, weight loss >10% of body weight.

Data from Carbone PP, Kaplan HS, Musshoff K, et al: Report of the Committee on Hodgkin's Disease Staging Classification, *Cancer Res* 1971 Nov;31(11):1860-1861.

A HAART regimen containing nucleoside reverse transcriptase inhibitors, active against HIV and hepatitis B, are recommended. For those infected with hepatitis C, the situation is different because hepatitis C–related liver failure is relatively rare with chemotherapy and thus antiviral treatment can wait until the completion of the chemotherapy.[51] Before HAART, the presence of an opportunistic infection, less than 100 CD4+ cells/μL of blood, bone marrow involvement, and increased age predicted poor survival, with patients often suboptimally treated because of poor tolerance to standard doses of chemotherapy. After HAART, two factors have become predictors of poor survival: a CD4+ cell count of less than 100 cells/μL and high-intermediate IPI scores.[52]

Therapy for AIDS-Related Systemic Non-Hodgkin Lymphoma

Prior to HAART, all regimens had in common reduced doses of chemotherapy. After 1996, it became clear that patients on HAART can receive standard doses of chemotherapy. The outcomes of treatment in the presence of HAART are related to the subtype of lymphoma and the specific treatment rather than the immunodeficiency status of the patient (Table 52–4). It is important that the use of HAART not contain ritonavir or cobicistat to avoid drug interactions because of the inhibition of cytochrome P-450 enzyme CYP3A4. Vigorous prevention of infections with prophylactic antibiotics, aggressive use of growth factors (G-CSF and pegylated G-CSF), and anti-CD20 antibodies

Table 52–4 Summary of Selected HIV-Related Lymphoma Trials

AZT, azidothymidine; CDE, cyclophosphamide, doxorubicin, and etoposide; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CR, complete response; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin hydrochloride; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating hormone; HAART, highly active antiretroviral therapy; m-BACOD, methotrexate with leucovorin, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone; MTX/LV, methotrexate and leucovorin; NR, not reported; OI, opportunistic infection; ORR, overall response rate; OS, overall survival; R, rituximab.

(rituximab) where indicated have improved the outcomes for these patients (Table 52–5). Although investigators were originally concerned that rituximab might compromise the immune status of patients with CD20+ B-cell lymphomas, studies have demonstrated that rituximab can safely be used for patients with 50 or more CD4+ cells/all of blood.

Regimens commonly used to treat patients with AIDS-related DLBCL include CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or rituximab plus CHOP (R-CHOP), R-CDE (rituximab, cyclophosphamide, doxorubicin, and etoposide). Progression-free survival rates at 2 years for these different treatment regimens are 70% for R-CHOP and R-CDE.[53–58] A phase 2 study of dose-adjusted EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin hydrochloride) plus rituximab (DA-EPOCH-R) showed a progression-free survival rate at 2 years of approximately 90% for dose-adjusted EPOCH-R.[59] A prospective trial in immunocompetent patients with DLBCL did not show an advantage of R-DA-EPOCH over R-CHOP.[60] However, in a recent large prospective study of EPOCH-R for patients with HIV seropositivity, six cycles of rituximab plus infusional EPOCH produced good results for first-line treatment of HIV-associated DLBCL, HHV8-positive DLBCL, and PELs, especially for those who achieved a complete response (CR).[61] Results from this study also suggested that, after two cycles of EPOCH plus rituximab, patients with HIV-associated lymphomas have excellent outcomes when therapy is limited to four cycles, reducing the risk of toxicity.

In the case of Burkitt lymphoma, CHOP and similar regimens are not recommended because the response is poor. Burkitt lymphoma was historically treated with R-HyperCVAD (rituximab plus cyclophosphamide, vincristine, doxorubicin, and dexamethasone)[62,63] or R-CODOX-M/IVAC (rituximab plus cyclophosphamide, doxorubicin, vincristine, methotrexate/ifosfamide, etoposide, high-dose cytarabine).[64] Both regimens achieved remissions of more than 92% and a 2-year overall survival rate of 49% (Figs. 52–3 and 52–4). However, EPOCH-R is now listed with other regimens and is a preferred therapy for HIV-associated Burkitt lymphoma, according to 2019 NCCN guidelines.[65] Such recommendations are supported by R-EPOCH results reported from phase 2 trials for HIV-associated DLBCL and high-grade lymphomas such as Burkitt lymphoma.[66,67] In a large meta-analysis, investigators have also found that DA-R-EPOCH has greater efficacy than that reported for R-CHOP for these patients.[68] In another analysis, a

Table 52–5 Suggested Supportive Care for the Patient with HIV Infection and Lymphoma or Other Malignancies

Indication	Drug(s)
Primary infection prophylaxis	
Pneumocystis carinii, Toxoplasma gondii	Trimethoprim-sulfamethoxazole 1 DS daily. Alternatives for patients with allergy to Bactrim-DS are dapsone 100 mg PO once a day or atovaquone 1500 mg once a day with food.
Oral and/or esophageal candidiasis	Fluconazole 100 mg daily
MAI complex (CD4 <50 cells/μL)	Azithromycin 1200 mg weekly
Secondary infection prophylaxis	
Herpes simplex infections	Acyclovir 400 mg bid or 200 mg tid
Cytomegalovirus infection	Ganciclovir 1 g tid
Mycobacterium avium complex	Clarithromycin 500 mg bid plus ethambutol
	15 mg/kg daily, with or without rifabutin 300 mg daily
Toxoplasma gondii	Sulfadiazine 1–1.5 g q6h, pyrimethamine 25–75 mg daily
	Leucovorin 10–25 mg daily qid
Cryptococcus neoformans	Fluconazole 200 mg daily
Salmonella bacteremia	Ciprofloxacin 500 mg bid
Hematopoietic growth factors	
For selected patients in whom the risk of febrile neutropenia ≥40%	G-CSF 5 μg/kg or GM-CSF 250 μg/m^2 SC daily beginning after completion of chemotherapy and continuing until neutrophil recovery
Antiretroviral agents	
Selecting patients for therapy	[a]Follow NIH guidelines
Role of therapy in controlling malignancy	
Kaposi sarcoma	Essential
Lymphoma	Unknown
Other tumors	Unknown
May be used with myelosuppressive drugs	General principles of HIV treatment: An INSTI, NNRTI, or PI combined with 2 NRTIs. Avoid regimens containing ritonavir or cobicistat (cytochrome P-450 enzyme CYP3A4 strong inhibitors). First Choice: NRTIs: emtricitabine/tenofovir alafenamide (Descovy) or abacavir/lamivudine (Epzicom); with an INSTIs: dolutegravir or raltegravir. Second choice: NNRTIs: rilpivirine (weak CYP3A4 inducer); efavirenz. Efavirenz can be combined with emtricitabine/tenofovir in a single capsule (Atripla). Strong inducer of CYP34A.
Avoid with myelosuppressive drugs/regimens	Zidovudine
Avoid with neurotoxic drugs/regimens	Didanosine, zalcitabine, stavudine
May alter the metabolism of cytotoxic drugs metabolized by cytochrome P-450 enzymes	All PIs and NNRTIs

bid, two times daily; DS, double strength; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; INSTI, integrase strand transfer inhibitor; MAI, *Mycobacterium avium-intracellulare*; NIH, National Institutes of Health; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTIs, nucleoside reverse transcriptase inhibitors; PI, protease inhibitor; qid, four times daily; SC, subcutaneous; tid, three times daily.

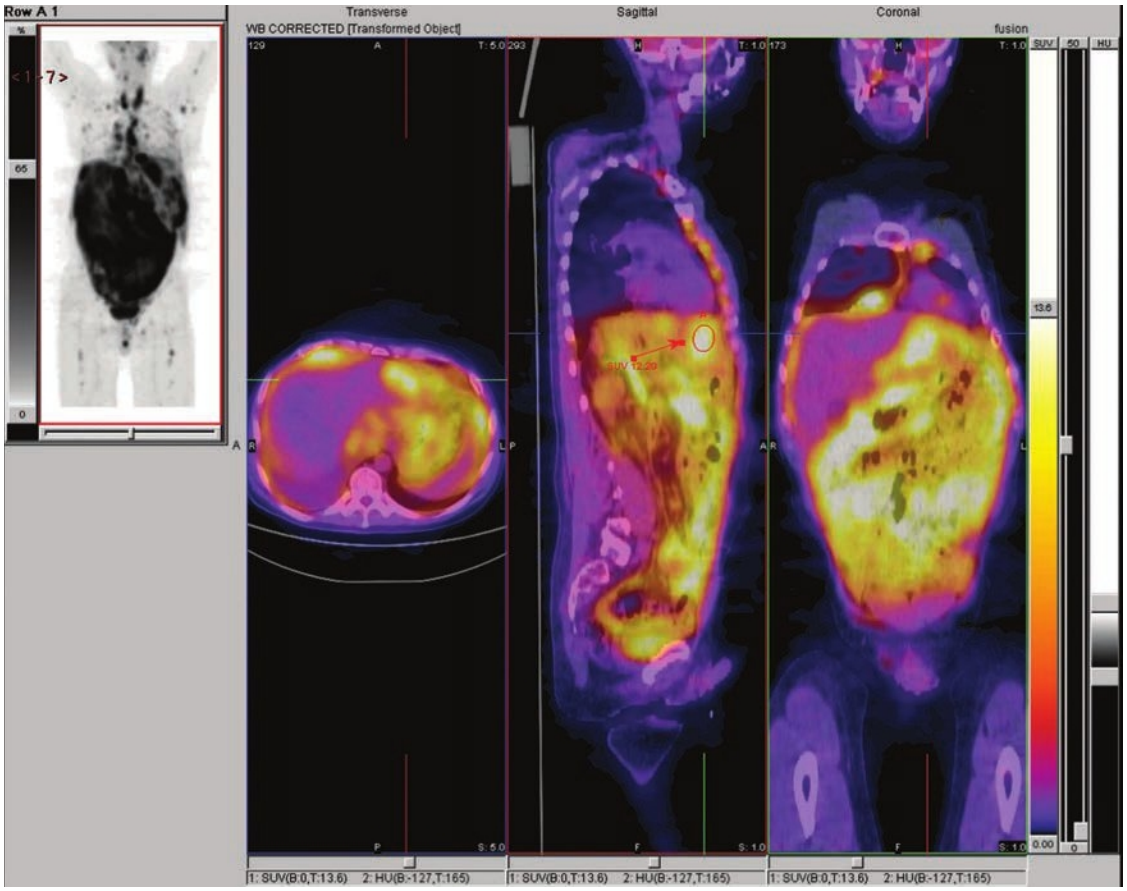

FIGURE 52–3 **Positron emission tomography/computed tomography (PET/CT) scan of a 51-year-old HIV-positive patient demonstrating extensive involvement of Burkitt lymphoma in the chest, abdomen, and pelvis.**

high proliferation rate predicted a better prognosis for such patients when they received R-EPOCH instead of R-CHOP.[69] A reported variation of the standard DA-EPOCH-R regimen, known as SC (for short)-R (rituximab days 1 and 5)-DA- EPOCH for HIV-related Burkitt lymphoma consists of a 4-day infusion of etoposide (50 mg/m^2/d), vincristine 0.4 mg/m^2/d, and doxorubicin (10 mg/m^2/d) admixed in the same solution, along with prednisone, at a dose of 60 mg/m^2/d orally on days 1 to 5. Cyclophosphamide is given at a dose of 750 mg/m^2 as a 2-hour infusion on day 5. Rituximab is given at a standard dose of 375 mg/m^2 on days 1 and 5.[60] Filgrastim is given subcutaneously starting on day 6 until the absolute neutrophil count (ANC) is 5000/μL (post nadir). Cyclophosphamide is increased or decreased from the previous course dose if the ANC nadir is more than 500/μL or less than 500/μL ANC, respectively. Importantly, only cyclophosphamide is dose-adjusted for hematologic toxicity. Patients receive one cycle after CR is established for a minimum of three cycles and a maximum of six cycles (Table 52–6). However, lower doses of cyclophosphamide in EPOCH-R for patients with HIV disease have also been described[59] and may provide similar results to standard-dose EPOCH-R. Patients with high-grade and Burkitt lymphomas should undergo PET and other CNS scans before therapy and should receive prophylactic intrathecal chemotherapy. For patients with relapsed or refractory lymphomas, R-ICE (rituximab, ifosfamide, carboplatin, and etoposide) or R-ESHAP (rituximab, etoposide, methylprednisolone, cytarabine, and cisplatin) can be of value, although patients with relapsed disease usually have poor outcomes with most standard chemotherapy regimens. Patients with disease responsive to salvage therapy should be considered for high-dose chemotherapy and autologous stem cell transplantation as consolidative therapy.[70]

AIDS-Related Non-Hodgkin Lymphoma: Primary Central Nervous System Lymphoma

Epidemiology and Pathogenesis

Primary CNS lymphoma became an AIDS-defining malignancy in 1983. Primary CNS lymphoma accounted for up to 15% of NHLs in HIV-infected patients compared with only 1% of NHLs in the

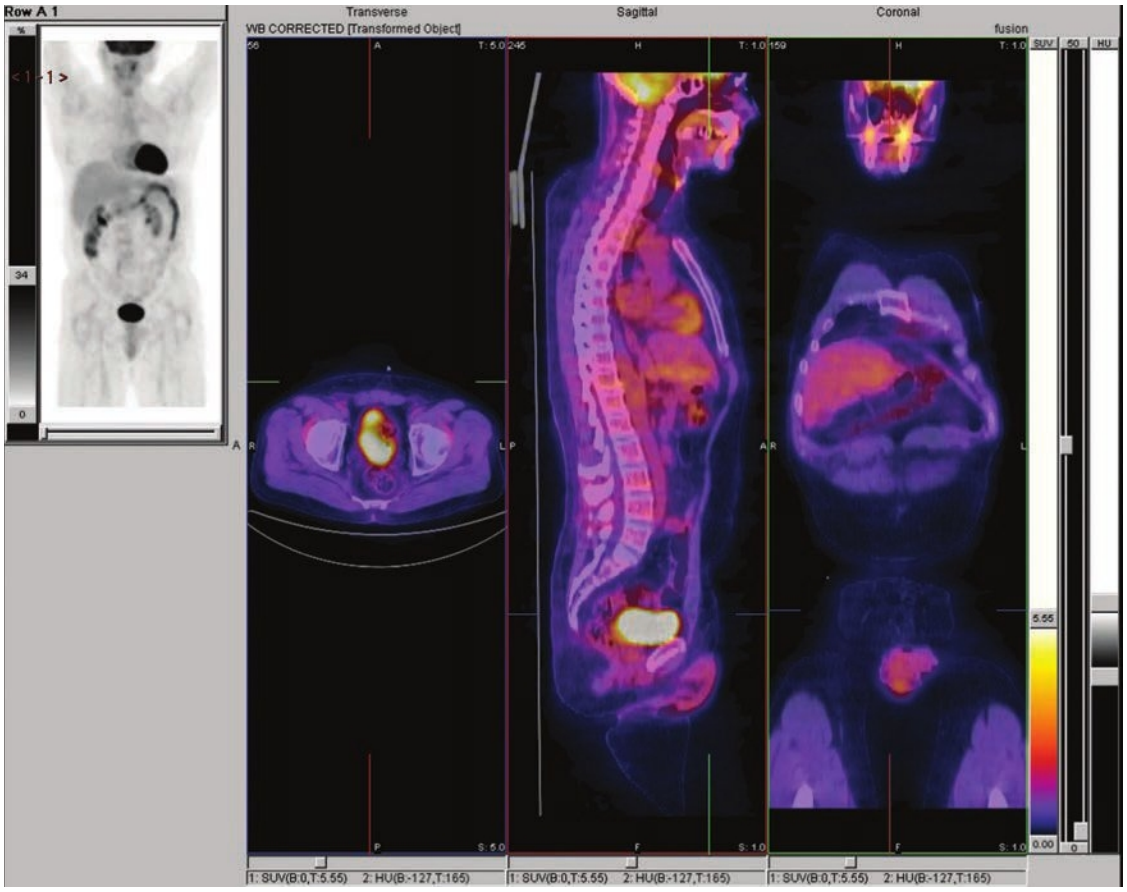

FIGURE 52–4 **The same patient as in Fig. 52–3. The PET/CT scan after four courses of hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone (hyperCVAD) alternated with high-dose methotrexate-ara-C and leucovorin rescue, reveals a dramatic improvement with no residual hypermetabolic activity. The patient went on to complete eight courses of treatment with hyperCVAD-HD methotrexate-Ara-C-leucovorin rescue. He remains in complete remission of the Burkitt lymphoma 4 years after treatment and on highly active antiretroviral therapy.**

general population. In the pre-HAART era, typical patients were men who were younger (median age, 40 years) than their immunocompetent counterparts, with CD4+ cell counts of less than 50 cells/μL of blood. The impact of HAART was evidenced by a significant decrease in the disease incidence after 1996 (from 313.2 per 100,000 person-years to 77.4 per 100,000 person-years).[3] The development of PCNSL is related to the effect of HIV immunodeficiency on the activity of EBV. The virus does not replicate in CNS tissue. Thus, infected B cells most likely reach the CNS in increased numbers as a result of the progression of the HIV infection. There is loss of capacity by specific T-cells for the production of IFN-γ in response to EBV peptides with increased expression of EBNA-2, LMPs, and EBERs. This pattern is seen when EBV transforms primary B cells in vitro. The expression of type III latency upregulates genes involved in transformation, including Bcl-*2* and *IRF-7*, and inactivation of *p53* and *Rb* tumor suppressor gene products.[71]

Clinical Presentation and Diagnosis

Patients with AIDS and PCNSL present with acute organic brain syndrome, in contrast to immunocompetent patients, in whom neurologic deterioration can be slow and progressive. Headaches, seizures, and focal neurologic signs and symptoms are common. Personality changes are frequent, and nausea and vomiting indicate an increased intracranial pressure. When the rare comatose state occurs, it indicates an acute intracranial catastrophe, such as intratumoral hemorrhage. Patients with a primary lesion in the brain and no history of systemic lymphoma usually have a brain lesion as the sole manifestation of the disease (Fig. 52–5). Radiologic diagnostic methods paired with analysis of the cerebrospinal fluid are the cornerstones of the diagnosis of PCNSL. Diagnostic MRI of the brain is preferred to CT scan because of the capacity of the former to detect small lesions. When MRI is not available, CT is acceptable because it allows detection of

Table 52–6 Short-Course Dose-Adjusted EPOCH[a]

Drug	Dose	Route	Treatment Days
Infused agents[b]			
Etoposide	50 mg/m²/d	CIV	1, 2, 3, 4 (96 h)
Doxorubicin	10 mg/m²/d	CIV	1, 2, 3, 4 (96 h)
Vincristine[c]	0.4 mg/m²/d	CIV	1, 2, 3, 4 (96 h)
Bolus agents			
Cyclophosphamide (cycle 1)	750 mg/m²/d	IV	5
Cyclophosphamide dose adjustment (after cycle 1)[d] nadir ANC <500/μL or platelets <25,000/μL for 2–4 days	↓ 187 mg/m²; route and treatment days remain unchanged below previous cycle	NA	NA
If the nadir ANC <500/μL or platelets <25,000/μL for more than 5 days, reduce cyclophosphamide by 50% of the initial full dose.	375 mg/m² below previous cycle; under Route and Treatment Days put NA		
Prednisone	60 mg/m²/d	PO	1, 2, 3, 4, 5
Rituximab	375 mg/m²	IVPB	1 and 5
Filgrastim	5 μg/kg/d	SC	6→ANC >5000/μL past nadir)
Next cycle[e]			Day 21

[a]Data are for cycle 1 except where noted in "cyclophosphamide dose adjustment."
[b]Etoposide, doxorubicin, and vincristine can be admixed in the same solution. Etoposide, doxorubicin, and vincristine are never dose-adjusted for hematologic toxicity.
[c]Vincristine dose should never be routinely capped.
[d]Dose based on previous cycle ANC nadir (complete blood count, twice-weekly) maximum cyclophosphamide dose, 750 mg/m².
[e]Begin day 21 if ANC ≥1000/μL and platelets ≥75,000/μL.
Intrathecal therapy: Intrathecal therapy with 12 mg of methotrexate or 100 mg of cytarabine is administered intrathecally on days 1 and 5 every 3 weeks beginning in cycle 3 for 8 doses for patients without central nervous system involvement. For patients with central nervous involvement please refer to original reference.
ANC, absolute neutrophil count; BSA, body surface area; CIV, continuous intravenous infusion; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin hydrochloride; IV, intravenous; IVPB, intravenous piggyback; NA, not applicable; PO, oral; SC, subcutaneous.

larger lesions (≥1 cm) and provides information about the safety of performing a lumbar puncture. Before and after HAART, the most important differential diagnosis of PCNSL has been cerebral toxoplasmosis, the most frequent cause of cerebral infection and masses in severely HIV-immunosuppressed patients.[72] In both PCNSL and cerebral toxoplasmosis, multiple lesions can occur, and both can also have enhancing ring lesions, so distinction between the two can be difficult. A positive serology for toxoplasmosis can be helpful if titers are greater than 1:256. If the toxoplasmosis serology is negative, the presence of EBV DNA found by PCR in the cerebral spinal fluid and a positive single-photon emission CT–thallium scan of the brain has high specificity for the diagnosis of PCNSL.[73,74] More recently, flow cytometry examination of the cerebrospinal fluid has been used to detect occult disease.[75]

During the early years of the AIDS pandemic, it was difficult to perform invasive procedures in patients afflicted by an infectious process of which little was known, and much was feared. These difficulties resulted in a series of practices borne out of necessity rather than rational approaches to the management and treatment of these patients such as the routine empirical treatment of brain lesions with antitoxoplasmosis therapy and gauging the diagnosis of the patient based on the clinical response to the antitoxoplasmosis treatment. Today, there is little room for continuation of such practices, and they should be avoided. They cause unnecessary delays in diagnosis and complicate the patient's management because there are potential side effects associated with treatment for an illness the patient may not have. Therefore, unless there is an absolute contraindication, the standard of care for a patient with a brain lesion and AIDS is the performance of a stereotactic biopsy of the brain, particularly in patients with a negative serology for toxoplasmosis.

Treatment of Primary Central Nervous System Lymphoma

HAART is the first step in the treatment of these patients. There is a clear correlation between the immune status of the patient and prognosis. The use of steroids and anticonvulsants is debated among some investigators concerned with the potential of steroids to confound the histologic diagnosis. However, a few days of steroids (4–5 days) can be of clinical benefit, particularly when there is an obvious mass effect. Anticonvulsive therapy administered for a few days

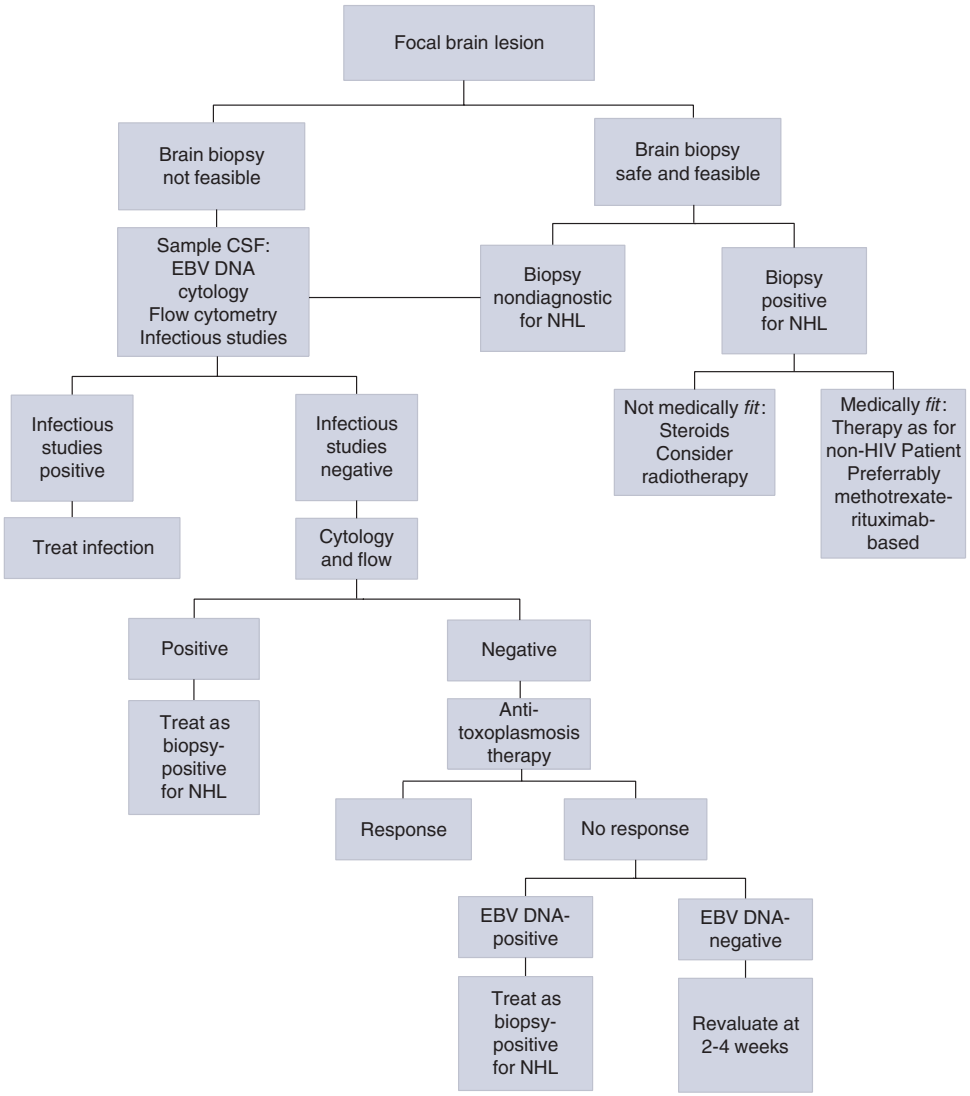

FIGURE 52–5 Evaluation of brain lesions in patients with HIV disease. CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; NHL, non-Hodgkin lymphoma. (Adapted with permission from Sparano JA. Clinical aspects and management of AIDS-related lymphoma, *Eur J Cancer* 2001 Jul;37(10):1296-1305.)

can allow the stabilization of the neurologic condition of the patient, controlling the risk of focal or grand mal seizures. Even solitary lesions of PCNSL tend to infiltrate surrounding tissues. Thus, there is no role for surgical resection in the treatment of this disease.

Before HAART, whole-brain radiotherapy was the standard of care for PCNSL, until it was replaced by best comfort measures, because the brains of severely immunocompromised patients tolerated the administration of radiotherapy poorly. Similar to immunocompetent patients with PCNSL, high-dose methotrexate and rituximab have replaced the administration of radiotherapy in patients with HIV and PCNSL. Investigators have suggested a modification of a standard regimen used for the treatment of patients without HIV, which includes rituximab 500 mg/m^2 on day 1 and methotrexate 3.5 g/m^2 and vincristine 1.4 mg/m^2 given only on day 2. Leucovorin rescue is given in standard fashion, and HAART treatment is initiated or continued. This modified regimen is administered for five to six cycles depending on the tolerance of the patient, followed by four courses of monthly maintenance with radiotherapy administered in a stereotactic manner at the discretion of the treating physician.[76] For patients not eligible to receive high-dose methotrexate, options include the use of temozolomide-rituximab and, in selected cases, focal radiotherapy followed by maintenance with an immunomodulatory agent such as lenalidomide or pomalidomide.[77–79]

New Therapies for Primary Central Nervous System Lymphoma

Activated Bruton tyrosine kinase signaling is common in PCNSL. For this reason, Bruton tyrosine kinases have been explored with evidence of activity in PCNSL although responses tend to be of short duration. This has prompted its exploration in combination regimens to achieve more durable responses. Another extremely promising new area is the potential use of immune checkpoint inhibitors. Based on the observation of alterations in the copy numbers of 9p24.1 and results of a small retrospective study, a multicenter clinical trial is in progress to investigate their activity in PCNSL and testicular cancer.[80]

HODGKIN LYMPHOMA: AN AIDS-DEFINING ILLNESS?

Epidemiology, Clinical Features, and Therapy

People infected with HIV have a 10-fold higher risk of developing HL than do HIV-seronegative persons. However, in contrast to KS and NHL, the risk is more pronounced in patients with HIV who only have moderate immunosuppression. In general, patients with HIV have a higher incidence of an unfavorable histology, including mixed cellularity and lymphocyte depletion subtypes of HL, when compared with that seen in patients without HIV infection. Instead of observing a decrease in HL in patients in the post-HAART era, as with certain NHL subtypes, investigators have noted an increase in the incidence of HL in patients with HIV.[81] This observation has made the relationship between immunodeficiency and HL uncertain. Despite the WHO inclusion as an AIDS-defining malignancy, HL is not considered by most experts as a true AIDS-associated disease. From the pathogenesis point of view, EBV is often associated with HIV-related HL, in the range of 80% to 100%. The Reed-Sternberg cells of HIV-related HL express the EBV-encoded LMP-1, known to have oncogenic properties.[82] However, despite this association, EBV virus biomarkers such as EBV DNA and antibodies have no prognostic value in patients with AIDS and HL treated with HAART.[83] Another recently described aspect of the pathogenesis of HL of great therapeutic importance is the 9p24.1 amplification in the Reed-Stenberg cell. The 9p24.1 amplicon is a recurrent genetic abnormality that increases PD-1 ligand expression. This amplicon also includes JAK-2 and Jak2/signal transducer and activator of transcription activity, which further increases PD-1 ligand transcription. Together with the known increased expression of PD-1 ligand as a result of the EBV infection, the PD-1 pathway is essential for HL survival and has become an important therapeutic target for immune checkpoint blockade in HL.[84] Also, in the post-HAART era, it has been postulated that an increase in CD4+ cells as a result of antiretroviral therapy fosters the development of the appropriate cellular milieu seen in HL in patients without HIV infection. These CD4+ cells, generated as a result of immune reconstitution by HAART, produce ligands for membrane receptors in the Reed-Sternberg cells that activate the classical NF-κB pathway.[81]

Clinically, patients with HIV and HL are young and usually have stage III or IV disease with B symptoms (fever, night sweats, and loss of >10% of body weight). Bone marrow involvement is frequent at the time of diagnosis.[85] In the pre-HAART era, the immunodeficiency of the patients limited the use of standard chemotherapeutic regimens in patients with HL. In the post-HAART era, the standards of care applicable to patients without HIV disease and HL have been applied successfully to patients with AIDS and HL once the HIV disease is controlled. Prior to HAART, Levine and colleagues in the AIDS Clinical Trial Group evaluated the efficacy of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) with G-CSF in 21 HIV-seropositive patients. There was an overall response rate of 62%, with 43% CR and 19% partial response. The median survival in this cohort was 1.5 years. Almost half the patients experienced grade 4 neutropenia, and 29% of patients developed opportunistic infections.[86] In this study, patients did not receive antiretroviral therapy while on treatment. After the introduction of HAART during treatment, investigators reported that ABVD induced a 91% complete remission rate and a median time to relapse of more than 36 months.[87] Other investigators used the Stanford V regimen, administering only short-term chemotherapy (12 weeks) with adjuvant radiotherapy. Of 59 patients who received this therapy, 69% completed the treatment without dose reduction or delays in the administration of the chemotherapy. Eighty-one percent of the patients achieved a complete remission, and with a median follow-up of 17 months, 33 (56%) of 59 patients were alive and free of disease.[88] After the introduction of HAART, the response rates for patients treated with ABVD or BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone) became essentially similar, irrespective of the patient's stage of the disease. However, more treatment-related mortality occurred in patients who received BEACOPP.[89] A more recent European study has confirmed that not only is ABVD as effective and less toxic, but that the overall survival is the same for both regimens.[90] Two new therapeutic interventions have significantly changed the landscape of the therapy of AIDS HL with ABVD. One is the addition of brentuximab vedotin, a chimeric

monoclonal antibody, conjugated to a toxin, monomethyl auristatin E, which selectively targets tumor cells expressing the CD30 antigen, typically expressed in HL and two, immune checkpoint blockade to which effects HL has exquisite sensitivity. It has now been demonstrated that both therapeutic interventions can be done in HIV patients with cancer without affecting the course of HIV infection and similar tolerance and effectivity as in non–HIV-infected patients with cancer.[91–93] The available data previously suggested that ABVD with HAART should be the initial treatment of choice for HIV-related HL. However, as demonstrated recently in the ECHELON-1 study, brentuximab vedotin combined with AVD (adriamycin, vinblastine, dacarbazine) is an option for patients with stage III–IV disease with no known neuropathy, if the IPI score is 4 or higher or bleomycin is contraindicated.[94] In a follow-up of 41 patients with HIV and stage II–IV HL, investigators reported 2-year progression-free survival and overall survival rates of 86% and 92%, respectively.[95] For patients with refractory disease, brentuximab vedotin alone or in combination with nivolumab[96] have become important choices in addition to usual regimens such as ICE or ESHAP. High-dose chemotherapy and autologous stem cell transplantation continue to be explored for patients who have disease progression while on treatment or relapse after remission induction. Thus, because of HAART, patients with HL and HIV disease can be treated with standard-of-care options that are similar to those used for non–HIV-infected patients with HL.

OTHER MALIGNANCIES AFFECTING HIV-INFECTED PATIENTS

Cervical Neoplasms

Epidemiology

In the early 1980s, reports appeared signaling an increased association between HIV infection and cervical intraepithelial neoplasia in HIV-infected women. It was not until 1993 that cervical cancer was officially added to WHO recommendations as an AIDS-related malignancy.[97] Women with HIV disease have a higher incidence of infection with multiple types of oncogenic HPV and a higher incidence of dysplastic changes of the cervix than women without HIV disease, events that can culminate in the development of cervical cancer (Table 52–7). There is no obvious association between the level of CD4+ cell count and cervical cancer, and the statistical correlations between the association of HIV and HPV-induced cervical cancer remains moderately strong at best. The decline observed for KS and PCNSL after HAART has not been seen in the incidence of HPV-related malignancies.

Table 52–7 Traditional Factors for Cervical Cancer Risk

History of more than six sexual partners
Cigarette smoking
Early age of first intercourse
History of sexually transmitted disease
Immunosuppression
Human papillomavirus

Data from Stier E. Cervical neoplasia and the HIV-infected patient, *Hematol Oncol Clin North Am* 2003 Jun;17(3):873-887.

Human papillomavirus infects the basal keratinocytes of the stratified epithelium, and its replication is coupled to the process of keratinocyte differentiation in the infected squamous epithelium. From an initial low-copy number in basal keratinocytes, there is a dramatic increase in the concentrations of proteins E1 and E2 by the time the keratinocytes differentiate and enter the stratum spinosum layer of the epithelium. In addition, for oncogenic strains of HPV such as 16, 18, and 31, there is also an increase in the expression of E6 and E7, which have a high oncogenic capacity manifested by the functional inactivation of p53 and R.[98,99] Regardless, this is a slow process, and it takes several years for an HPV-induced cervical lesion to transform into cancer. For these reasons, there is uncertainty regarding the relationship between HIV and cervical cancer as an AIDS-related malignancy.

Cervical Cytology and Screening

Papanicolaou tests in HIV-infected women have a high prevalence of cytologic abnormalities, ranging from 20% to 40%. Women with negative Pap smears will, over the course of 3 to 5 years, develop cytologic abnormalities at a higher rate than will HIV-negative women, and there is evidence of a higher rate of progression to cervical cancer after the longevity induced by HAART.[100] Therefore, it is imperative that patients with HIV infection be screened with Pap smears, colposcopy, and biopsy when needed for the early detection of cervical cancer. Pap smears interpreted as demonstrating "atypical squad-mouse cells" cannot exclude a high-grade squamous intraepithelial lesion (HGSIL) and must be evaluated with colposcopy (see Fig. 52–4). Current US Public Health Service and Infectious Diseases Society of America guidelines recommend Papanicolaou tests every 6 months during the first year after HIV diagnosis; if both tests are normal, annual screening is suggested (Fig. 52–6).[101]

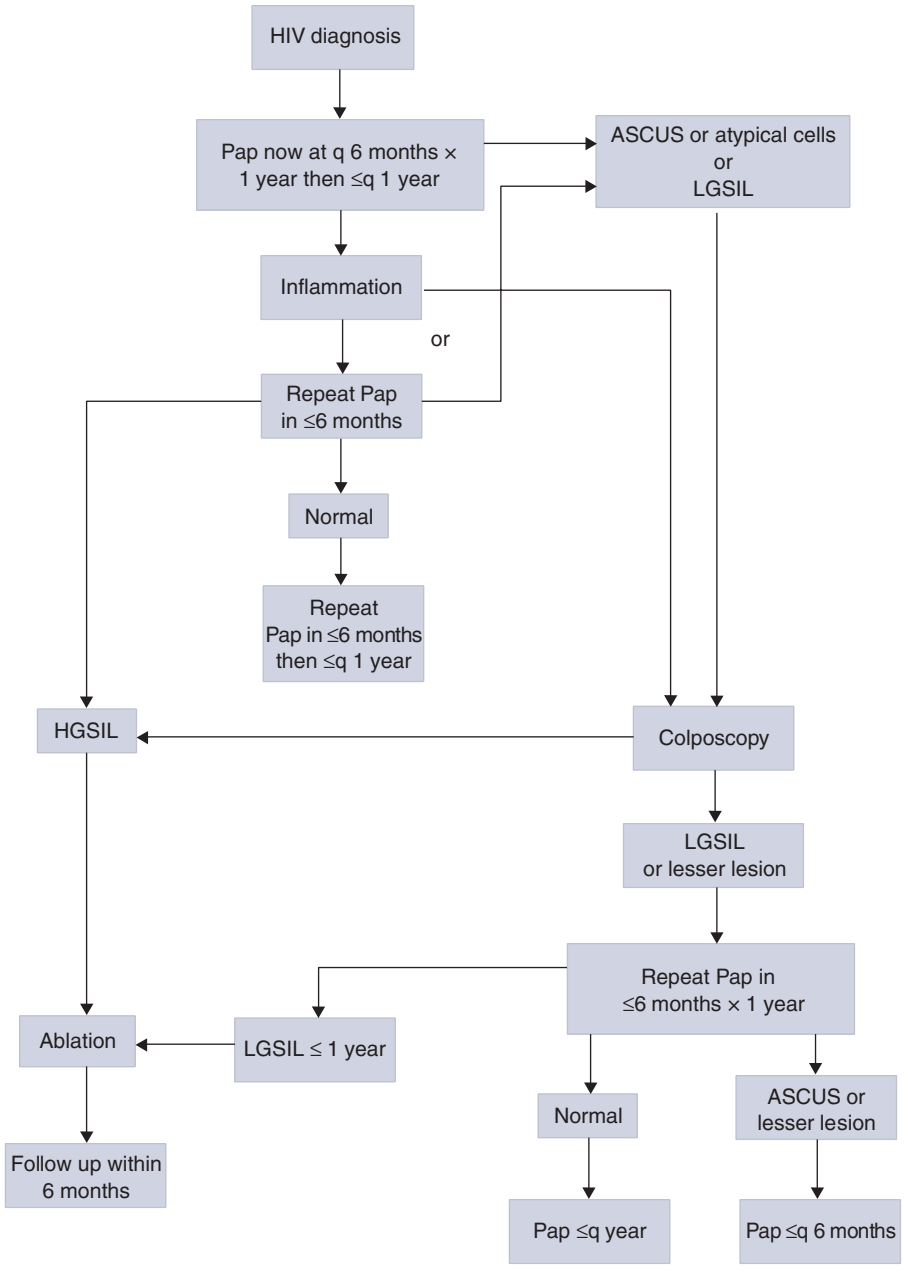

FIGURE 52–6 **Screening/treatment algorithm for cervical cancer. ASCUS, atypical squamous cells of undetermined significance; HGSIL, high-grade squamous intraepithelial lesion; LGSIL, low-grade squamous intraepithelial lesion; q, every.**

Despite controversies regarding the relationship between HIV, HPV, and cervical cancer, the increased incidence of infections by oncogenic HPV types in patients with HIV in contrast to non–HIV-infected women highlights the importance of mandatory cervical screening of HIV-infected women. However, recent studies have suggested that HIV-infected women are not being offered cervical screening, even though older women without HIV for whom the relevance of the screening may not be considered as important are routinely screened. Clearly, educational efforts are necessary as the number of HIV-infected women increases in the United States and elsewhere.

Treatment for Cervical Cancer

Because cervical intraepithelial neoplasia grade 1 lesions rarely progress and often go away on their own, the American Society for Colposcopy and Cervical Cytopathology recommends close observation

of them. However, treatment of invasive cervical cancer is the same as for HIV-seronegative women: surgery in early stages and a combination of surgery and chemoradiotherapy in intermediate stages. For cervical intraepithelial neoplasia grade 2, the preferred mode of treatment is the loop electrosurgical excision procedure. Cryotherapy and laser surgery can also be used, although these methods are usually reserved for larger lesions. Chemotherapy alone is used for more advanced cases, although the immune status of the patient can influence the response to treatment.[102]

One of the most important advances against HPV-induced cervical cancer has been the development of preventive HPV vaccines. The HPV vaccines made of viral-like particles display a remarkable structural and antigenic similitude to HPV virions and can induce the production of high titers of neutralizing antibodies.

Two versions of HPV viral-like particle vaccines are available for immunization of humans against HPV. Gardasil (Merck, Sharp, and Dohme) has viral-like particles of HPV subtypes 16 and 18 (oncogenic subtypes) and 6 and 11 (the causes of genital warts). Cervarix (GlaxoSmithKline) contains viral-like particles of HPV subtypes 16 and 18. They are both administered intramuscularly and have demonstrated almost 100% protection in clinical trials before their approval by the FDA. They should be used before the initiation of sexual activity, and neither have demonstrated therapeutic efficacy in the treatment of preexisting infections. Future work is aimed at increasing the immunogenicity of the viral-like particles and expanding the number of HPV oncogenic subtypes available for vaccination.[103]

Anorectal Carcinoma

Infection of the anogenital tract in men with oncogenic strains of HPV has the same consequence as it does in women. After HAART, the incidence of this disease has increased as patients live longer and the biological characteristics unique to the HPV oncogenic transformation are expressed over time (Table 52–8). The incidence of anal cancer has increased from 19.0 per 100,000 person-years in the pre-HAART era (1992–1995) to 48.3 persons per 100,000 person-years in the immediate post-HAART period (1996–1999) to 78.2 per 100,000 person-years more recently (2000–2003; $P < .001$).[104]

The same subtypes of HPV and pathogenic mechanisms involved in the oncogenic activity of HPV in women also apply to men. The screening and treatment of CIN 2 and 3 is of relevance in these patient populations. There has been a greater understanding of the need for anal screening of both men and women with HIV disease (Fig. 52–7).[99] The treatment of HGSILs includes the use of local therapies such as podophyllotoxin, liquid nitrogen, and laser surgery (Fig. 52–8). Investigators have recommended that men with HIV infection and anal HPV–related lesions undergo Papanicolaou tests every 6 months the first year after diagnosis and yearly thereafter. Invasive lesions are treated as in the general population, with the use of chemoradiotherapy followed by salvage surgery when there is no response or relapse after initial treatment.[105,106]

Other Malignancies

Patients with HIV can develop other malignancies not necessarily associated with HIV. For example, the incidence of lung cancer continues to increase in this population. In general, smoking is one of the most important negative factors predicting poor survival in patients with HIV, even in the presence of HAART. Patients with HIV often see malignant tumors develop at an earlier age and tend to have atypical presentations, and frequently their tumors follow a very aggressive course.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

In patients with advanced HIV disease (<100 CD4+ cells/μL of blood), the initiation of HAART can be accompanied by a paradoxical worsening of established infections or the appearance of new ones. This phenomenon is most frequent in patients who have tuberculosis or cryptococcal disease as their opportunistic infection but can happen with any other type of infection. This syndrome is known as immune reconstitution inflammatory syndrome (IRIS). The management of IRIS consists of the administration of specifically indicated therapies and a short course of steroids for 1 to 2 weeks with a rapid taper. The recommended dose of prednisone is 1 to 2 mg/kg per day. Antiretroviral therapy should only be interrupted

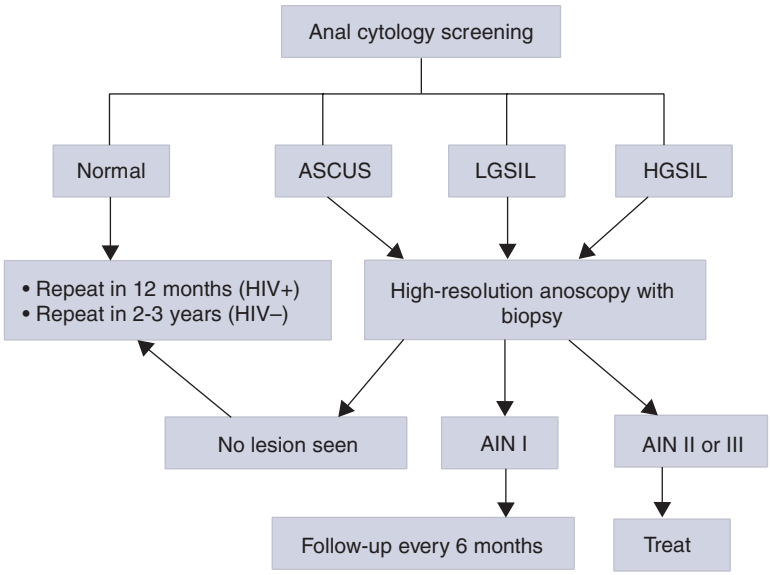

FIGURE 52–7 Protocol for screening anal intraepithelial neoplasia (AIN). ASCUS, atypical squamous cells of indeterminate significance; HGSIL, high-grade squamous intraepithelial lesion; HIV, human immunodeficiency virus; LGSIL, low-grade squamous intraepithelial lesion. (Reproduced with permission from Chin-Hong PV, Palefsky JM. Natural history and clinical management of anal human papillomavirus disease in men and women infected with human immunodeficiency virus, *Clin Infect Dis* 2002 Nov 1;35(9):1127-1134.)

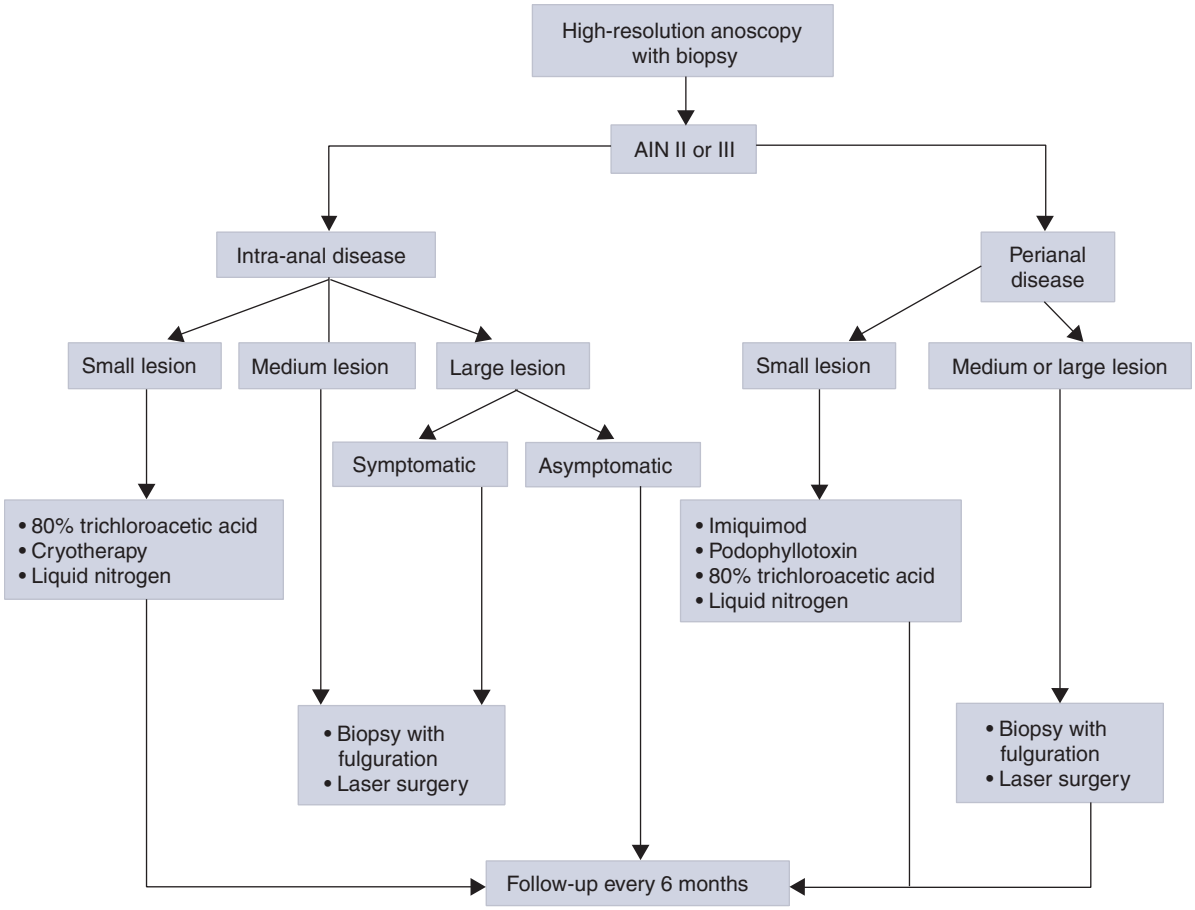

FIGURE 52–8 Treatment of anal intraepithelial neoplasia (AIN) II and III. Imiquimod and podophyllotoxin have not been approved by the FDA for this indication. (Reproduced with permission from Chin-Hong PV, Palefsky JM. Natural history and clinical management of anal human papillomavirus disease in men and women infected with human immunodeficiency virus, *Clin Infect Dis* 2002 Nov 1;35(9):1127-1134)

in severe cases because most patients respond to the use of steroid or antiinflammatory agents depending on the severity of the IRIS. Because the management of patients with AIDS-related malignancies involves a multidisciplinary team and, given the importance of the use of HAART in the management of patients with AIDS and malignancies, treating oncologists must be familiar with this condition to avoid unnecessary delays or interruptions in the HAART of their patients.[107]

MD ANDERSON CANCER CENTER AND THE AIDS PANDEMIC

When the AIDS pandemic began, Houston quickly became an AIDS epicenter, occupying the fourth place among cities with the highest number of AIDS cases in the United States for several years. The Department of Epidemiology, under the leadership of Peter W. Mansell and its Director, Guy Newell, took a leading role in studying methods for the prevention of AIDS and organizing public education efforts. Their work, together with the collaboration of R. Palmer Beasley, Dean of the University of Texas Health Science Center School of Public Health, the Department of Immunology and Biological Therapy, under the direction of Evan Hersh, and the collaboration of immunologists and virologists including James M. Reuben and Blaine F. Hollinger, was recognized with one of the first AIDS Treatment Evaluation Units Grants awarded for basic science and clinical research in AIDS. This work led to the creation of the Institute for Immunological Disorders under the direction of Peter W. Mansell and Adan Rios. Although the institute was ahead of its time, it opened doors for a humane treatment of patients with AIDS and the development of new therapies and strategies for research of the disease. This base of knowledge was instrumental in development of community strategies subsequently applied in the management and treatment of AIDS in the state of Texas. This effort extends to current times with the pioneering work done at the institution in the treatment of Burkitt lymphoma in patients with HIV by Drs Jorge Cortes, Debbie Thomas, and Houston AIDS community physicians using what is considered today a standard strategy for treatment of AIDS-related malignancies: the use of HAART in combination with the best-known strategy for the treatment of the malignancy.

CONCLUSIONS

The complexities of the AIDS pandemic are captured in the history of the AIDS-related malignancies (Table 52–9). The introduction of effective anti-HIV therapy or HAART in 1996 brought a profound change in the overall management of cancer in patients with HIV. One important predictor of good outcomes in the therapy of cancer and HIV is the administration of HAART.[108] The common goals for treatment of patients with AIDS and cancer are to treat HIV with HAART and the cancer with the same standards of care that exists for patients without HIV disease, along with vigorous prophylaxis of opportunistic infections, supportive therapy including growth factors, and appropriate nutritional and emotional support.

Table 52–9 AIDS-Associated Cancers[a]

Cancer Type	Observed Cases	Expected Cases	Relative Risk	Etiologic or Contributing Factors
Kaposi sarcoma				KSHV
Men	5583	57.3	97.5[b]	
Women	200	1.0	202.7[b]	
Non-Hodgkin lymphoma				EBV and KSHV
Men	2434	65	37.4	
Women	342	6.3	54.6	
Cervical, invasive				HPV
Women	133	14.7	9.1	
Hodgkin lymphoma				EBV

Table 52–9 AIDS-Associated Cancers[a] (*Cont.*)

Cancer Type	Observed Cases	Expected Cases	Relative Risk	Etiologic or Contributing Factors
Men	160	20	8	
Women	20	3.1	6.4	
Tongue				HPV and EBV
Men	17	9.3	1.8	
Women	5	0.7	7.1	
Rectal, rectosigmoidal, and anal				HPV (anal carcinoma)
Men	75	22.7	3.3	
Women	9	3.0	3.0	
Liver (primary only)				HCV,[c] HBV, alcohol
Men	36	7.1	5.1	
Tracheal, bronchial, and lung				Smoking[d]
Men	217	66.1	3.3	
Women	50	6.7	7.5	
Brain and CNS				EBV for CNS lymphoma
Men	42	13.4	3.1	
Women	7	2.0	3.4	
Skin, excluding Kaposi sarcoma				HPV[e] and ultraviolet light exposure
Men	133	6.4	20.8	
Women	8	1.1	7.5	
Melanoma, skin				
Men	24	17.3	1.4	
Testicular				
Men	38	25.6	1.5	
Colon				
Men	32	38.2	0.8	
Women	5	6.3	0.8	
Prostate				
Men	37	53.7	0.7	
Breast				
Women	47	59.9	0.8	
Ovarian				
Women	6	7.8	0.8	

[a]Data are based on the observed number of cases in HIV-positive individuals (men and women aged 15–69 years), expected cases based on the incidence in a nonimmunocompromised population in New York State (NYS), relative risk, and etiologic factors. Data from the AIDS/Cancer Matched Cohort NYS, 1981–1991.
[b]Relative risk for Kaposi sarcoma (KS) is lower than in other studies, probably because the background population in NYS is enriched with population groups (eg, Italian, Greek, and Jewish) that have an increased risk for classic KS.
[c]HCV contributes to increased incidence of liver cancer, particularly in HIV-infected men with hemophilia, and in intravenous drug users.
[d]The increase in lung cancer might be confounded by the fact that HIV-infected individuals have been reported to smoke more cigarettes per day than HIV-negative individuals.
[e]In Africa, HPV and ultraviolet light exposure have been implicated in the high incidence of conjunctival squamous carcinoma, and HPV is also implicated as the cause of skin cancers seen after an organ transplant. Misdiagnosis of KS might also contribute to increased risk of skin cancer.
CNS, central nervous system; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HPV, human papillomavirus; KSHV, Kaposi sarcoma–associated herpesvirus.

MD ANDERSON PRACTICE TIPS

- Every patient with newly diagnosed lymphoma should undergo a test for seropositivity for HIV 1/2. Patients also should undergo repeat testing at the time of relapse therapy. Viral loads and lymphocyte subset counts are tested before therapy if the antibody test is positive.
- If a patient with HIV seropositivity and newly diagnosed cancer is receiving HAART before initiation of therapy for the cancer, HAART should be continued throughout treatment. However, if liver function become abnormal during therapy, it may be necessary to temporarily discontinue HAART until the completion of treatment, at which time HAART may be restarted. For the patient who has not begun HAART at the time of therapy for the cancer, HAART may be delayed until the completion of therapy, depending on the type of treatment necessary and the lymphocyte counts.
- Most patients with advanced classical HL and HIV now have results with BV (A)-AVD that are as good as those reported for patients without HIV-seropositivity and is the recommended choice for those with advanced (stage III–IV) disease. Patients with limited disease (stage I–II) have positive results with therapy as do those without HIV disease.
- Patients with aggressive B-cell lymphomas should undergo EPOCH-R and CNS prophylaxis with methotrexate, with doses determined by the performance status of the patient and lymphocyte counts. Reduced doses may be necessary for those with low lymphocyte counts, with subsequent escalated dose adjustments determined by neutrophil and platelet nadirs. Patients achieving PET negativity after two cycles may only need two more cycles of therapy. Those with CNS disease or marrow disease require specialized therapy, as for patients without HIV disease.
- Patients with HIV seropositivity should undergo annual HPV cervical and anal testing for the virus by PCR. Other screening tests should be administered as for patients without HIV disease.
- For patients with AIDS-KS with minimal tumor burden, HAART initiation constitutes frontline therapy of their AIDS-related KS. This approach can control these lesions for long periods of time, often more than one year, and in many instances results in complete disappearance of KS lesions. Patients with extensive disease or visceral involvement can receive specific systemic KS therapies in addition to HAART.

53 Carcinoma of Unknown Primary

Gauri R. Varadhachary
Kanwal P. Raghav
Ryan W. Huey

KEY CONCEPTS

- Carcinoma of unknown primary (CUP) is defined as biopsy-proven metastatic cancer where a primary site is unidentifiable after adequate workup.
- CUP is a rare tumor with an incidence of less than 10 per 100,000 individuals and constitutes nearly 2% of all cancers diagnosed in the United States.
- Favorable and specific clinicopathologic subsets in CUP should be identified and treated with selective and aggressive treatments.
- Limited data support the use and therapeutic impact of molecular profiling assays for tissue of origin (ToO) determination in CUP.
- Chemotherapy for patients with CUP can be either empiric or site-specific (guided by putative primary site determined by clinicopathologic factors), and novel effective therapies for known primaries may impact the treatment decision.
- Overall prognosis in CUP is poor, but a great degree of heterogeneity based on patient and disease characteristics exists.

OVERVIEW

Carcinomas of unknown primary (CUPs), with their heterogeneous presentations, pose a challenge diagnostically and therapeutically. Depending on the extent of evaluation, CUP comprises about 2% of all malignancies.[1–3] A working definition for CUP is biopsy-proven metastatic cancer with no identifiable primary source by history; physical examination; chest radiography; complete blood cell count; chemistry; computed tomography (CT) of the chest, abdomen, and pelvis; prostate-specific antigen (PSA) in men; and mammography in women.[2] The natural history of disease for CUP is diverse and is dependent on multiple variables, such as, age, number of metastatic sites, dominant area of disease, and histology. This considerable heterogeneity presents a challenge to the systematic study of CUPs. In addition, the emergence of sophisticated imaging, robust immunohistochemistry (IHC), and genomic and proteomic tools have challenged the "unknown" designation. Depending on histologic features, sites of disease, and performance status, a small but significant minority of patients will be long-term survivors, and it is important to identify these groups of patients.[4,5]

This chapter discusses the evaluation of patients with CUP and optimal therapeutic strategies in the era of sophisticated diagnostics. The differing natural histories in CUP, depending on both the sites of disease and histology, are also discussed. Studies showed that in this population a search for the primary tumor beyond "routine" evaluation is unrewarding in the majority of patients.[5] This fact has caused much consternation for both patients and physicians. The foundation for cancer treatment traditionally relies on identification of the tumor origin, thereby allowing treatment to be chosen based on the known natural history, as well as specific therapies, that have proven to be effective for the cancer; this is becoming even more important with the rapid emergence of targeted therapies. Without knowledge of the primary site, the oncologist is often hesitant to recommend therapy, especially given the disease heterogeneity. Although most patients with metastatic CUP have tumors that respond poorly to current treatments and will consequently have a poor prognosis, it has become evident over the last two decades that subsets of patients with CUP have a favorable prognosis and respond to chemotherapy or can be treated successfully with regional

therapy alone. The current era of sophisticated diagnostics and introduction of targeted therapies has been particularly important in the CUP setting; this cancer entity is the epitome of personalized therapy.

EPIDEMIOLOGY

The incidence of CUP cancers as estimated from the cancer registries and databases of "unknown and unspecified cancers" is reported to be approximately 2% of all cancers.[6] This is probably an overestimation because this group includes a mix of patients: those with true CUP, those with primaries not yet diagnosed at the time of death, and those with difficult-to-diagnose tumors. Further, improved imaging allowing identification of small primary tumors suggests that the incidence of true CUP is decreasing.

A minority of patients (10%) with CUP have a history of an antecedent cancer. In autopsies performed before the advent of CT, the occult primary tumor was identified in 60% to 80% of cases. In one autopsy series, the two most commonly identified primary sites were the pancreas (20%) and lungs (18%).[7,8] Given the current high-quality CT imaging and positron emission tomographic (PET) scans, it is unclear whether these cancer profiles are still the majority.

The classification of CUP continues to evolve. The last four decades have seen a shift in our understanding of CUP. First, improved imaging increased our confidence for the entity termed *occult primary*. Later, "favorable" CUP subsets were determined, based primarily on histopathology, the pattern of spread of select types of CUP, and serum markers. Subsequently, with the advent of novel IHC markers and advances in diagnostic pathology, tissue of origin (ToO) profiles were described that assigned additional putative primary sites to CUP cancers based on IHC patterns. Current research involves the application of proteomic and genomic tools to CUP cancers.

BIOLOGY, CHROMOSOMAL ABERRATIONS, AND MUTATIONAL PROFILING

CUPs, despite their heterogeneity, are a clinically unique oncologic entity; as such, they share many common features that set them apart from other malignancies. The central unifying clinical feature of CUP is the absence of a detectable primary tumor. Previous studies have shown that, even after an autopsy, the primary site will not be identified in 20% to 40% of cases; that number is likely much lower with significant improvements in imaging. It is not known why primary carcinomas exhibit this unique biological behavior. One current hypothesis is that the acquisition of a "metastatic phenotype" is an early event in CUPs, soon after oncogenesis, thus enabling cells to metastasize early, before the development of a clinically detectable tumor.[9] It has also been hypothesized that the primary tumors may regress or involute before the metastases become clinically evident, attributed to a host immunologic response. A third hypothesis is that the primary tumor is exposed to antiangiogenic factors locally, whereas the metastases acquire the angiogenic phenotype after a period of dormancy.[10]

Several studies have demonstrated a specific nonrandom pattern of chromosomal aberrations that seems to be unique to CUPs. These data suggest that some of these genetic changes may be the underlying cause of the metastatic phenotype. CUP is characterized by greater genetic instability, with massive genomic alterations, when compared with other distant metastases. In a study by Pantou and colleagues,[11] cytogenetic profiling of tumors from 20 patients with CUP was performed, revealing an average of 11 chromosomal changes per case. Of the three histologic subtypes in this study, adenocarcinomas had not only the highest number of cytogenetic changes (16 vs 3) but also involvement of distinct sites (4q31, 6q15, 10q25, and 13q22) when compared with carcinomas or undifferentiated malignancies. The latter group was distinguished by the involvement of changes at 11q22. Overall, the most commonly rearranged chromosomal regions were 1q21, 3p13, 6q21–23, 7q22, 11p12–5, and 11q14–24. The number of cytogenetic alterations was found to be prognostically relevant. Median survival was significantly greater for patients with five or fewer cytogenetic changes compared with those with more than five changes (3 vs 18 months; $P = .003$). An older study of 12 CUP cell lines also demonstrated a preponderance of chromosome 1 abnormalities. These changes were observed on both the long arm (eg, 1p deletion, isochromosome 1p, and translocations with a 1p breakpoint) and on the short arm (1q21), suggesting the importance of chromosome 1 in the biology of CUPs.[12] Chromosome 1p aberrations are also commonly associated with advanced malignancies.

Chromosome 12 abnormalities have also been shown in CUP. This is of particular interest because one of the observed alterations, isochromosome 12p (i12p), is present in as many as 80% of germ cell tumors. Motzer and colleagues reported that 30% of patient tumors in their series had either i12p or 12q deletions. The presence of either of these two cytogenetic abnormalities was found to be predictive of a complete response to cisplatin-based chemotherapy (75% vs 17%; $P = .002$).[13,14] In the current era of

sophisticated IHC, we rarely miss a patient with an extragonadal presentation and seldom order cytogenetics to inform therapeutic plans.

The tumor suppressor gene *p53* is commonly mutated in human cancers, especially in advanced malignancies. Paradoxically, this does not seem to be true in CUP. Bar-Eli and colleagues found *p53* mutations to be less frequent than expected (26%) in CUP after evaluating 15 biopsy specimens and eight cell lines.[15] However, work by other researchers evaluating IHC studies of *p53* in CUP has found this protein to be highly expressed in 70% of the tumors examined.[16,17] Nevertheless, *p53* expression has not been found to have prognostic relevance. Molecular studies have also demonstrated the overexpression of other oncogenes, such as c-*myc*, *ras*, *bcl-2*, and *Her2/neu*, in CUPs, but none have been found to have any correlation with either survival or response to chemotherapy.[18]

NATURAL HISTORY AND CLINICAL PRESENTATION

The clinical course of patients with CUP varies widely. Median survival in large retrospective studies has ranged from 11 weeks to 11 months. In a study from the MDACC, the 5-year overall survival (OS) rate was only 11%. Although survival is poor as a whole, there are certain prognostic variables that correlate with longer survival, including disease limited to one organ site, involvement of lymph nodes only, and histologic diagnosis of squamous or neuroendocrine carcinoma. Variables suggestive of a poor prognosis include male sex, histologic diagnosis of adenocarcinoma, and metastatic involvement of the liver, lungs, bone, pleura, or brain (Table 53–1).[4]

Table 53–1 Favorable Versus Poor Prognosis Carcinoma of Unknown Primary

Favorable Prognosis	Poor Prognosis
Extragonadal germ cell syndrome	Liver metastases (non-neuroendocrine)
Isolated single small metastasis	Pleural or lung metastases
Papillary peritoneal adenocarcinoma (women)	Adrenal metastases
Isolated axillary adenocarcinoma (women)	Multiple brain metastases
Cervical adenopathy (squamous cell)	
Isolated inguinal adenopathy	
Neuroendocrine histology	

By performing multivariate analyses on a consecutive series of 1000 patients with CUP with classification and regression tree (CART) analysis, Hess and colleagues[4] were able to more closely study the interactions between different clinical variables and how this influenced survival.

Patients with CUP present with symptoms and signs similar to those of patients with advanced malignancies of known origin. In one review, the most common symptoms at presentation of CUP were general deterioration (73%), digestive symptoms (58%), liver enlargement (58%), abdominal pain (56%), respiratory symptoms (45%), ascites (26%), and node enlargement (16%).[19] Most patients with CUP present with multiple metastases, with three or more organs involved. In patients with a dominant (or single) site of metastasis, the most common reported sites were liver (25%), bone (22%), lungs (20%), lymph nodes (15%), pleural space (10%), and brain (5%).

DIAGNOSTIC EVALUATION

In the past, minimalist diagnostic strategies had been advocated, limiting the scope of initial evaluations to differentiate only between treatable and untreatable disease. Others have supported a more aggressive approach, wherein a complete assessment of the extent of the disease and detection of the primary tumor site are attempted. In our experience, a more pragmatic approach is better. Extensive evaluation of all patients presenting with metastases is an expensive and wasteful extreme that does not benefit patients. In one study, the average cost of evaluating a patient with CUP was $17,973 and much higher with recent testing.[20,21] In that study, mean survival was 8.1 months, representative of the natural history of CUP, with only 18% of patients surviving one year. However, a strictly minimalist approach may result in the oversight of treatable and potentially curable neoplasms.

An important determinant of the appropriate extent of evaluation for any patient with CUP is whether the data obtained by a diagnostic test will influence treatment decisions. If a treatable or potentially curable cancer is strongly suspected (eg, a germ cell tumor or lymphoma or oligometastatic disease treated with surgery or multimodality therapy), further investigation should proceed until a precise clinical diagnosis can be made, provided that therapy is not unreasonably delayed. The recommended general approach at the present time is thus one of a directed evaluation based on clinical presentation and pathologic findings; predictions of tumor origin or mutations from molecular profiling techniques may also play a role in streamlining the scope of evaluation.

Physical Examination and Laboratory Tests

A thorough medical history and physical examination, including a digital prostate examination in men and a breast and pelvic examination in women, should be performed. Determination of the patient's performance status, nutrition, and the presence or absence of concomitant medical illnesses and malignancy-related complications (eg, paraneoplastic syndromes or painful metastases) that may affect patient care is required.

Laboratory tests should include routine biochemical and hematologic surveys. The role of tumor markers in the evaluation of patients with CUP is often not diagnostic. Most tumor markers are nonspecific and are not useful for identifying a primary site or for prognostic purposes. Adenocarcinoma markers (eg, carcinoembryonic antigen, cancer antigen [CA] 125, CA 15-3, and CA 19-9) are often elevated in patients with CUP and cannot be reliably used to identify a specific primary site or to predict either OS or the exact burden of metastatic disease.[22–24] Serum tumor markers may play a role in helping to evaluate patients for responses to therapy, although levels are not always predictive of response to chemotherapy.

Their selective use in a directed approach is more helpful than ordering a large battery of tumor markers on all patients who present with CUP. Men who present with metastatic adenocarcinoma and CUP with osteoblastic bone metastases should have PSA and prostatic acid phosphatase levels measured. In all men with undifferentiated (or poorly differentiated) midline carcinomas, β-human chorionic gonadotropin and α-fetoprotein levels should be measured, especially if the clinical presentation suggests an extragonadal germ cell tumor. In patients with hepatic tumors, α-fetoprotein levels should also be measured if there are risk factors or pathologic characteristics that suggest the possibility of primary hepatocellular carcinoma.

Diagnostic Imaging and Invasive Studies

In the absence of contraindications, a baseline intravenous contrast CT scan of the chest, abdomen, and pelvis is the standard of care, as supported by the National Comprehensive Cancer Network and National Institute for Health and Clinical Excellence (NICE) CUP radiology guidelines.[25–27] Patients with CUP should then be approached in a "directed" fashion. Endoscopy of the upper and lower gastrointestinal (GI) tract is indicated for patients with abdominal complaints, ascites, liver metastases, or other findings in the initial workup and pathology that are indicative of a possible GI primary tumor.

All women with CUP and adenocarcinoma should undergo mammography. In cases of suspicious findings on a breast examination and negative mammography findings, patients should have breast sonography and a biopsy as indicated. Because both the sensitivity (23%–29%) and specificity (71%–73%) of mammography in detecting an occult carcinoma are low, breast magnetic resonance imaging (MRI) has been evaluated as an alternative in patients with a high suspicion for breast primary cancer. In the setting of isolated axillary adenopathy, MRI is sensitive in detecting occult primary breast cancers (>75%) and should be performed in women with isolated axillary adenopathy and negative mammography findings.[28–33] Women with adenocarcinoma presenting with metastatic sites other than cervical or axillary adenopathy that are compatible with breast cancer (ie, bone, liver, or lungs) may also undergo breast MRI if the mammography findings are negative.[32,33]

Patients with upper or midcervical adenopathy with a squamous cell carcinoma on pathology should undergo a thorough head and neck evaluation, including panendoscopy (ie, laryngoscopy, bronchoscopy, and esophagoscopy) with random biopsies. Ipsilateral or (more often) bilateral tonsillectomy has also been recommended as part of the staging process because this has been shown to identify an occult primary lesion deep in the tonsillar crypts in up to 30% of patients with this presentation of CUP.[34–36] CT of the head and neck region is routinely done as part of the initial workup. In addition, the utility of 18-fluorodeoxyglucose positron emission tomography (FDG-PET) has been well documented in patients with squamous carcinoma and cervical adenopathy; small prospective and retrospective studies suggest that a primary head and neck tumor is identified in 25% to 30% of these patients.[36–42] A retrospective review found that the primary tumor site was identified in 44% of these patients undergoing PET-CT fusion scans, and this modality appears to be emerging as a superior alternative to either PET or CT alone.[38,39]

Outside the indication given previously, the role of PET-CT is unclear. Several small studies have evaluated the utility of PET in patients with CUP.[43,44] Moller et al reviewed ^{18}FDG-PET as a diagnostic tool for patients with extracervical CUP.[44] They identified four publications (152 patients); these studies were retrospective and heterogeneous in their inclusion criteria, study design, and diagnostic workup before FDG PET–CT. The primary tumor was detected by FDG PET–CT in 39% of patients with extracervical CUP. Lung was the most commonly detected primary tumor site (≈50%). Pooled estimates of sensitivity, specificity, and accuracy of FDG PET–CT in the detection of the primary tumor site were 87%, 88%, and 87.5%, respectively. They concluded that FDG PET–CT may have a role in identification of the primary tumor in extracervical CUP; however, prospective studies with more uniform inclusion criteria are warranted. Although not studied

prospectively, PET-CT scans may be useful in selected patients with solitary metastases before definitive locoregional therapies and in follow-up of patients with predominant bone disease.[2]

Histopathologic Evaluation

All pathologic material obtained at biopsy from a patient with CUP should be evaluated by an experienced pathologist familiar with CUP workup. The pathologist should also be informed of the patient's pertinent history and clinical findings so that he or she can recommend further analysis on the basis of this information. In the realm of CUP, pathology trumps radiology. Collaboration between the pathologist and treating oncologist is critical. Adequate tissue sampling is essential.

The CUP cancers include adenocarcinoma, poorly differentiated adenocarcinoma (60%); poorly differentiated carcinoma (PDC), undifferentiated carcinoma, or undifferentiated neoplasm (30%); squamous cell carcinoma (5%); and neuroendocrine cancer (2%). Rarely (2%), CUP can present as mixed tumors, including sarcomatoid, basaloid, and adenosquamous carcinomas (Table 53–2).

Adequacy of tissue is essential, especially when the pathologist has to make a diagnosis from deep fine-needle aspirations and there is insufficient tissue for IHC staining. The diagnosis of a poorly differentiated neoplasm implies that the pathologist is unable to classify it into any of the general neoplastic categories (carcinoma, lymphoma, melanoma, or sarcoma).

Table 53–2 Major Histologic Findings in Carcinoma of Unknown Primary

Histology	Proportion (%)
Well to moderately differentiated adenocarcinoma	55
Poorly differentiated adenocarcinoma	30
Squamous	6
Neuroendocrine	4
Undifferentiated malignancy	5

Subsequent evaluation of this group of poorly differentiated lesions by means of special IHC techniques is warranted because some of these patients will have tumors that are potentially curable and very responsive to treatment. Many IHC reagents are at the disposal of the pathologist, making the histologic classification of the tumor easier (Table 53–3).

Especially useful are the antibodies to common leukocyte antigens present in lymphoma and the antibodies to PSA present in most prostate cancers. Other useful IHC markers include cytokeratin CK7, CK20, and thyroid transcription factor (TTF-1). Thyroid transcription factor is a nuclear transcription factor that is normally expressed in lung and thyroid tissues and in their neoplasms. Staining positive for TTF-1 is frequent in lung cancer, especially in adenocarcinomas

Table 53–3 Commonly Utilized Immunoperoxidase Stains to Assist in the Differential Diagnosis of Poorly Differentiated Neoplasms

Stain	Likely Primary Site
Estrogen/progesterone receptor, gross cystic disease fluid protein-15, low molecular weight cytokeratin	Breast cancer
Thyroid transcription factor, CK7, CK20, surfactant protein A precursor	Lung cancer
Prostate-specific antigen, epithelial membrane antigen, alpha-methylacyl coenzyme A racemase/P504S	Prostate cancer
Leukocyte common antigen, CD3, CD4, CD5, CD20, CD45	Lymphoma
Vimentin, desmin,[a] factor VIII[b]	Sarcoma
Chromogranin/synaptophysin, neuron-specific enolase, cytokeratin	Neuroendocrine tumor
Epithelial membrane antigen, β-human chorionic gonadotrophin, α-fetoprotein, placental alkaline phosphatase	Germ cell tumor
CK7, CK20,[c] uroplakin III	Urothelial malignancies
S100, vimentin, human melanomablack-45, neuron-specific enolase	Melanoma
CK7, CK20,[c] caudal type homeobox-2, carcinoembryonic antigen	Colorectal cancer

[a]Positive in desmoid tumors, rhabdomyosarcomas, and leiomyosarcomas.
[b]Positive in angiosarcomas.
[c]Whereas a $CK7^{+}/CK20^{-}$ staining pattern is typical of lung neoplasms, $CK7^{-}/CK20^{+}$ is suggestive of a colorectal primary. Dual $CK7^{+/}CK20^{+}$, however, is suggestive of urothelial primary.

(60%–75%) and small cell lung cancers (66%–87%); however, it is inconsistently expressed in squamous cell carcinoma. Among the various monoclonal antibodies against various cytokeratins, CK7 and CK20 can help differentiate between different solid tumors. (For instance, CK7 is more commonly associated with pulmonary or gynecologic malignancies, whereas CK20 is frequently seen in GI adenocarcinomas.) The $CK7^{+}/CK20^{-}$ immunophenotype, in conjunction with TTF-1 staining, is suggestive of a lung primary and is a highly sensitive and specific method for differentiating primary pulmonary adenocarcinomas from metastatic extrapulmonary adenocarcinomas (Fig. 53–1).[45–49] In contrast, the $CK7^{-}/CK20^{+}$ immunophenotype is suggestive of a colorectal primary site. $CK7^{+}$ and $CK20^{+}$ dual staining suggests a malignancy of urothelial or pancreaticobiliary origin. Using light microscopy and IHC, a putative primary tumor may be assigned in up to one-third of CUP cases. Immunohistochemistry can also suggest biomarker studies with potential therapeutic impact (eg, *Kras*, epidermal growth factor receptor, Her2, and anaplastic lymphoma kinase mutations).

Hep par 1 is an antigen whose expression is confined to benign and malignant hepatocytes and aids in the diagnosis of hepatocellular carcinoma in patients with CUP presenting with liver lesions. In women, depending on the pathology and pattern of metastasis, estrogen receptor and progesterone receptor staining is done to look for a breast primary. Another marker for a breast primary is gross cystic disease fluid protein 15, which is present in 62% to 72% of breast cancers.

Dennis and colleagues[50] have identified other novel molecular markers using a bioinformatics approach. All publicly available gene expression data from various adenocarcinomas were pooled together, and four novel proteins not previously recognized as tumor markers were found to be significantly upregulated. This was confirmed by reverse transcription–polymerase chain reaction. One example was lipophilin B, which was found to be restricted to breast, ovarian, and prostate cancers.

The use of cytogenetic analysis in the diagnosis of CUPs is limited. Specific chromosomal abnormalities have been identified in several types of lymphoma (8;14 translocation in small non–cleaved-cell non-Hodgkin lymphoma), germ cell tumors (i12p), and Ewing sarcoma (t11;22 or t21;22). In the cytogenetic study by Pantou et al,[11] lymphoma was diagnosed in four patients with CUP on the basis of the presence of immunoglobulin (Ig) H/Alk-1 rearrangement, which was identified by fluorescence in situ hybridization. In addition, one patient was diagnosed with Ewing sarcoma owing to detection of characteristic rearrangement of chromosomes 11 and 22. In the era of novel and sophisticated IHC, cytogenetics is rarely ordered to help with therapy decisions. Most useful are patterns and groups of IHC used in an effective algorithm that can prove to be clinically appropriate and cost-effective, although the approach to this is not uniform in the community.[51,52]

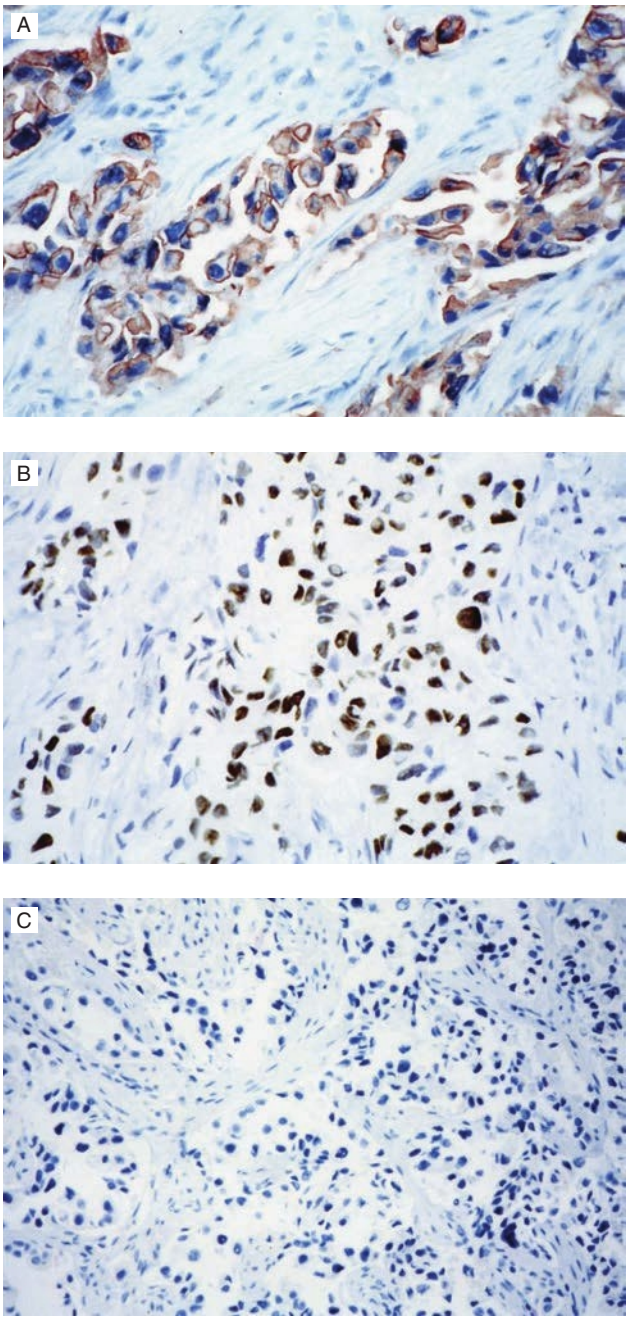

FIGURE 53–1 Immunohistochemical stains performed on the biopsy specimen from a patient with primary metastatic adenocarcinoma to a supraclavicular lymph node. Immunoperoxidase stains were positive for CK-7 (A) and TTF-1 (B) but negative for CK-20 (C), thus suggestive of metastatic non–small cell lung cancer. (Used with permission from Dr. Nelson Ordoñez, Department of Pathology, MDACC.)

Tissue of Origin Studies of Carcinomas of Unknown Primary

ToO molecular profiling using DNA microarray and reverse transcription–polymerase chain reaction is a promising technique to establish the putative primary diagnosis in patients with CUP.[53,54] The performance of these assays in known cancers has been validated using independent blinded sets of tumor samples, with an accuracy of approximately 90%.[55–57] The feasibility of using formalin-fixed small biopsy or fine-needle aspiration samples makes this practical for use in the clinic setting.

Messenger RNA- or microRNA-based ToO assays have been studied in prospective and retrospective CUP trials. Recently, a genome-derived algorithm has used artificial intelligence to predict ToO, taking into account multiple molecular features of a tumor. In CUP, these assays and algorithms suggest a specific primary tumor in about 70% of patients studied.[58–65] Because by definition the primary tumor site is not known in CUP, validation of site prediction in CUP remains a challenge. Results from multiple small studies suggest that ToO predictions are likely accurate. Indicators include (1) concordant results of ToO testing and the appearance of a latent primary during the course of the patient's illness (or many years later); (2) strong correlation between ToO assay results and diagnostic IHC (both suggesting a single putative primary); and (3) a prospective study demonstrating that patients treated with ToO-based site-directed therapy had survival similar to those with the corresponding known primary.[66]

In the United States, there are currently three commercially available Medicare-approved tests. They differ in the platform used, the number of potential cancers identified, the size and histologic samples of the training set, and the reporting format. All three assays report on identifying a putative primary in about 75% to 85% of patients with CUP. No comparative studies have been conducted, although in our personal experience, when IHC is diagnostic, all three tests usually produce similar results.

A prospective, single-arm study evaluated the role of the 92-gene assay to predict the ToO and assay-directed site-specific therapy in patients with CUP.[66] The authors concluded that the median OS of 12.5 months (95% CI 9.1–15.4) for patients who received assay-directed site-specific therapy compares favorably with previous studies using empiric therapy. Biliary and urothelial profiles were 33% of the predictions. Unfortunately, firm conclusions of therapeutic impact cannot be drawn from this study given the nonrandomized design, statistical biases, confounding variables such as use of subsequent lines of (empiric) therapy, and the heterogeneity of the CUP cancers.

Two prospectively defined blinded studies of difficult-to-diagnose primary cancers (several poorly differentiated) have reported on the diagnostic accuracy of ToO molecular profiling over IHC. Samples were evaluated by IHC/morphology analysis or the ToO molecular profiling test.[67] Accuracy was defined based on comparison with pathology of known primary. In one, the assay demonstrated overall accuracy of 79% for tumor classification versus 69% for IHC/morphology analysis ($P = .019$). Mean IHC use was 7.9 stains per case (range 2–15). The other study also confirmed similar findings[68]; the assay accurately identified 89% of specimens compared with 83% accuracy using IHC ($P = .013$). In the subset of poorly differentiated and undifferentiated carcinomas, assay accuracy exceeded that of IHC (91%–71%; $P = .023$). These results have important implications for management of CUP cancers and warrant a study of an integrated algorithm evaluating ToO molecular profiling complementing IHC in select patients.

Multiple clinical trials have been designed to evaluate the therapeutic impact of ToO molecular profiling assays, including one that has been reported, detailed below, and others that are ongoing. These data and other creative trial designs are urgently needed to study CUP subsets and the impact of these assays on survival and quality of life in patients with CUP.

Next-Generation Sequencing in Carcinomas of Unknown Primary

As our molecular understanding of cancer improves, more therapies are being used to target specific molecular features of a cancer rather than the ToO. Next-generation sequencing has emerged as a diagnostic tool to discover these molecular features, which likely have therapeutic implications for patients with CUP. Ross and colleagues retrospectively studied 200 consecutive CUP tumor specimens that underwent comprehensive genomic profiling using the hybrid-capture–based FoundationOne assay.[69] The DNA extracted from these CUP tumor specimens was analyzed after hybridization capture of 3769 exons from 236 cancer-related genes and 47 introns of 19 genes commonly rearranged in cancer. There were 125 adenocarcinomas of unknown primary site (ACUPs) and 75 non-adenocarcinomas (non-ACUPs). The authors reported that a large number of CUP samples (85%) harbored at least one clinically relevant genomic alteration with the potential to influence and personalize therapy. The mean number of genomic alterations was 4.2 per tumor. The ACUP tumors were more frequently driven by genomic alterations in the receptor tyrosine kinase/Ras/mitogen-activated protein kinase signaling pathway than non-ACUP tumors. The authors concluded that comprehensive genomic profiling can

identify novel treatment paradigms and suggested that early testing may have utility in CUP management.

As diagnostic approaches and the design of clinical trials evolve, molecular pathways have emerged as treatment targets regardless of the ToO. Both the mismatch repair pathway and TRK fusions have been studied across multiple tumor types.[70,71] Given the therapeutic implications, these should be considered for testing in patients with CUP as part of a broad molecular analysis.

Liquid Biopsies in Carcinomas of Unknown Primary

Since the discovery of fragments of tumor-derived DNA shed into the bloodstream, there has been considerable interest in liquid biopsies in the role of cancer diagnostics and treatment.[72] Advances in DNA analysis have allowed for the genotyping of circulating tumor DNA (ctDNA), which has been used for mutational detection in some cancers, such as epidermal growth factor receptor mutations in non–small cell lung cancer.[73] Liquid biopsies have the benefit of being less invasive than a tumor biopsy, making the collection of serial samples much easier for the patient. Another benefit is the potential to overcome tumor heterogeneity and molecular differences in primary versus metastatic tumors. In CUP, the role of liquid biopsies has been examined by a group studying up to 70 genes using next-generation sequencing of ctDNA.[74] Of 442 patients studied, 66% had one or more characterized alteration, most commonly TP53. This work highlights the feasibility for ctDNA and its potential for future utility. However, one limitation of liquid biopsies is determining the biological significance of each mutation, because many can be found in healthy individuals. Further work is needed to delineate these differences.

MANAGEMENT OF SPECIFIC CLINICOPATHOLOGIC SUBGROUPS

Carcinomas of Unknown Primary Presenting as Isolated Brain Metastases

In as much as 15% of patients presenting with brain metastases, the primary site remains unknown.[75,76] The important factor in treating patients with brain lesions is to distinguish patients with metastatic disease from those with primary brain tumors. Once this distinction has been made, patients with single metastatic lesions should be considered for surgery, and those with multiple lesions should receive radiotherapy. In a recent small prospective study, patients with CUP who had single brain metastases treated with gross total resection and subsequent whole-brain radiotherapy (WBRT) had a median survival of 13 months. Patients with CUP who had multiple brain metastases and who underwent either WBRT alone or gross resection of symptomatic lesions followed by adjuvant WBRT had a median survival of only 6 to 8 months.[76] Stereotactic brain radiation is often used in the CUP setting using the same principles as for brain metastases from known primary cancers.

Carcinomas of Unknown Primary Presenting as Metastatic Cervical Adenopathy

In this subgroup, patients present with high- to midcervical or -supraclavicular adenopathy; on histopathologic analysis, these tumors are squamous cell or PDCs. For squamous cell carcinoma, the primary site is eventually identified during follow-up in approximately 20% of patients, with the tonsil being the most common site, followed by the pyriform sinus and base of the tongue.

Adenocarcinoma is much less common and generally derives from either metastatic nonpapillary thyroid carcinoma or advanced malignant disease from a distant site (GI tract, lung, or breast carcinoma presenting as a metastatic supraclavicular node). Of all malignancies of the head and neck, only 5% to 10% are classified as unknown primary after imaging and panendoscopy. The prognosis for patients with cervical CUP overall is better than that for other CUP clinical subgroups, but even within this group, significant heterogeneity exists. Yalin et al,[77] in a retrospective study of 107 patients with cervical CUP (62% PDC, 24% squamous carcinoma, and 14% adenocarcinoma), reported a 5-year OS rate of 35.5%. In another retrospective study by Issing et al,[78] 5- and 10-year OS rates were 42.7% and 30.6%, respectively. The prognosis is significantly worse in the presence of any of the following: adenocarcinoma, level III/IV lymphadenopathy, multiple lymph nodes, and bulky disease.

Patients with supraclavicular adenopathy have a far worse prognosis than those with adenopathy in other lymph node–bearing areas. Carcinoma affecting supraclavicular lymph nodes on the right most commonly arises from occult primary tumors of the lungs and breast. When disease affects the lymph nodes on the left side, spread from intra-abdominal malignancies by way of the thoracic duct (Virchow node) is an additional possibility.

The management of cervical CUP in patients has become increasingly controversial, primarily because of the question of postoperative radiation therapy. The notion of adjuvant irradiation of all potential mucosal sites has been questioned because of the absence of any demonstrated survival benefit in randomized studies. To date, postoperative radiation therapy in cervical CUP significantly improves locoregional control, but

this does not translate into improved OS. This being said, combined-modality therapy (surgery and radiation therapy) is better than either modality alone.[79] Most patients with only cervical or supraclavicular involvement should have regional therapy consisting of surgery, postoperative radiation therapy, and close follow-up. Patients who undergo an excisional biopsy for diagnosis usually do not need additional surgery if no gross disease is left behind, only a single lymph node measuring less than 6 cm is involved, and no extracapsular extension is noted on pathologic review. If any of these features is present, a neck dissection is indicated. In addition, for patients with squamous cell carcinoma, unilateral tonsillectomy ipsilateral to the presenting neck mass is commonly advocated as part of the surgical treatment because occult tonsillar carcinomas are usually found in 18% to 39% of patients who undergo tonsillectomy.[78,79] Identification of the primary site would thereby reduce morbidity by limiting the field of radiation and would improve surveillance.

In patients with N1 or N2a disease (squamous cell), it is unclear whether postoperative radiation improves local control because studies have been contradictory. In this case, close surveillance would also be an acceptable option after surgery. All other patients should receive postoperative radiation to the bilateral neck covering all potential occult primary sites (ie, nasopharynx, oropharynx, and hypopharynx). The 3-year survival rate after radical neck dissection or radical neck irradiation ranges from 35% to 60%. Within this group, patients with N1 disease have a better prognosis; patients with N3 disease, regardless of the local treatment modality used (surgery, radiotherapy, or both), fail to achieve complete remission in 65% of cases.

Although the role of chemotherapy in patients with cervical CUP remains poorly defined, extrapolation of phase 2/3 data in head and neck cancer indicates a role in patients with advanced nodal disease (N3). A recent large meta-analysis of more than 10,000 patients in 63 trials with head and neck squamous cell carcinoma treated with chemotherapy demonstrated a small but significant absolute survival benefit of 4% at 5 years.[80] Intensive concurrent chemoradiotherapy in unresectable squamous cell head and neck cancers with cisplatin/5-fluorouracil–based and cetuximab-based regimens has resulted in improved complete response rates, locoregional control, and preservation of organ function, albeit at the cost of significant toxicities.

Women with Carcinomas of Unknown Primary and Isolated Axillary Adenopathy

Women who present with adenocarcinoma in the axillary lymph nodes compose another subset with a more favorable prognosis. Disease in these patients is often managed as that for women with stage II breast cancer. Isolated axillary adenopathy is an uncommon presentation of breast cancer, accounting for only 1 to 3 of every 1000 diagnosed breast cancers. Mammography and ultrasonography should be performed, and biopsies should be performed on any identified lesions. If mammography findings are normal, additional imaging of the breast with MRI is indicated because of its greater ability to detect small primary breast tumors (70%–95% sensitivity). MRI has a very low false-negative rate. Of approximately 40 women reported in the literature with isolated axillary adenocarcinoma and negative breast MRI findings, only four were found to have breast cancer at surgery or during follow-up.[81]

The present recommended management of disease in women with CUP of the axilla includes axillary dissection, axillary radiotherapy for those at high risk of local recurrence (eg, extracapsular invasion or >4 positive lymph nodes), and appropriate systemic therapy for breast cancer, depending on age, menopausal status, and biomarkers. If breast MRI findings are negative, neither mastectomy nor breast irradiation is recommended.[82–84] If the breast MRI is positive or suspicious, radiation to the breast is usually recommended. The prognosis is not as favorable in men who present with axillary adenopathy only.[82]

This management paradigm is changing as molecular profiling complements pathology as a diagnostic tool in this subset of patients. All women with axillary adenopathy do not have occult breast cancer. Profiling for ToO can help with treatment decisions especially if the IHC does not correlate with breast cancer and estrogen receptor, progesterone receptor, and Her-2 status is negative.

Carcinomas of Unknown Primary Presenting as Isolated Inguinal Adenopathy

A few patients with CUP present with inguinal adenopathy. Undifferentiated (anaplastic) carcinoma is identified in at least half of these cases. Some of these anaplastic "carcinomas" appear to be melanomas with no obvious primary skin lesion. The remaining patients have squamous cell carcinomas arising from the skin, genitourinary tract, anus, or pelvis. A detailed investigation for primary lesions in these areas is important because curative therapy is available for carcinomas of the anus, vulva, vagina, and cervix, even with spread to regional lymph nodes. In patients with carcinomas and PDCs confined to the groin nodes, where no primary site was identified, a superficial groin dissection should be performed with or without radiation therapy. Bimodality therapy with surgery and radiation may increase the risk of significant lymphedema and requires careful planning. Chemotherapy, before definitive therapy and

in the context of a clinical trial, may be offered to patients with bulky locoregional adenopathy and is not an uncommon practice in the clinic.

Carcinomas of Unknown Primary and Isolated Pleural Effusions

Most patients with isolated pleural effusions have adenocarcinomas, which may sometimes be difficult to differentiate from mesotheliomas. Newer IHC markers (eg, calretinin, CK 5/6, and WT1 [Wilms tumor-1]) that are more sensitive in differentiating epithelioid malignant mesothelioma from pulmonary adenocarcinoma can assist in the diagnosis.[85] Additional IHC markers, including TTF-1, CK 7/20, and breast markers, should routinely be done as first- and second-tier diagnostics to aid in treatment. If the effusion reaccumulates quickly, pleurodesis may be attempted to slow the rate of fluid re-accumulation, or as done more often (as of this writing), a pleural catheter with daily aspirations is preferred (this can be removed after chemotherapy response is noted and the flow decreases). Chemotherapy is initiated in most patients based on their IHC profile, and taxane plus carboplatin versus gemcitabine plus cisplatin are commonly used doublets.

Carcinomas of Unknown Primary Presenting as Malignant Ascites

Patients with malignant ascites usually belong to one of two subsets, each with a very different natural history of disease. The first group consists of patients with mucin-producing adenocarcinoma who may present with ascitic fluid that contains signet-ring cells. These patients often have multiple peritoneal implants, with the primary site most likely being the GI tract (ie, stomach, small bowel, appendix, colon, or pancreaticobiliary). Given the current armamentarium of drugs available for treatment of metastatic colon cancer and the improved survival rate, it is important to consider those combinations for patients with IHC suggestive of colon profile ($CK20^+$, $CK\ 7^-$, and $CDX\text{-}2^+$). The second patient subset is composed of women with primary serous papillary peritoneal carcinomatosis. This disease is often also associated with pelvic adenopathy or masses. These patients may have elevated CA 125 levels but do not have detectable ovarian cancer. Some investigators consider these patients to have true unknown primary ovarian tumors or primary serous carcinomas of the peritoneum.[86,87] Disease management should be the same as for women with ovarian carcinoma. A prolonged median survival of 13 months, with 25% of patients having a progression-free survival lasting more than 2 years, was reported for paclitaxel/carboplatin-based chemotherapy in patients with peritoneal carcinomatosis. In this study, a high overall response rate (ORR) and number of complete responses were reported for this subgroup of patients with CUP (68.4% and 20%, respectively).

Carcinomas of Unknown Primary Presenting as Isolated Bony Metastases

When bone metastases are detected, men should be evaluated for prostate cancer and women for breast cancer given that they may be candidates for hormonal therapy, which is relatively easier compared with cytotoxic therapies. Other cancer profiles include lung, cholangiocarcinoma, renal, and, rarely, melanoma. Patients with a single bony metastasis may be candidates for surgery or radiation and then monitored. Patients with disease at multiple sites and good performance status and whose tumors progress after radiation therapy should be offered a trial of chemotherapy. Many experimental agents are currently available in ongoing clinical trials. Therapy with bone-seeking radioisotopes (eg, strontium 89) may be useful in the treatment of disseminated painful bone metastases in a few patients. Bisphosphonates are routinely used as in other malignancies, such as multiple myeloma, breast cancer, and prostate cancer. Often, PET-CT is the imaging modality of choice to follow response to therapy for disseminated osseous metastatic disease.

Carcinomas of Unknown Primary Presenting as Hepatic Metastases

Patients with hepatic metastases constitute 30% to 40% of people with CUPs; they compose a clinical subgroup with a relatively poor prognosis, with reported median OS between 49 days and 7 months. The most important diagnostic considerations in this class are to distinguish primary liver and biliary tumors (hepatocellular carcinoma and cholangiocarcinoma) from cancers that have metastasized to the liver, and to identify patients with neoplasms of a more indolent nature (eg, neuroendocrine tumors). A careful pathologic review with IHC of liver biopsy specimens is therefore essential. The two most common histologic findings in primary CUP of the liver are adenocarcinoma (55%) and poorly differentiated/undifferentiated carcinoma (30%). The recommended initial therapy for unresectable disease is systemic chemotherapy, and surgery may be considered as an option for those with resectable disease.

Neuroendocrine Tumors of Unknown Primary Site

Neuroendocrine tumors compose about 4% of all CUPs and commonly present with diffuse liver or bone metastases. Histologically, neuroendocrine tumors can

be well differentiated or low grade, with features that are typical of carcinoid or islet cell tumors exhibiting a more indolent behavior. Management of these tumors should be similar to established guidelines for metastatic low-grade neuroendocrine tumors from a known primary site. In patients with limited disease, surgical resection or chemoembolization may be appropriate. If not amenable to local therapy, then targeted therapy is considered with (anti–vascular endothelial growth factor agents, including sunitinib, or mammalian target of rapamycin inhibitors, including everolimus).

A second group involves high-grade neuroendocrine tumors that may present as PDC by light microscopy but have strong neuroendocrine features revealed by IHC (ie, neuron-specific enolase, chromogranin A, and synaptophysin positive). These high-grade neuroendocrine tumors are treated like small cell lung carcinoma with etoposide plus platinum or irinotecan plus platinum combinations, with high reported response rates.

Carcinomas of Unknown Primary and Extragonadal Germ Cell Syndrome

As a group, patients who have undifferentiated carcinoma or PDC are younger than 50 years and present with rapidly growing midline tumors involving the lymph nodes, mediastinum, or retroperitoneum; their tumors have been found to be very responsive to chemotherapy, particularly to platinum-containing regimens. It is believed that these patients have poorly differentiated extragonadal germ cell tumors. They have response rates to chemotherapy of 35% to 50%, and those who achieve a complete response often enjoy a durable remission. In a prospective study by Hainsworth and colleagues of 220 patients with PDC or poorly differentiated adenocarcinoma (PDAC) treated between 1978 and 1989 with cisplatin-based chemotherapy regimens, approximately half of the patients had a predominant tumor location in the mediastinum, retroperitoneum, or peripheral lymph nodes. The ORR was 63%, with 26% complete responses and an actuarial 10-year disease-free survival rate of 16%.

However, this was not found to be true by Lenzi and colleagues,[4] who retrospectively reviewed the clinical outcomes of 337 patients with PDC/PDAC. No prolonged survival was observed in this cohort of patients, and no significant survival advantage resulted from cisplatin-based chemotherapy. Moreover, elevated serum levels of α-fetoprotein or β-human chorionic gonadotropin, contrary to other reports in the literature, were not found to be predictive of an improved median OS. This discrepancy may have resulted from several confounding factors.

First, older studies of extragonadal germ cell syndrome included patients with PDCs who in actuality did not have CUP but had other highly treatable malignancies.[4] In a study by Hainsworth et al,[88] of the 36 long-term survivors, 20% were subsequently found to have either lymphoma,[5] testicular cancer,[1] or leiomyosarcoma.[1] Conversely, in the study by Lenzi, patients in whom the primary site was identified were excluded from the analysis. Most of these patients were found to have highly treatable malignancies, such as lymphoma (6%), breast cancer (8%), ovarian cancer (3%), germ cell tumors (2%), and prostate cancer (1%). Exclusion of these patients would significantly reduce response and median survival rates.

Second, even among patients with PDC/PDAC of unknown primary, significant heterogeneity exists. In the study by Lenzi, CART analysis of 337 patients revealed different groups with widely discrepant survival times. The group with the longest median OS (40 months) included patients with PDC, lymph node involvement, and only one or two metastatic sites. By contrast, patients with non–lymph node metastases had a very poor prognosis, with a median OS of only 7 months.[4]

Sarcomatoid Carcinoma

Sarcomatoid carcinoma is a rare histologic subtype of CUP characterized by poorly differentiated carcinoma with a sarcomatoid component or a true mixed-lineage neoplasm. This rare group of patients often has an aggressive disease course and poor prognosis. In a study of 48 patients, median OS was 11 months and patients were often resistant to chemotherapy. On multivariate analysis, patients with poor performance status and high neutrophil-to-lymphocyte ratio had shorter survival.[89]

Carcinomas of Unknown Primary and Single Sites Discovered Incidentally on Resection

CUPs are notorious for unusual, isolated presentations. Such lesions may appear on the skin, in single isolated lymph nodes removed during surgery for benign unrelated conditions, and at other, even more unusual sites. Patients should be examined for primary tumors and other sites of metastasis, as described previously. If no primary tumor and no additional sites of metastasis are found, complete removal of the lesion must be ensured; this often requires additional excision with wider margins (if skin or subcutaneous). The patient may then be monitored without therapy and in selected cases are candidates for radiation. Many such patients may enjoy prolonged survival. Patients with isolated skin lesions may have an undifferentiated primary integumentary tumor with a potential for cure after adequate local surgical treatment.

CHEMOTHERAPEUTIC STRATEGIES FOR CARCINOMAS OF UNKNOWN PRIMARY

Combination regimens using newer chemotherapeutic agents have demonstrated greater benefit than have older single-agent therapies for CUP cancers. Several difficulties arise when survival and response rates reported in different chemotherapy trials are compared. For example, histologic criteria for patient selection often varied from study to study. Moreover, in older studies, IHC methods were not used to evaluate pathologic specimens. Despite these difficulties, no study has firmly established any chemotherapy regimen as the "gold standard" in CUP. The median survival in most studies, regardless of regimen, has ranged between 5 and 13 months, with response rates of less than 30% and without a significant improvement in survival (Table 53–4).

Nevertheless, patients with certain clinical subtypes (eg, peritoneal carcinomatosis and lymph node–predominant disease) do benefit from chemotherapy. Historically, cisplatin-based combination chemotherapy regimens were frequently used to treat patients with CUP. Response rates in the literature range from 12% to 26% and median survival from 5 to 7 months. Combining paclitaxel with carboplatin has modestly improved both survival and response rates. In patients with widespread metastases and poor performance status, however, systemic chemotherapy is unlikely to be beneficial, and only supportive therapy is usually indicated.

In a phase 2 study by Hainsworth and colleagues, patients with CUP ($n = 55$) received paclitaxel (200 mg/m^2 on day 1), carboplatin (AUC = 6, day 1), and oral etoposide (50 mg alternating with 100 mg days 1–10) every 21 days.[90] Most were previously untreated, with only four having received prior chemotherapy. Most patients had moderately to well-differentiated adenocarcinoma (55%) or PDC/PDAC (38%), with squamous (2%) and neuroendocrine (5%) histologic findings less prevalent. The dominant sites of disease were lymph nodes (25%), liver (16%), and lungs (16%). Approximately 24% of patients in the study had multiple sites of disease, with 42% of those having more than two metastatic sites. Response rates were equivalent in all histologic subgroups, with a reported ORR of 47% and a median OS of 13.4 months. This regimen was well tolerated, with myelosuppression the most common grade 3/4 toxicity. No treatment-related deaths were reported.

Briasoulis and colleagues[91] found equivalent response rates and median OS in CUP with carboplatin (AUC = 6) and paclitaxel (200 mg/m^2) without oral etoposide. In this phase 2 trial, patients ($n = 77$) were given a maximum of eight cycles of chemotherapy. In addition, granulocyte colony-stimulating factor was administered on days 5 to 12. The proportions of differing histologic subtypes were comparable with those in the Hainsworth study: adenocarcinoma (61%), undifferentiated (35%), and squamous (4%). Three distinct clinical subsets were present in this study: peritoneal carcinomatosis (25%, mostly women); visceral or bony metastases (43%); and predominant nodal or pleural disease (30%). The reported ORR, median response duration, and median OS were 38.7%, 6 months, and 13 months, respectively. Although response rates were equivalent for adenocarcinoma and undifferentiated carcinoma, significant differences were seen among the three clinical subsets: liver/bone or disseminated metastases (ORR 15.1%; median OS 10 months); nodal/pleural disease (ORR 47.8%; median OS 13 months); and peritoneal (ORR 68.4% [75% for women]; median OS 15 months); $P = .01$. Three patients with nodal-predominant disease had durable responses lasting longer than 2 years. Grade 3/4 neutropenia was only 4%, with two reported deaths from septicemia.

The role of cisplatin in combination with either gemcitabine or irinotecan for patients with previously untreated CUP was assessed in a phase 2 study.[92] The proportion of histologic subtypes were adenocarcinoma (60%–67%), poorly differentiated adenocarcinoma (15%–18%), undifferentiated (13%–15%), and unavailable (3%–10%). The ORR was 55% in patients receiving cisplatin and gemcitabine and 38% in those receiving cisplatin and irinotecan. The trial was not designed to make statistical comparisons between the two groups. Median survival times in the two groups were 8 months for gemcitabine and cisplatin and 6 months for irinotecan and cisplatin.

The results of docetaxel in combination with carboplatin in one small phase 2 study appear to be inferior to those of the paclitaxel/carboplatin combination in the trials mentioned. The ORR was 22%, the median OS was 8 months, and the 1-year OS rate was 29%. Differences in sites of disease and histology among these three studies may account for the discrepancy. Severe grade 3/4 myelosuppression was more frequent with docetaxel (50%) than with paclitaxel, with two reported deaths from septicemia.[93] Docetaxel was also studied in combination with gemcitabine in a phase 2 study. The ORR was 40% and median OS was 10 months.[94]

Patients with undifferentiated or PDCs not fitting into the extragonadal germ cell or neuroendocrine clinical subgroups have traditionally been given a trial of a cisplatin-based regimen. Patients with squamous cell carcinomas who require chemotherapy are also often treated effectively using a cisplatin-based regimen.

Table 45-4 Selected Phase 2 Studies in Carcinoma of Unknown Primary

Overall Survival

There has been significant interest in using ToO studies to guide selection of therapy for patients with CUP. Several trials have been designed to address this question, and one has been reported. In this trial, 130 patients underwent gene expression profiling to predict tumor origin, and then were assigned to either site-specific therapy or empiric paclitaxel and carboplatin.[95] The 1-year survival rate was 44% in the site-specific treatment group and 54.9% in the empiric chemotherapy group; $P = .264$; the authors concluded that gene expression profiling directing site-specific chemotherapy failed to improve survival compared with an empiric chemotherapy approach. However, favorable CUP subsets were excluded and there was an imbalance in predicted tumor types between arms.

The role of salvage chemotherapy in CUP is poorly defined. Gemcitabine has been published as second-line therapy in patients with previously treated CUP. In a phase 2 study by Hainsworth and colleagues,[96] gemcitabine was administered weekly at 1000 mg/m^2 (on days 1, 8, and 15 of a 28-day cycle). All patients ($n = 39$) received two cycles and were then evaluated for response. Chemotherapy was continued for a maximum of six cycles for either an objective response or stable disease. Approximately 90% of patients had failed a prior regimen containing platinum and a taxane. Most patients had either adenocarcinoma (59%) or PDC/PDAC (31%). Median time to progression was 5 months. Gemcitabine was well tolerated, with 92% of patients receiving two or more cycles. The most common grades 3–4 toxicities were fatigue/weakness and mucositis/esophagitis.

Hainsworth et al[97] reported on a combination-targeted therapy trial of bevacizumab and erlotinib in 51 patients; 25% were chemotherapy naïve with advanced bone or liver metastases, and 75% had been treated with one or two chemotherapy regimens. Responses were noted in four patients (8%), and 30 patients (59%) experienced stable disease or a minor response. The median OS duration was 8.9 months, with 42% of patients alive at 1 year.

The evolution of clinical trials examining the role of treatments based on molecular characteristics rather than site of origin has important implications for CUP and may lead to additional treatment options. In an analysis of 389 cases, 1.8% were found to be microsatellite instability-high.[98] Although treatment response data were not reported in this cohort, pembrolizumab is approved for patients with microsatellite instability-high cancer regardless of site of origin.[70] In addition, another study using next-generation sequencing of 333 patients found 30% with "potentially targetable genomic alterations."[99] Although not all genomic alterations in various cancers have been shown to be responsive to targeted therapy, one patient was found to have an NTRK1 fusion. Larotrectinib is a treatment option available to patients with TRK-fusion–positive cancers and has a role in this small patient population.[71]

Although evaluation of empiric regimens was the preferred approach in the past, with the emergence of modern molecular diagnostic trials that help define CUP subtypes, our focus has shifted from empiric combinations to more tailored regimens, especially as directed by IHC and, where helpful, ToO or mutational profiles. Further, as therapies for known cancers improve and become more selective based on evolving predictive markers, the newer therapeutic approaches should be evaluated in the appropriate CUP subtypes as well.

FUTURE TRENDS

Advances in pathology, cancer therapeutics, and clinical trial design all have the potential to benefit patients with CUP in the coming years. Pathologic advances provide opportunities to tailor IHC use based on algorithms, which can improve diagnostic yield and also conserve tissue, which may be needed for ToO studies or next-generation sequencing.[100] The role of immunotherapy has yet to be well defined in CUP, and it is currently best used in the context of a clinical trial. Furthermore, multiple biomarkers to predict the efficacy of immunotherapy are being studied, including the microsatellite-instability pathway, tumor mutational burden, and programmed cell death ligand 1, among others. Ongoing studies may address these unanswered questions.[101] Clinical trial design has evolved to include basket trials, which look at groups of patients with similar genomic alterations rather than site of origin. These approaches, along with other novel clinical trial designs, have important therapeutic implications for CUP, because they may provide evidence of benefit to this rare patient population.

SUMMARY

All patients with CUP should undergo a directed diagnostic evaluation for the primary tumor and a detailed pathologic evaluation of the metastatic specimen. A subset of patients defined by clinicopathologic criteria and considered to have favorable prognosis benefit significantly from selective or aggressive treatments. For most patients who present with advanced disseminated CUP, the prognosis remains poor, and no unique empiric combination therapy of established efficacy is available. We have moved away from the paradigm of "one treatment fits all" to a more focused approach that integrates clinical presentation, pathologic evaluation, and the evolving diagnostic tools. Molecular profiling and next-generation sequencing–based studies allow for more sophisticated ToO testing. In addition, these tools allow for therapy targeting specific mutations or molecular characteristics of a tumor to individualize CUP treatments. However, for this approach to be successful, it will require both additional molecular insights and novel drugs that are effective against specific mutations.

MD ANDERSON PRACTICE TIPS

- Adequate pathologic evaluation is the cornerstone of diagnosis. In any case of inadequate sample that may introduce sampling bias or limit pathologic workup, a repeat biopsy is strongly recommended.
- Multidisciplinary approach involving close communication between medical oncology, pathology, radiology and surgical/radiation oncology (for oligometastatic disease) is extremely valuable in devising an appropriate treatment strategy.
- Focused evaluation based on the clinicopathologic profile of the patient is recommended and is the most cost-effective and clinically effective strategy and prevents delays in treatment. Unnecessary and invasive testing should be avoided.
- Although limited data exist regarding the role of molecular profiling, we encourage use of next generation sequencing because it can provide clues with regard to putative origin and also identify a small subset of tumors where molecularly-driven therapy may be beneficial.
- Although the absolute benefit of site-specific versus empiric chemotherapy is unclear, we endorse the paradigm of tailoring therapy to a putative primary, if discernible.
- Participation in clinical trials (interventional or translational) should be encouraged for all patients and early referral to academic CUP programs be considered for select patients.

54 Pediatric Cancers

Branko Cuglievan
Wafik Zaky
Richard Gorlick
Douglas Harrison

KEY CONCEPTS

- Patients with many common pediatric neoplasms, such as acute lymphoblastic leukemia (ALL), Wilms tumor, non-Hodgkin lymphoma, Hodgkin lymphoma, and germ cell tumors, have survival rates approaching or even exceeding 90%. However, progress has been limited for patients with some types of solid tumors, high-grade gliomas, and diffuse intrinsic brainstem gliomas.
- Patients with ALL, the most common cancer in children, typically present with hepatomegaly or splenomegaly, pallor, fever, and/or bruising. ALL's genetic interrogation has enabled us to employ risk-based treatment strategies that have led to a cure rate greater than 98% in some ALL subtypes. Those with unfavorable cytogenetic factors, suboptimal responses to chemotherapy, or those who relapse require treatment with aggressive regimens and will benefit from novel treatment modalities.
- Hodgkin lymphoma, the most common neoplasm among adolescents ages 15 to 19, commonly presents with painless supraclavicular or cervical adenopathy with or without the involvement of the mediastinum. Fever higher than 38 °C, drenching night sweats, and weight loss more than 10% of body weight within 6 months have been classified as "B symptoms" and affect staging and prognosis. Interim assessment with 18-fluorodeoxyglucose–positron emission tomography scan has allowed recognizing favorable responders who benefit from less toxic therapy.
- In children, the central nervous system (CNS) neoplasms are mostly infratentorial. Patients present with increased intracranial pressure, which manifests as macrocephaly, vomiting, and developmental delay in infants and headache, vomiting, blurred vision, and altered mental status in older children. A gross total resection is the surgery goal, whenever it is safe and feasible. Chemotherapy and radiation therapy typically follow for the malignant CNS tumors except for chemoresistant tumors like ependymoma.
- Non-neural solid tumors vary considerably by histology, tumor cell of origin, symptom spectrum, age at presentation, treatment, and outcome. The majority are treated with a multidisciplinary approach that includes surgical resection, radiation, and/or systemic chemotherapy. In some instances, like neuroblastoma and Wilms tumor, treatment is also determined by the patient's risk status, which incorporates biologic features.
- In pediatric cancer survivors, long-term side effects of therapy include cardiovascular dysfunction in those exposed to anthracyclines and/or radiation, neurocognitive deficits, endocrinopathies, and secondary CNS tumors in patients who received radiation to the CNS, and breast and thyroid cancer for those exposed to radiation to the chest.

Over the past five decades, the treatment of children and adolescents with cancer has improved dramatically.[1] Patients with many common pediatric neoplasms, such as acute lymphoblastic leukemia (ALL), Wilms tumor (WT), non-Hodgkin lymphoma (NHL), Hodgkin lymphoma (HL), and germ cell tumors, have survival rates approaching or even exceeding 90%.[2] However, progress has been limited for patients with some types of solid tumors, high-grade gliomas, and diffuse intrinsic brainstem gliomas. As in adults, pediatric patients who present with metastatic disease, who have a disease that does not respond to standard frontline therapies, and/or who have disease relapse face a grim prognosis despite intensive multimodal treatments that in survivors can cause long-term morbidity and disability.[3] Thus, cancer is the leading cause of disease-related morbidity and mortality in childhood and is second only to accidents as a cause of pediatric death in the United States and other developed countries.[1]

Understanding the proteomic and genomic landscapes of pediatric diseases may enable us to implement novel treatment strategies. Unfortunately, the relative rarity of these cancers precludes the substantive preclinical research necessary to find and develop potential therapeutic targets and limits the number of patients who can be enrolled in trials of novel therapeutic strategies. Furthermore, extrapolating the clinical activity and safety of the novel agents employed in adults is not always conceivable; the etiology and biology of pediatric cancer differ from those of adult cancer (Fig. 54–1).[2]

In this chapter, we present a few examples of common pediatric tumors and briefly describe some of the most important therapeutic advances for each.

PEDIATRIC LEUKEMIA

Acute Lymphoblastic Leukemia

ALL is the most common cancer diagnosed in children and adolescents in the United States.[1] ALL originates in a B- or T-lymphocyte precursor that proliferates and disrupts normal hematopoiesis. The disease can involve the liver, spleen, lymph nodes, thymus, meninges, and gonads.[4] Patients typically present with hepatomegaly or splenomegaly, pallor, fever, and/or bruising. Some patients demonstrate central nervous system (CNS) disease and have clinical evidence of cranial nerve involvement at diagnosis. A lumbar puncture can confirm the presence of leukemic blasts in that site with bone marrow aspirate and biopsies used to make the diagnosis.

Immunophenotyping, a critical element of the initial workup of patients with ALL, can differentiate between T-cell precursors and B-cell precursors and between these cell types and mature B cells.[4] The extensive genetic interrogation of ALL has enabled us to classify the disease into prognostically and therapeutically essential subtypes and identify candidate molecules for targeted therapeutics.[4]

Some high-risk features are: (1) age less than 1 year or more than 10 years, (2) an initial white blood cell count more than 50,000 µL, (3) CNS involvement, (4) testicular involvement, (5) T-lineage ALL, and (6) suboptimal induction response. Unfavorable cytogenetic factors include hypodiploidy (<44 chromosomes or a DNA index <0.81), Philadelphia chromosome (Ph+); t(9;22)(q34.1; q11.2); *BCR-ABL1,* t(v;11q23.3); *KMT2A*-rearranged, BCR-ABL1-like (Ph-like); and iAMP21.

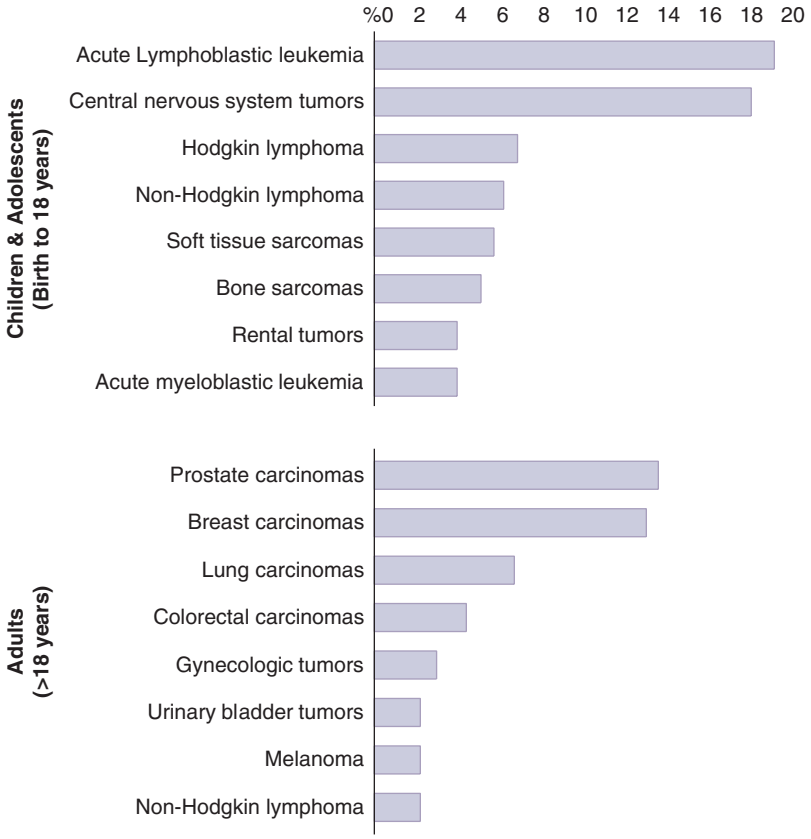

FIGURE 54–1 Graph demonstrating the different spectrum of neoplasms in children and adults.

Favorable cytogenetics are precursor B subtypes with *ETV6-RUNX1* translocation and high hyperdiploid ALL (>50 chromosomes or a DNA index >1.16) with simultaneous trisomy 4 and 10.[5,6]

With the use of risk-directed treatment and supportive care, patients with ALL have a 5-year overall survival (OS) rate of approximately 80%; for patients with some ALL subtypes, the cure rate is greater than 98%.[7]

Space precludes describing upfront treatment, which is usually on the Children's Oncology Group treatment protocols, so we will focus on novel therapies in this chapter.

Blinatumomab is a bispecific T-cell engager antibody construct that directs CD3-positive effector memory T-cells to target CD19-positive leukemia cells. The efficacy of blinatumomab in pediatric patients with relapsed/refractory ALL was demonstrated in an international, single-arm phase 1/2 study (NCT01471782).[8] Similarly, inotuzumab ozogamicin, a humanized CD22 monoclonal antibody conjugated to calicheamicin, elicited complete remissions in 67% of 51 pediatric patients with overt marrow disease. No patient developed sinusoidal obstruction syndrome during inotuzumab therapy; however, 11 of 21 (52%) patients who underwent hematopoietic stem cell transplantation after inotuzumab developed sinusoidal obstruction syndrome.[9] CD19 single-targeting chimeric antigen receptor T-cell therapy has recently emerged as a new modality to treat B-lineage malignancies.[10] Numerous current pediatric frontline ALL protocols integrate immunotherapy. The Children's Oncology Group is conducting randomized trials of blinatumomab plus cytotoxic chemotherapy in standard-risk patients with ALL (AALL1731, NCT03914625), inotuzumab plus cytotoxic chemotherapy in high-risk patients with ALL (AALL1732, NCT03959085), and tisagenlecleucel in high-risk patients with ALL with minimal residual disease (AALL1721, NCT03876769).[10]

Acute Myeloid Leukemia

Pediatric acute myeloid leukemia (AML) accounts for approximately 15% of all pediatric leukemias and has an incidence of seven cases per million among children younger than 15 years.[11] AML is characterized for being a profoundly heterogeneous disease at both the molecular and clinical levels. For more than three decades, numerous international cooperative groups have sought to develop a therapeutic strategy fundamentally composed of four or five phases of intensive chemotherapy consisting of an anthracycline and cytarabine backbone.[12] Patients who have high-risk mutations or whose disease relapses undergo allogeneic hematopoietic stem cell transplantation.[7,11,12] In recent clinical trials, the 5-year event-free survival rates of pediatric patients with AML have been 49% to 64%[7,13]; however, bone marrow relapse still occurs in as much as one-third of cases.[14] This subset of patients continues to have poor long-term outcomes, with an OS rate of less than 40%.[12] For pediatric patients with AML, the main treatment objective is the achievement of a complete remission that can be consolidated with a potentially curative hematopoietic stem cell transplantation.[7,13,14] Patients who do not have a complete remission after reinduction therapy with salvage chemotherapy or those who have a subsequent relapse have little chance of cure.[13] Making additional progress against this aggressive hematologic disease requires novel drugs directed toward distinct pathways and new molecular targets.

In 2014, the Children's Oncology Group conducted a phase 3 trial of the antibody-drug conjugate gemtuzumab ozogamicin, which targets CD33, and revealed decreased rates of relapse compared with conventional chemotherapy only.[15] CPX-351, a liposomal formulation of cytarabine and daunorubicin, demonstrated favorable responses in pediatric patients with relapsed AML.[16] Recently, the BCL-2 inhibitor venetoclax has shown promising activity in combination with hypomethylating agents and low-dose cytarabine.[17]

PEDIATRIC LYMPHOMA

Hodgkin Lymphoma

HL is the most common neoplasm among adolescents ages 15 to 19 years, with an estimated incidence of 29 cases per million.[1] The World Health Organization classification divides HL into two main types: classic HL and nodular lymphocyte–predominant HL.[18]

Classic HL, which accounts for most cases of childhood HL in the United States, is characterized by the presence of giant multinucleated Reed-Sternberg cells. Virtually all Reed-Sternberg cells express CD30, whereas 75% to 85% express CD15.[19] CHL is further divided into four subtypes according to pathologic features: (1) nodular sclerosis (the most common subtype in adolescents and young adults); (2) mixed cellularity; (3) lymphocyte-rich; and (4) lymphocyte-depleted. Epstein-Barr virus-positive CHL is frequently present in mixed cellularity classic HL, in males, and in developing countries. Nodular lymphocyte–predominant HL, which is more indolent than CHL, expresses CD20 but rarely expresses CD30 or CD15.[19]

Patients with HL commonly present with painless supraclavicular or cervical adenopathy with or without the involvement of the mediastinum.[20] Fever higher than 38 °C, drenching night sweats, and weight loss more than 10% body weight in 6 months have been classified as "B symptoms" and affect staging and

prognosis.[21] Physical examination, thoracic radiography, computed tomography (CT), and 18-fluorodeoxyglucose–positron emission tomography are used to determine the stage through the Ann Arbor Staging System.[21]

Children and adolescents with HL have had a 5-year survival rate of 94% since 2002, compared with an 81% survival rate in the early 1970s.[2,3] In the United States, the Children's Oncology Group has studied the ABVE-PC regimen (comprising doxorubicin bleomycin, vincristine, etoposide, prednisone, and cyclophosphamide) and its derivatives across risk groups.[22] Radiotherapy of the involved field or node given at lower doses (15–25 Gy) is used mostly in patients with suboptimal responses and high disease burden.[22] Brentuximab vedotin, an antibody-drug conjugate comprising an anti-CD30 antibody conjugated by a protease-cleavable linker to the potent antimicrotubule agent monomethyl auristatin E, is approved for relapsed HL.[23] The Children's Oncology Group has evaluated the brentuximab vedotin-AVEPC regimen for high-risk HL in a phase 3 trial (NCT02166463); the results are pending. The composite results of trials NCT02181738 and NCT01592370 demonstrated that nivolumab, a humanized IgG4-κ monoclonal antibody against programmed cell death receptor–1, has clinically meaningful activity against classic HL.[24] Currently, the Children's Oncology Group is conducting a phase 3 randomized study of nivolumab versus brentuximab vedotin plus doxorubicin, vinblastine, and dacarbazine in patients with newly advanced classic HL (NCT03907488). The prognosis for relapsed HL is generally favorable given the use of high-dose chemotherapy and autologous hematopoietic stem cell transplantation.[21]

Non-Hodgkin Lymphoma

NHL comprises a varied group of malignant lymphoid neoplasms that arise from B- or T-cell precursors, mature B cells, or mature T-cells.[18,25] Most NHLs are high-grade and aggressive. The NHL section of this chapter focuses on mature B-cell NHL. Numerous subtypes of NHL that occur in adults rarely occur in children.

Burkitt lymphoma, an aggressive neoplasm that arises from germinal center B cells, frequently presents in the abdomen, head, and neck.[26] Less common sites of involvement are the testes, bone, bone marrow, skin, and CNS. Burkitt lymphoma can have a 24-hour doubling time and often undergoes spontaneous tumor lysis. The tumor cells express a mature B-cell phenotype that typically lacks the terminal deoxynucleotidyl transferase and is positive for pan-B-cell markers (CD19, CD20, CD22, and CD79a) and surface immunoglobulin with either κ or λ light chains.[26] Burkitt lymphoma expresses distinguishing chromosomal translocations juxtaposing the c-*myc* oncogene and immunoglobulin locus regulatory elements such as t(8;14) and, more rarely, t(8;22) or t(2;8). Cytogenetic evidence of c-*myc* rearrangement is the gold standard for the diagnosis of Burkitt lymphoma.[19] Cases with "double-hit" translocations involving *MYC* and *BCL6*, and rare cases with "triple-hit" translocations involving *MYC, BCL2,* and *BCL6,* are more common in adults.

Diffuse large B-cell lymphoma represents 10% to 20% of pediatric NHL.[25] Most patients present with enlarging symptomatic masses in the neck or abdomen, or, in the case of primary mediastinal large B-cell lymphoma, the mediastinum.[19] Unlike Burkitt lymphoma, diffuse large B-cell lymphoma less often involves the CNS and bone marrow.[19] The Murphy Staging System is the most widely used staging scheme for NHL.[27]

In pediatrics, the treatment for Burkitt lymphoma and diffuse large-cell lymphoma is usually identical. In the United States, the Children's Oncology Group has added rituximab to baseline chemotherapy with FAB/LMB-96 therapy with excellent outcomes.[28] Primary mediastinal B-cell lymphoma carries a worse prognosis in pediatric patients, and many centers in the United States treat these patients with the dose-adjusted EPOCH-R regimen (etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and rituximab; typically given for six cycles) with filgrastim and no radiation therapy.[29] The safety and effectiveness of chimeric antigen receptor T-cell therapy in pediatric patients with relapsed or refractory mature B-cell NHL are being evaluated in clinical trials (NCT03610724, NCT02625480).[30]

CHILDHOOD CENTRAL NERVOUS SYSTEM TUMORS

CNS tumors are the most common childhood cancer and the leading cause of cancer-related mortality in this population.[31] The overall incidence rate is 5.65 to 11.20 per 100,000 population, depending on the age group. Approximately 4700 pediatric CNS tumors are diagnosed each year in the United States. According to a recently published report of the Surveillance, Epidemiology, and End Results (SEER) program, the most common location is the infratentorial tumor (43.2%), followed by the supratentorial (40.9%), the spinal cord (4.9%), and multiple sites (11%).

Many environmental factors have been interrogated with only exposure to ionizing radiation associated with increased risk of CNS tumors (ie, meningioma), whereas allergy and atopic diseases were associated with decreased risk (ie, glioma).[31] Furthermore, having a first-degree relative with a CNS tumor has been shown to increase the risk twofold.[31]

The clinical presentation of a patient with a CNS tumor depends on the tumor location, stage, and patient age at diagnosis. The most common presentation is increased intracranial pressure, which presents as macrocephaly, vomiting, and developmental delay in infants and as headache, vomiting, blurred vision, and altered mental status in older children. Depending on location, patients may have motor weakness, sensory changes, seizures, bowel or bladder symptoms, ataxia and dysarthria, or cranial nerve neuropathies. Endocrine abnormalities are common in midline tumors like craniopharyngioma and germ cell tumors.

The OS has improved in the last few decades owing to advances in imaging, chemotherapy, modalities of radiation therapy, as well as surgical navigation techniques. A gross total resection is the goal, whenever it is safe and feasible. Chemotherapy and radiation therapy typically follow for the malignant CNS tumors, except for chemoresistant tumors like ependymoma.

Low-Grade Gliomas

Low-grade gliomas (LGGs) are the most common pediatric CNS tumors and associated with two cancer predisposition syndromes, neurofibromatosis I (NF1) and tuberous sclerosis syndrome. Surgical resection, if feasible, is the most effective therapeutic option, with complete resection of LGG leading to greater than 90% survival, whereas less than total resection leads to nearly 60% survival. Further therapy depends on several factors, including tumor location, amount of residual tumor, patient age, and/or association with NF1. For progressive LGG, first-line chemotherapy is a combination of vincristine and carboplatin. In a study of children with progressive LGG, 56% had an objective response and 3-year progression-free survival (PFS) was 68%.[32] Recently, molecular testing of progressive LGG has identified translocations of BRAF in 70% of LGGs, whereas the BRAF V600E mutation occurs in 5% to 10%, with potential response to selumetinib and vemurafenib, respectively.[33]

High-Grade Gliomas

High-grade gliomas (HGGs) including diffuse intrinsic pontine glioma (DIPG) are common CNS tumors in children. Their outcome remains poor despite the use of multimodal therapy with surgery, radiation therapy, and chemotherapy. For hemispheric HGG, the strongest prognostic factors are the extent of resection and histologic grade. Temozolomide as a radiosensitizer followed by adjuvant temozolomide had a 3-year PFS and OS of 11% and 22%, respectively.[34] This study demonstrated comparable survival with less toxicity than nitrosourea-based regimens, resulting in temozolomide becoming standard treatment. On the other hand, adding temozolomide did not add survival benefit to patients with DIPG, with a median survival similar to radiation therapy alone at 10 months. Focal radiation therapy remains the standard of care for newly diagnosed DIPG, with more than 200 clinical trials over the last three decades failing to show superior outcome to radiation alone.[35] Recently, whole-genome, whole-exome, and methylation profiling have identified six molecular subgroups in pediatric HGG, with each subgroup having its own clinical characteristic and driving genomics.[36] Frequent somatic mutations in histone H3 genes, *TP53* and *ACVR1*, have been reported in DIPG recently.[37] Fusion genes were also found in nearly half of DIPGs involving the neurotrophin receptor genes, *NTRK1* and *NTRK2*. Mutations targeting receptor tyrosine kinase–RAS-PI3K signaling, histone modification or chromatin remodeling, and cell cycle regulation were found in 68%, 73%, and 59% of pediatric HGGs, respectively, including in midline gliomas.

Medulloblastoma

Medulloblastoma is the most common pediatric malignant CNS tumor, with a peak age of incidence at 5 years. Medulloblastoma is known to be associated with familial cancer syndrome in less than 1% of patients, Gorlin (PTCH mutation, Sonic Hedgehog [SHH] receptor) and Turcot (mismatch repair genes) syndromes. Age younger than 3 years at diagnosis, residual tumor after resection, anaplastic histology, and metastatic disease are high-risk features and associated with poor outcome. Children with localized disease have a greater than 80% 5-year PFS compared with disseminated disease, which has less than 40% 5-year PFS.[38] Treatment typically is multidisciplinary, including surgery, chemotherapy, and radiation in newly diagnosed children older than 3 years. An alternative treatment approach for patients younger than 3 years old is to avoid radiation and use high-dose chemotherapy and autologous stem cell rescue.[39] Recent genomic studies have identified four subtypes of medulloblastoma with distinct cellular origins, clinical characteristics, and outcome, namely WNT, Sonic Hedgehog (SHH), Group 3, and Group 4.[40] The WNT and Group 3 subtypes have the best and worst prognosis, respectively. MYC amplification, 17p loss, and p53 mutation are other markers associated with poor outcome regardless of the molecular subgroup.

Ependymoma

Ependymoma accounts for 10% of childhood CNS tumors, with 70% occurring in the posterior fossa. The mean age of patients is 6 years at diagnosis. Genome-wide DNA methylation patterns, have led to the recognition of nine molecular subgroups across all three

anatomic compartments including supratentorial, posterior fossa, and the spinal locations.[41] More than 70% of supratentorial ependymomas express the *C11orf95–RELA* gene fusion, which is a downstream target of nuclear factor-κB signaling. Despite recent identification of driver oncogenes and molecular subtypes of ependymoma, treatment remains challenging. Surgery is the primary treatment modality, with the extent of surgical resection a major prognostic factor. Residual disease, younger age, anaplastic histology, and posterior fossa location are associated with poor outcome. Treatment of brain ependymomas consists of attempting complete surgical resection and adjuvant radiation therapy. The benefit of adjuvant chemotherapy to surgical resection and radiation therapy has been investigated in the Children's Oncology Group trial, with final results pending. Spinal myxopapillary ependymoma is a grade I neoplasm with spinal dominance, and the preferred standard of care is surgical resection followed by adjuvant focal radiation therapy for residual or progressive disease.

NON-NEURAL SOLID TUMORS

Although non-neural solid tumors (NNSTs) individually are markedly less common than leukemia and CNS tumors in the pediatric population, when grouped together they make up approximately 44% of all pediatric malignancies in patients under the age of 20.[42] NNSTs vary considerably by histology, tumor cell of origin, symptom spectrum, age at presentation, treatment, and outcome. The majority are treated with a multidisciplinary approach that includes surgical resection, radiation therapy, and/or systemic chemotherapy. They are typically divided broadly between malignancies that develop from primitive embryonic structures—such as neuroblastoma and WT—and sarcomas. Pediatric sarcomas will be further differentiated between those that arise from bone such as osteosarcoma and Ewing sarcoma versus those that develop from soft tissue such as rhabdomyosarcoma and non-rhabdomyosarcoma soft tissue sarcoma.

Neuroblastoma

Neuroblastoma is the most common pediatric NNST, with approximately 650 new cases diagnosed in the United States annually.[43] Neuroblastoma is derived from cells that originate from the primordial neural crest, which will eventually give rise to the sympathetic nervous system. The median age at diagnosis is 23 months, with the vast majority of patients diagnosed before age 5 years.[44] The most common primary location for neuroblastoma is the adrenal gland, accounting for 65% of cases. The remainder will develop along the sympathetic ganglia lining the spinal cord.[44] Neuroblastoma is a catecholamine-secreting tumor, and urinary catecholamines—specifically homovanillic acid and vanillylmandelic acid—are elevated in the majority of children with neuroblastoma. Neuroblastoma metastasizes to bone, bone marrow, and liver (less commonly to the CNS and lungs). Staging includes chest abdomen and pelvis CT, bone scintigraphy, bilateral bone marrow biopsies, and iodine-123 metaiodobenzylguanidine study to document the extent of disease.[44] Treatment is determined by a patient's risk status, which incorporates biologic features—including pathologic information and genetic alterations such as the presence of amplification of the proto-oncogene N-*myc*, patient age, and stage.[45] In certain cases, low-risk patients may be cured with surgical resection alone. Patients with intermediate-risk disease sustain high event-free survival and OS but often will require systemic chemotherapy and/or surgical resection.[45] Historically, patients with high-risk disease fared poorly despite extensive therapy that included intensive chemotherapy, surgical resection of the primary, and autologous stem cell transplant. Recent advances in immunotherapy have led to the incorporation of anti-GD2 antibody therapy with dinutuximab, which targets the GD2 glycoprotein, which exhibits high expression in neuroblastoma into frontline and salvage therapy. The addition of dinutuximab to neuroblastoma therapy has improved OS from 46.5% to 66.5% for patients with high-risk neuroblastoma.[46]

Wilms Tumor

WT is the most common pediatric malignancy of the kidney, with 500 diagnosed cases annually in the United States.[47] WT maintains a peak age at diagnosis of 2 to 3 years and arises from primitive embryonic renal precursors. Histology is prognostic in WT. Classical WT is composed of varying proportions of three cell types: blastemal, epithelial, and stromal. The presence of anaplasia in the tumor imports a worse prognosis and delineates unfavorable histology.[48] Two loci (WT1 on chromosome 11p13 and WT2 on chromosome 11p15) have been linked to a predisposition to WT. Several genetic syndromes associated with mutations in these loci are associated with an increased incidence of WT, including Beckwith-Wiedemann syndrome and WAGR syndrome, among others.[49] Despite this genetic association, the majority of WT cases are sporadic with no genetic propensity identified. WT metastasizes to the lungs, liver, lymphatic system, and rarely to the contralateral kidney. Similar to neuroblastoma, treatment is stratified by a patient's individual risk status, which incorporates stage as well as specific biologic features. Patients with WT have excellent outcomes and are treated with a multidisciplinary approach that will include surgical resection (usually via nephrectomy) in addition to systemic chemotherapy and, in some cases,

consolidative radiation therapy depending on the stage of the tumor.[48]

Sarcomas

Sarcomas make up 13% of all pediatric malignancies diagnosed under age 20 years.[42] The most common pediatric sarcoma of bone is osteosarcoma, with approximately 400 new cases diagnosed in the United States annually.[50] Osteosarcoma has a predilection for the metaphysis of long bones, although it can arise in the axial skeleton as well. Patients are typically treated with systemic chemotherapy and surgical resection of the primary tumor as well as sites of metastatic disease. Osteosarcoma is generally not radiosensitive, and radiation therapy is typically not done.[51,52] Ewing sarcoma is the second most common pediatric bone sarcoma, with approximately 200 children diagnosed annually in the United States.[50] The tumor most commonly arises in the diaphysis of long bones, although it can also arise in the axial skeleton or in soft tissue sites. The tumor is thought to develop from primitive embryonic cells that give rise to the parasympathetic nervous system. The presence of the EWS-FLI-1 translocation confirms the diagnosis of Ewing sarcoma.[53] Patients are treated with intensive systemic chemotherapy as well as surgical resection and/or radiation therapy because the tumor is highly radiosensitive.[54,55] Rhabdomyosarcoma is the most common soft tissue sarcoma seen in pediatric patients, with approximately 350 cases diagnosed annually in the United States.[47] Because it shares markers of primitive embryonic precursors of skeletal muscle, it was historically thought to be a tumor of primitive muscle precursors. However, rhabdomyosarcoma may develop in areas of the body where no skeletal muscle exists, thus the cell of origin for rhabdomyosarcoma remains an area of active research.[56] Treatment typically is multidisciplinary and includes systemic chemotherapy, radiation therapy, and/or surgical resection, which is determined by an extensive risk classification system that incorporates histologic subtype and cytogenetics, tumor-node-metastasis stage, and the location of the primary tumor.[57–60] Pediatric sarcomas most commonly metastasize to the lungs or other bony sites. The presence of metastatic disease at diagnosis is a poor prognostic indicator. Staging evaluation includes CT or magnetic resonance imaging of the primary tumor, chest CT to evaluate for pulmonary metastases, and bone scintigraphy to evaluate for bone metastases. Recent data have suggested that ^{18}FDG-PET/CT may be more effective to identify bone or soft tissue metastases.[61–63]

Outcomes for pediatric sarcomas have not changed in several decades, obviating the need for novel molecular targets and approaches. Recent work has focused on improved understanding of the biology behind these tumors to identify novel agents that can be tested in early-phase clinical trials. These include but are not limited to tyrosine kinase inhibitors, histone deacetylase inhibitors, mechanistic target of rapamycin inhibitors, immunomodulatory agents such as nivolumab, and chimeric antigen receptor T-cell therapies, all of which show promise, and are under active investigation. The hope is that a better understanding of sarcoma biology will yield novel targets to exploit and lead to improved outcomes (Table 54–1).

CHILDHOOD CANCER SURVIVORSHIP

Epidemiology of Childhood Cancer Survivors

Cure rates for children with cancer have improved dramatically over the past 70 years, with current cure rates estimated to be approximately 80%.[64] This has led to a large and increasing population—as many as 500,000 survivors currently living in the United States—of childhood cancer survivors (those who are alive 5 years after their initial diagnosis) who have unique physical, mental, and psychosocial health needs.

Late Effects in Childhood Cancer Survivors

As cure rates for children and adolescents diagnosed with cancer were improved, it became important to understand the degree to which patients' cancer diagnoses and treatment impacted their lives moving forward. The Childhood Cancer Survivorship Study (CCSS) was one of the first and largest cohort studies to report the long-term outcomes for young patients treated for cancer.[65] The CCSS reported that the lifespan of childhood cancer survivors is significantly lower than the general population.[66] Early deaths between 5 and 10 years post diagnosis were mostly secondary to disease relapse or disease progression. Importantly, two-thirds of survivors will have at least one chronic health condition, whereas one-third will have at least one severe or life-threatening illness.[67] Long-term side effects of therapy, those occurring more than 5 years after diagnosis, are common and span all areas of health and well-being. Risk factors for some of the most severe late effects include: exposure to anthracyclines and/or radiation for the development of cardiovascular dysfunction; radiation to the CNS for the development of neurocognitive deficits, endocrinopathies, and secondary CNS tumors; and radiation to the chest for the development of breast and thyroid cancer.[68–70] Survivors at risk for late effects should be seen in a specialized survivorship program and the Children's Oncology Group

Table 54–1

Pediatric Neoplasm	Novel Agents	Molecular Target
Leukemia		
Acute lymphoblastic leukemia	Blinatumomab	Bispecific T-cell engager; targets CD19
	Inotuzumab	ADC; targets CD22
	Tisagenlecleucel	Chimeric antigen receptor T-cell therapy; targets CD19
Acute myelogenous leukemia	Gemtuzumab ozogamicin	ADC; targets CD33
	CPX-351	Liposomal formulation of cytarabine and daunorubicin
	Venetoclax	BCL-2 inhibitor
Lymphoma		
Hodgkin lymphoma	Brentuximab vedotin	ADC; targets CD30
	Nivolumab, pembrolizumab	Anti–PD-1
Non-Hodgkin lymphoma	Axicabtagene ciloleucel	Chimeric antigen receptor T-cell therapy; targets CD19
Central Nervous System Tumors		
	Selumetinib, vemurafenib, trametinib	MEK 1/2 inhibitor
	Veliparib	PARP inhibitor
	Dabrafenib	BRAF inhibitor
	Vorinostat, entinostat	HDAC inhibitor
	Bevacizumab	VEGF-A inhibitor
	Pembrolizumab, nivolumab	Anti–PD-1
	Indoximod	IDO inhibitor
Non-Neural Solid Tumors		
	Dinutuximab	Anti-GD2
	Crizotinib	ALK and ROS1 inhibitor
	Pembrolizumab, nivolumab	Anti–PD-1
	Ipilimumab	Anti–CTLA-4
	Pazopanib	VEGFR, PDGFR and FGFR Inhibitor
	Cabozantinib	C-MET, VEGFR-2 and AXL Inhibitor
	Palbociclib	CDK4 and CDK6 Inhibitor

publishes guidelines for the risk-based screening and management of late effects (www.survivorshipguidelines.org).

Improvements in Long-Term Survival

Long-term outcomes for children and adolescents treated for cancer are improving, with patients diagnosed in the 1990s living significantly longer than patients diagnosed in the 1970s.[71] This is likely the result of both more effective upfront therapies, resulting in fewer late relapses, as well as reduction in some of the most toxic therapies. For example, anthracycline doses are capped for most patients to reduce cardiotoxicity, patients with ALL receive intrathecal chemotherapy instead of cranial spinal radiation, patients with CNS tumors rarely receive radiation therapy before the age of 2, and fewer patients with HL receive radiation to the chest because of response-based treatment.[22,72] With the use of newer immunotherapies, it will be important to determine the potential late effects associated with these novel treatments.

CONCLUSION

We have made remarkable advances in pediatric cancer treatment outcomes. The challenge for the future is to identify and employ novel treatment strategies for pediatric neoplasms whose outcomes remain suboptimal and have not changed in decades. New treatments will lead to more progress and even better outcomes.

MD ANDERSON PRACTICE TIPS

- The efficacy of blinatumomab in pediatric patients with relapsed/refractory ALL was demonstrated in an international, single-arm phase 1/2 study and will now be incorporated in the frontline treatment of ALL. Blinatumomab, CD19 single-targeting chimeric antigen receptor T-cell therapy, and stem cell transplant can be considered in the relapse setting.
- In relapsed AML, the use of CPX-351, a liposomal formulation of cytarabine and daunorubicin, demonstrated favorable responses and will now be randomized as a frontline strategy. Recently, the BCL-2 inhibitor venetoclax has shown promising activity in combination with hypomethylating agents and low-dose cytarabine and should be considered in treatment-refractory cases.
- In HL, novel anti-PD1 nivolumab and anti-CD30 antibody conjugate brentuximab vedotin have shown meaningful activity in treatment-refractory cases. The use of these agents as part of frontline therapy or instead of autologous stem cell transplant in a relapsed setting is being studied.
- Molecular testing of LGGs has identified translocations of BRAF in 70% of LGG, whereas the *BRAF* V600E mutation occurs in 5% to 10%, with a potential response to selumetinib and vemurafenib, respectively.
- In medulloblastoma, recent genomic studies have identified four subtypes with distinct cellular origins, clinical characteristics, and outcome, namely WNT, Sonic Hedgehog (SHH), Group 3, and Group 4. The WNT and Group 3 subtypes have the best and worst prognosis, respectively. Patients in inferior-outcome molecular subgroups are encouraged to participate in clinical trials.
- Outcomes for pediatric sarcomas have not changed in several decades, obviating the need for novel molecular targets and approaches. The use of tyrosine kinase inhibitors, histone deacetylase inhibitors, mechanistic target of rapamycin inhibitors, immunomodulatory agents such as nivolumab, and chimeric antigen receptor T-cell therapies all show promise and are under active investigation.

KEY CONCEPTS

- The cancer genomics era has been driven by rapid technological and computational advancements, which have enabled large-scale multidimensional analyses of rare and common cancers and precursor lesions.
- The vast majority of human cancers are characterized by both inter- and intratumor molecular heterogeneity, which adds further complexity to the identification of robust and clinically useful biomarkers.
- Clonal molecular evolution is evident throughout multiple stages of tumor development and has critical implications for the development of treatment resistance and metastasis.
- Driven by the development of cost-effective and robust clinical next-generation sequencing (NGS) assays, somatic mutation profiling has been broadly integrated into clinical practice for patients with hematologic malignancies and advanced solid tumors. The long-term clinical benefit of comprehensive mutation profiling remains to be defined.
- Despite the widespread application of tumor mutation profiling in practice, interpretation of the results and therapeutic decision making remains challenging. Institutional resources and/or publicly available decision tools should be consulted to help guide providers and patients.
- Large-scale studies such as the NCI-MATCH study and the MD Anderson IMPACT study, provide a critical framework for matching patients with biomarker-driven clinical trials, which is a hallmark of precision oncology.

CANCER GENES: HISTORICAL PERSPECTIVE

Over the past 50 years, multiple discoveries have had an impact on our understanding of key genomic events that influence the development of malignant growth. After many large-scale sequencing projects of cancer genomes, we now understand that many genetic alterations in specific cancer genes are responsible for the development and progression of the disease. These alterations may occur at the level of the patient's germline, predisposing to inherited forms of cancer that may develop in many tissues throughout the body. Genetic alterations may also be somatic, or newly acquired changes within the genes of an individual cell or group of cells over time, and a result of environmental stresses. Somatic alterations may come in many forms, including single-base substitutions, insertions or deletions of DNA fragments, rearrangements and rejoining of DNA from alternative locations in the genome, and copy number increases and reductions. Should these alterations affect key cancer genes, malignancy may develop.

In the early 1970s, the study of retroviruses that reverse transcribe RNA into DNA found that certain retroviruses, when incorporated into host cells, have the ability to transform normal cells into rapidly dividing tumors.[1] Rous sarcoma virus, isolated by Peyton Rous, was the first retrovirus found to cause sarcoma in chickens.[2] Later, hybridization studies proved that the Rous sarcoma virus gene, termed *v-src*, was homologous to a highly conserved eukaryotic gene, *c-src*. *Src* became the first known viral oncogene.[3] In contrast to highly transforming retroviruses, weakly transforming viruses can insert themselves into the genome near proto-oncogenes—normal genes that when mutated give rise to an oncogene—and induce cancer. Activation of proto-oncogenes to oncogenes, through activating point mutations, gene amplification, or

chromosomal translocation events, can occur independent of retroviral transformation and cause cancer.

In 1981, Shih and colleagues showed that normal NIH3T3 mouse fibroblast cells could be made cancerous by the introduction of total genomic DNA from human cancers.[4] Isolation of the specific DNA segment responsible for this transforming activity led to the identification of the first naturally occurring, human cancer–causing sequence change—the single-base G > T substitution that causes a glycine-to-valine substitution in codon 12 of the *HRAS* gene.[5] These experiments demonstrated the causal relationship between oncogenic mutations and cancer. The discovery of *HRAS* and many other oncogenes altered our understanding of cancer and expanded our knowledge of driver mutations that can be targeted to treat disease.

Another commonly referenced class of cancer-related genes is the tumor suppressor gene. Such genes are frequently involved in cell-cycle regulation, inhibition of cellular proliferation, and DNA repair. When functioning normally, they act as barriers to unregulated tumor growth. However, dysfunction of both copies of the gene are usually required to initiate tumor development because only one functioning copy is needed to regulate the cell. In 1971, Alfred Knudson was the first to theorize about the role of tumor suppressor genes in cancer development.[6] He described the two-hit hypothesis: The development of cancer was caused by the loss of inherited regulatory genes that functioned to suppress tumor formation, subsequently followed by the somatic loss of the normal homologous allele. In nonhereditary forms, both alleles would be somatically affected.[6,7]

The first tumor suppressor gene to be identified was the retinoblastoma (*RB*) gene, found to cause childhood cancers of the retina. In the hereditary form, one copy of the *RB* gene is usually defective, with a second mutation or deletion of the normal gene leading to early cancer development. Hereditary forms frequently affect the bilateral eyes. Sporadic retinoblastoma is much rarer and occurs when there is homozygous deletion or somatic mutation of both normal copies of the gene. Sporadic retinoblastoma usually presents later in life than the hereditary form and usually effects only one eye.

In the mid-1980s, Webster Cavenee and colleagues localized the retinoblastoma gene to a small region on chromosome 13 and found that both the inherited and sporadic varieties had the same secondary abnormalities, leading to homozygosity of mutations in the *RB* region.[8] In 1986, Friend et al isolated human complementary DNA mapping to the *RB* gene.[9] The following year, Fung[10] and Lee[11] both cloned *RB* using chromosome walking.[10,11] Huang and colleagues later proved a causative relationship between the defective *RB* gene and cancer by performing rescue experiments of the neoplastic phenotype in *RB*-mutated retinoblastoma cells with wild-type *RB*.[12] Aside from retinoblastoma, many tumors have subsequently been found to have defects in the *RB* gene, which may play a role in the establishment of these cancers.

NEXT-GENERATION TOOLS IN THE CANCER GENOMICS ERA

Pivotal studies of the 1980s and 1990s gave rise to the fundamental concept of cancer as a genetic disease. However, it was the completion of the Human Genome Project[13] in April 2003, and subsequent publication of the first human reference genome, that created a new era of opportunity for systematic discovery and characterization of somatic alterations in cancers.[14–16] This era has expanded rapidly in both scale and scope—that is, moving beyond a catalog of somatic DNA alterations and toward higher-order aspects of tumor biology.

Early studies of vertebrate and invertebrate genomes relied heavily on Sanger's "dideoxy method," in which a single large DNA fragment of interest (up to ~1000 base pairs [bp] in length) is amplified and then sequenced using chain-terminating polymerase chain reaction (PCR) with fluorescently-labeled nucleotides.[17] Indeed, de novo assembly of the first reported human genome succeeded largely through the implementation of costly and labor-intensive Sanger sequencing efforts in parallel, which simultaneously highlights its robustness and limitations as a sequencing approach in the context of complex diseases.[18] Achieving a better understanding of complex genetic diseases on a population level required novel high-throughput approaches that prioritized cost efficiency and scale. Accordingly, within the past two decades, this challenge has been met with the rapid development and application of next-generation sequencing (NGS) methods.[14,15,19]

To better appreciate the advantages and limitations offered by NGS technology, it is helpful to consider at least two important characteristics shared across the variety of platforms currently in use.[20–22] First, the majority of NGS technology development has centered on short-read sequencing, wherein a library of millions of variable-length DNA fragments are read simultaneously using a polymerase- or ligation-based sequencing-by-synthesis reaction, producing reads of 35 to 400 bp. Paired-end short-read sequencing is a variation of this approach in which both ends of each small DNA fragment are read. Among other properties, short-read sequencing enables massive parallelization, which consequently lowers the per-base pair and per-run costs of DNA sequencing. Importantly, however, making use of short-read NGS output (which can range from 600 megabases [Mb] to 15 gigabases [Gb] of data in a single instrument run)

also requires the computationally intensive and error-prone step of realigning (or mapping) individual reads to a reference genome. Therefore, in parallel with the emergence of novel sequencing-by-synthesis chemistries, a multitude of computational tools have been developed to robustly and efficiently align short-read NGS data against a reference genome.[23] This step may then be followed by any number of downstream analyses, most importantly the detection of single-nucleotide variations (SNVs), short insertions or deletions (indels), and large structural alterations (such as copy number gain, loss, or translocation) all by comparison with a reference genome. A second shared characteristic of NGS technology is the ability to process DNA from multiple samples in parallel. This is achieved through in vitro capture, barcoding, amplification, and pooling of small DNA fragments isolated from different samples of interest. The NGS output is then demultiplexed computationally so that reads for each sample can be analyzed separately. Commonly used next-generation platforms include the Illumina and Ion Torrent systems. In just more than a week, a solitary run on an Illumina HiSeq 4000 sequencer can generate 200 GB of data.

Building on this technological platform, cancer genomics studies have applied NGS towards a number of different goals, each focused on interrogating unique aspects of complex tumor biology. With respect to systematic discovery of DNA mutations in cancer, common NGS applications include whole-genome, whole-exome, and targeted-exome sequencing of tumor samples. NGS-based approaches are also widely used for the analysis of messenger RNA (mRNA-seq) and epigenetic markers.

In research settings, DNA from bulk fresh/frozen tumor tissue is sequenced and compared against a "normal" or (germline) reference genome, which is derived either from a matched normal tissue sample from the same individual patient or a panel of unmatched normal tissue samples from a population of patients. By comparison against the normal reference genome, the goal of tumor NGS DNA analysis is to identify somatic (rather than germline) mutations. More recently, single-cell sequencing (eg, single-cell RNA-seq) has massively expanded our insights into the clonal structure of tumor cell and stromal cell populations within a single sample.[24]

INSIGHTS FROM LARGE-SCALE SEQUENCING OF CANCER GENOMES

The overarching goal of the cancer genomics era has been to discover novel and clinically meaningful insights into the pathogenesis and molecular evolution of cancers. Toward this goal, several large-scale profiling studies have been undertaken over the past 10 years, including The Cancer Genome Atlas and the International Cancer Genome Consortium. Together, these studies have set out to systematically characterize the multidimensional landscape of several different tumor types.[25,26] In the sections below, we summarize key insights gained from this work.

Tumor Mutation Burden and Mutation Signatures

Although some cancer types may be driven by a single alteration alone, others may contain driver mutations in multiple different genes, each contributing to various aspects of tumor initiation, invasion, proliferation, and metastasis. For example, leukemias and other hematologic malignancies tend to harbor somatic mutations in approximately 9.6 genes per tumor.[27,28] By comparison, solid organ tumors such as colon, breast, brain, and pancreas contain an average of 33 to 66 genes with coding sequence mutations.[28] Within these solid tumors, the most common type of somatic alterations are SNVs (90.7% missense, 7.6% nonsense, and 1.7% alterations of splice sites or untranslated regions) and the remainder are indels.[28]

In many cases, the difference between the mutational landscape of one tumor type versus another is a reflection of varying toxic environmental factors or mutational processes that are prevalent within each tumor type. This phenomenon can be observed not only with respect to the number of mutations in a given tumor (ie, tumor mutation burden), but also the specific distribution of SNVs (ie, a mutation signature). As an example, acquired or inherited defects in DNA repair mechanisms—such as in the Fanconi pathway, the DNA mismatch repair pathway (Lynch syndrome), or the proofreading domains of DNA polymerases *POLE* or *POLD1*—are associated with markedly increased tumor mutation burden.[29,30] Even tumors of the same type may display a wide distribution of mutation frequencies. In 2013, Lawrence et al published a study examining 27 different cancer types, showing a wide variance in the frequency of nonsynonymous mutations that ranged more than 1000-fold across cancers within a given subtype (Fig. 55–1).[31] As previously described, this study showed a high frequency of mutations in melanoma and lung cancer, thought to be caused by ultraviolet radiation and tobacco carcinogen exposure, respectively, with more than 100 mutations/Mb. The frequency of mutations in melanoma and lung cancers was also quite variable, however, ranging from 0.1 to 100 mutations/Mb. Although less extreme than the latter cancers, mutation frequencies observed in acute myelogenous leukemia ranged widely from 0.01 to 10 mutations/Mb. This was despite the overall low number of mutations (0.37/Mb).[31] Furthermore,

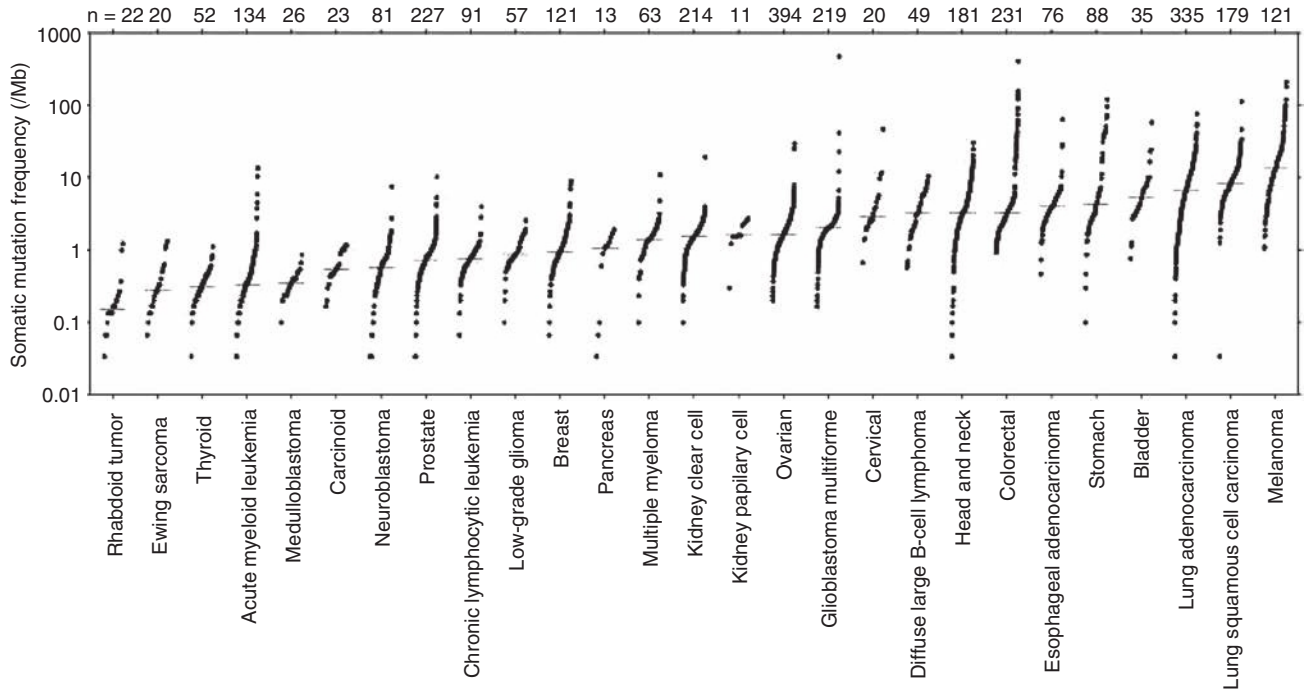

FIGURE 55–1 Whole-exome somatic mutation frequencies in 3083 tumor-normal pairs. Each dot represents a tumor-normal pair. The *y* axis is the total somatic mutation frequency. Tumor types are ordered on the *x* axis (lowest to highest) by their median somatic mutation frequency. (Reproduced with permission from Lawrence MS, Stojanov P, Polak P, et al. Mutational heterogeneity in cancer and the search for new cancer-associated genes. *Nature*. 2013;499[7457]:214-218.)

Alexandrov and colleagues analyzed NGS sequencing data from 7042 cancers and demonstrated that these tumors exhibited greater than 20 discrete mutational signatures based on the distribution of transition and transversion alterations. Some signatures could be found across cancer types (ie, APOBEC cytidine deaminase signature), and other signatures were found in a single cancer class. Kataegis, or regional hypermutation, was also found in many cancers.[32]

Despite the number of mutations present, not all mutations contribute to the production and growth of tumor cells. Identifying the background mutation rates for tumors as described previously was integral to our understanding of those genes that play a key role in the development of the tumor and confer a selective growth advantage. These alterations in genes are termed *driver* mutations. Those genes that are present within the tumor but do not contribute to tumor formation are deemed *passenger* mutations.[33] Driver mutations may not all contribute to tumor growth in the same manner, and some driver mutations may be integral to certain steps of tumor development (proliferation vs invasion). Common driver mutations that occur in cancer genes include *PTEN, EGFR, TP53, IDH1, RB1, KRAS,* and *BRAFI.*[34] In addition, some mutations originally deemed passenger mutations may become drivers once treatment leads to eradication of sensitive clones and provides a niche for already present, resistant clones to develop.[35]

Functional Impact of Structural Alterations in Cancer

Chromosomal gains, losses, and translocations are some commonly observed hallmarks of cancer. Somatic copy number alterations may span the entire chromosome or one arm of a chromosome, although they may be limited to particular regions of the genome.[36] It has been reported that an average cancer cell may have gains or losses involving a quarter of its chromosomes, with smaller, local events affecting about 10% of the genome.[37] Many of these focal events occur in "peak" regions, affecting a median of 6 to 7 genes (although up to 150–200 genes in some cases). Because of the broader effect of amplification and deletion events, it is difficult to interpret which genetic alterations contribute to carcinogenesis.[38,39]

Chromosomal translocations are associated with both hematologic and solid organ malignancies, particularly leukemias, lymphomas, and sarcomas. In some tumors, translocations can result in the fusion of genes normally found at a distance from each other or bring genes closer to enhancer or promoter elements, resulting in alteration in their normal expression patterns. The number of translocations may differ between

cancers depending on their degree of genomic instability.[40] As discussed further in the chapter, translocations can become targets for cancer treatment.

Tumor Heterogeneity and Clonal Evolution

Molecular and phenotypic heterogeneity is a hallmark of human cancer. As outlined above, not only do different tumor types harbor varying numbers of mutations, but even different sets of driver mutations can give rise to the same tumor type. Conventionally, this is referred to as *intertumoral*. In melanoma, for example, *BRAF* mutations are present in about 50% to 60% of patients, allowing for the majority, but not all, patients to benefit from *BRAF* inhibitors.[41,42] Intertumoral heterogeneity therefore may have profound implications for antineoplastic drug development, because an individual patient's tumor may respond to a drug differently depending on the presence or absence of the target of interest. The challenges of integrating NGS profiling in clinical development are outlined later in this chapter.

Furthermore, although mutations may vary among individuals with the same type of cancer, individual tumors and/or their metastatic lesions may also have cells with distinct mutations and, by extension, phenotypes. This is termed *intratumoral* heterogeneity.[43] This added complexity may account for partial responses to treatment and therapeutic resistance within an individual when treated with chemotherapy or targeted agents. Two classically described theories regarding the development of intratumoral heterogeneity include the cancer stem cell hypothesis and the clonal evolution model. In the cancer stem cell hypothesis, it is suggested that a small, distinct population of cells retain the ability to grow and divide. These cells are responsible for the maintenance of the tumor. As is seen with noncancerous stem cells throughout the body, epigenetic modifications can cause these cells to differentiate into their biologically diverse nonrenewable constituents. These diverse, differentiated cancer cells compose the bulk of the tumor, yet do not necessarily contribute to its expansion and tumorigenic potential.[44] In the clonal evolution model, with time, genetic and epigenetic events accumulate in cells; if these changes confer a competitive advantage, they will allow selective growth of distinct clones that survive over others.[44] It is possible that both phenomena can occur in the same tumor. Figure 55–2 depicts the two models.[45]

The expansion of subclones may occur in a linear or branched fashion.[46] In 2012, Gerlinger and colleagues published a paper in the *New England Journal of Medicine* using multiregional whole-exome sequencing of four renal cell carcinoma samples to elucidate the subclonal architecture and branched evolution of the disease. They found that the majority of driver alterations were subclonal, which acted as a confounder when identifying pertinent driver mutations. This study also demonstrated the unconventional pattern of mutations with regional patterns of heterogeneity. Mutational convergence was also seen with multiple subclonal mutations found in the same driver genes, however at different loci.[43]

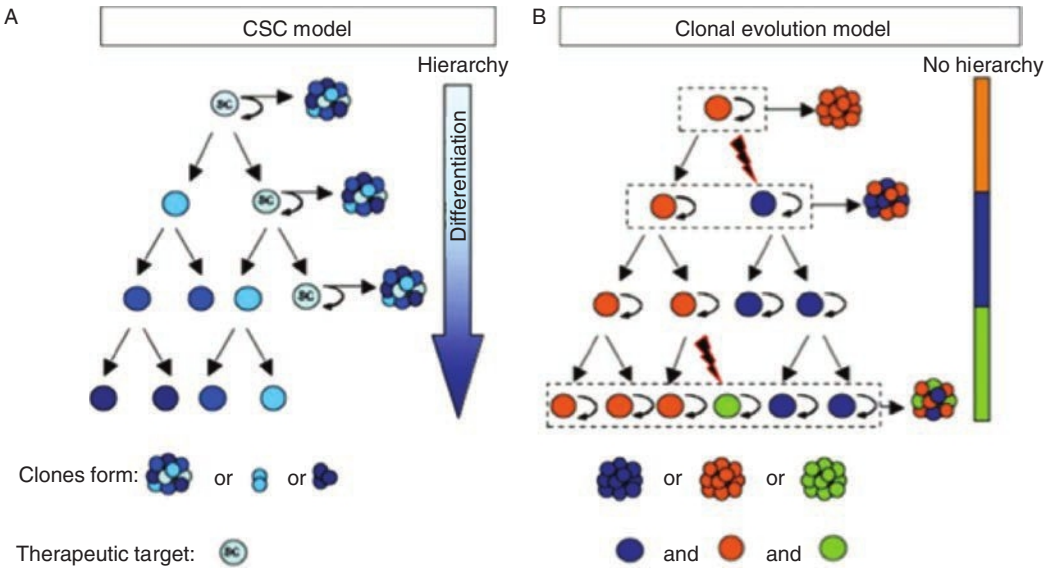

FIGURE 55–2 Models of intratumoral heterogeneity. (A). The cancer stem cell model: a specialized subpopulation of cancer cells possesses the capacity of self-renewal and differentiation. This leads to formation of a hierarchical lineage system of subclones (B). The clonal evolution model: genetic mutations lead to multiple cell populations without distinct cellular hierarchy. Most cells are assumed to retain self-renewing capacity. CSC, cancer stem cell. (Adapted with permission from Laks DR, Visnyei K, Kornblum HI. Brain tumor stem cells as therapeutic targets in models of glioma. *Yonsei Med J.* 2010;51[5]:633-640.)

In stark contrast to the former study, in 2015, Zhang and colleagues and Bruin and colleagues published two studies concurrently in *Science* examining multiregional samples from non–small cell lung cancer specimens.[47,48] Unlike renal cell carcinoma, the mutational architecture of the lung-cancer specimens showed more limited branching of subclones, with the majority of driver mutations being truncal. Patients whose disease relapsed also had a higher degree of subclonal mutations than those whose disease did not. Smoking-related mutations decreased over time, despite an increase in APOBEC-associated mutations. This may speak to an etiology of treatment resistance as a result of increased diversity of alterations.[47] Similar conclusions have also been made in the case of colorectal cancers.[49,50] Dang et al performed whole-genome and targeted deep sequencing of paired primary and metastatic tumor samples in patients with metastatic colorectal cancer. Although many truncal driver mutations were shared between primary and metastatic tumors, their analyses also revealed evidence of subclonal heterogeneity between different metastatic foci (including clones that were not observed in the primary tumor). This finding suggests polyclonal seeding from both the primary tumor and, potentially, metastatic tumors as well.

Altogether, these studies highlight vast differences between the patterns of intratumoral heterogeneity between cancer subtypes and the need for a greater understanding of how such heterogeneity impacts personalized cancer therapy. Indeed, the optimal framework or model for understanding clonal evolution in cancers remains the subject of intense study and debate.[51,52]

Molecular Landscapes of Premalignancy

Importantly, the molecular complexity of cancer revealed through large-scale NGS profiling must also be reconciled with (and refine) classic models of tumorigenesis. In a simplified model, the stepwise transformation of normal human tissue into invasive/malignant tumors is driven by sequential acquisition and selection of mutations that give a growth advantage to the cells in which they occur. In Fig. 55–3, we show how this model has been used to describe the acquisition of mutations during progression of myeloproliferative neoplasia and how this has an impact on clinical outcomes.[53] Here, for example, myeloproliferative neoplasms have been classified as *JAK2* or *TET2* mutation–positive or –negative. Those positive for both mutations can then be further examined to assess whether the order of mutation acquisition has an impact on phenotype, clinical presentation, and outcomes. The *TET2*-first tumors gain a self-renewal advantage but do not overdivide. Secondary *JAK2* mutants then compete with the *TET2*-alone clones, leading to overpopulation of terminal cells. When

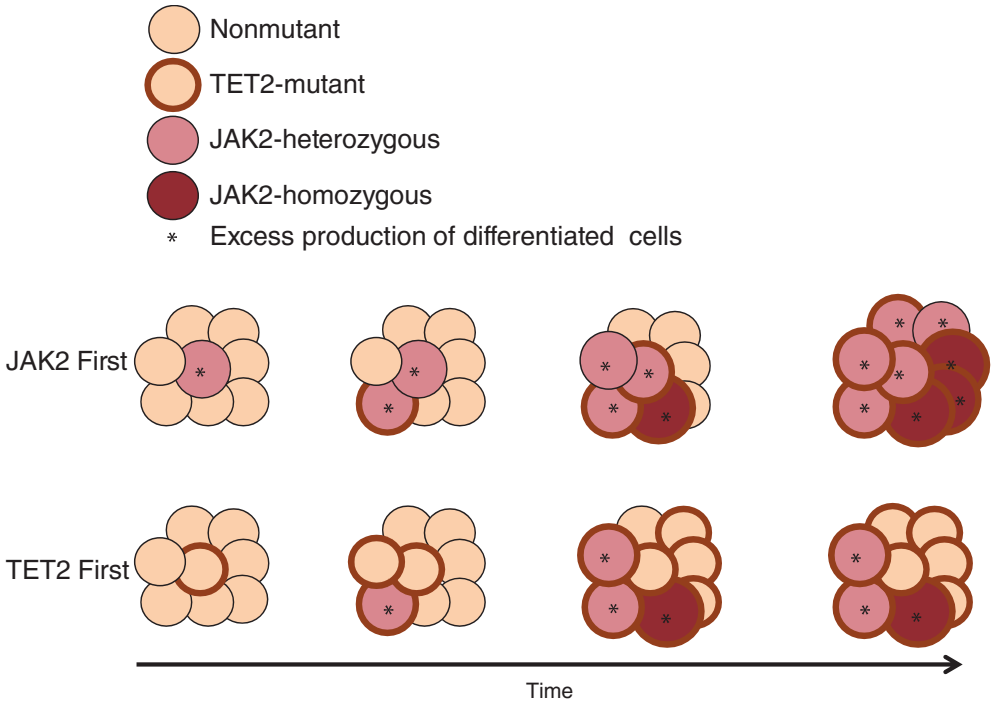

FIGURE 55–3 **Multistep cancer progression of myeloproliferative neoplasia: order of mutation acquisition influences the evolution of disease. This model depicts single hematopoietic units acquiring mutations over time.**

JAK2 homozygosity occurs as a last event, this clone has limited space to expand. This may account for the slower clinical presentation of *TET2*-first mutants. The *JAK2*-first mutants produce excess differentiated cells. After secondary *TET2* mutation acquisition, stem cells obtain a self-renewal advantage, and *JAK2–TET2–* mutant cells expand.

Loss of heterozygosity of *JAK2* V617F (either before or after *TET2* mutation) leads to expansion and resultant excess of differentiated cells. Subsequently, *JAK2*-first patients present more frequently as having polycythemia vera and have an elevated risk of thrombotic events.

An accurate understanding of the sequence of mutational events leading to cancer will allow us to build more reliable tumor models that recapitulate the evolution of the cells from normal to malignant phenotype. Furthermore, this understanding will guide the development of novel, personalized approaches for cancer interception and early detection. Toward this end, multiple large-scale collaborative efforts are now ongoing, under the umbrella of the National Institutes of Health precancer atlas initiative, to systematically characterize the landscape of pre-invasive and normal human tissue.[54] Thus far, one important perspective gained from these efforts is the prevalence of cancer-associated somatic DNA mutations in histologically normal tissue, a phenomenon conventionally known as "field cancerization."[55] For example, in 2019, Yizhak and colleagues performed next-generation RNA sequencing of approximately 6700 normal tissue samples from 29 different anatomic sites.[56] Their analyses revealed evidence of a mosaic clonal expansion of histologically normal cells with cancer gene and hotspot mutations. The rate of somatic mosaicism was highest in sun-exposed skin, lung, and esophageal tissue and was positively correlated with age, which provides evidence for both environmental and age-related mutagenic processes.

CLINICAL CANCER GENOMICS

As our understanding of the molecular landscape of cancer has grown, so has the endeavor to translate novel insights into improved clinical outcomes for patients. Indeed, the integration of cancer genomics into clinical oncology practice is itself a rapidly evolving field that faces unique challenges.[57,58] Namely, as opposed to research cancer genomics, which uses highly selected fresh-frozen tumor tissue samples, clinical cancer genomics applications must perform robustly in the setting of limited tissue *quantity* (eg, diminutive tumor biopsy or surgical specimens) and *quality* (eg, controlling for artifacts resulting from formalin-fixation and paraffin-embedding [FFPE] or normal tissue contamination). Moreover, clinical cancer genomics applications must yield results on a clinically meaningful timescale (ie, short turnaround time).

A comprehensive review of the history of clinical cancer genomics is beyond the scope of this chapter. However, it is important to highlight milestone developments that have helped address the aforementioned challenges, especially in regard to DNA sequencing. First, with respect to limited tissue quantity, a key advancement was the development of clinical NGS assays that are suited to low-input DNA.[59,60] Before this refinement, clinical assays were limited to so-called "hotspot" mutation testing, whereby only a subset of commonly mutated exon(s) or codon(s) in known cancer genes were targeted for sequencing. However, the adaptation of enhanced PCR amplification or target enrichment methods enabled rapid expansion beyond hotspots toward full-exon coverage of an entire gene panel or whole-exome sequencing. Second, accounting for the variable quality of clinical tumor specimens required further optimization of preprocessing steps. Although FFPE is widely used for archiving clinical tissue specimens, it is also known to introduce a number of artifacts in downstream sequencing (eg, C>T transitions and increased mutation calls) as a result of nucleic acid fragmentation, DNA crosslinks, or abasic sites.[61–64] Therefore, a key refinement in clinical genomic testing has been to improve methods for DNA extraction, deparaffinization, and downstream bioinformatic filtering. Similarly, it was critical to account for the fact that many clinical biopsy specimens are truly admixtures of neoplastic and non-neoplastic (normal) tissue, which has the effect of diluting mutated DNA fragments against a library of otherwise normal DNA (eg, 1 sequencing read out of 100 may harbor a mutation, implying a variant allele frequency of 1%). As such, deep sequencing (1000× coverage) and microdissection to reduce normal tissue contamination became important strategies to achieve adequate sensitivity for subclonal mutations with low variant allele frequency.

Altogether, methodologic enhancement over the past 10 years has resulted in analytical validation and integration of a number of clinical genomic assays into Clinical Laboratory Improvement Amendments (CLIA)–accredited laboratories, each with capability to detect somatic SNVs, indels, structural alterations and/or gene fusions at low-allele fractions across a wide panel of genes. This includes commercially available assays such as Oncomine, FoundationOne® (by Foundation Medicine) and Tempus, as well as institutional assays such as the Memorial Sloan Kettering–Integrated Mutation Profiling of Actionable Cancer Targets (MSK-IMPACT) assay.[65–68] Notably, in addition to single variant detection, many common assays will also report tumor mutation burden and microsatellite instability, which are now established as clinically relevant biomarkers. At MDACC, we have iteratively

developed and deployed a tissue-based multigene NGS assay, targeting a panel of known cancer genes (146, as of this writing) that are commonly mutated in multiple tumor types. In addition to having adequate FFPE tumor sample, the assay requires the collection of a whole-blood specimen from the patient, which yields a source of germline DNA to serve as a control. Efforts are currently underway to expand our institutional assay to include more than 600 cancer-related genes, tumor mutation burden, and microsatellite status.

Another landmark development in the past several years has been the use of liquid biopsies. Although serum-based biomarkers are commonly used to diagnose and track cancer progression, these indicators are often not elevated or are nonspecific. In addition, they are often prognostic rather than predictive of response to therapy. Furthermore, although the tissue-based assays described above are used in many clinical contexts, it is important to acknowledge that many factors (eg, tumor location and the patient's clinical status) can make tumor biopsies technically challenging, high risk, or nondiagnostic. This is particularly a problem with solid tumors, where intratumor heterogeneity may result in subclonal mutations remaining undetected. To address these challenges, the principle innovation underlying liquid biopsies relies upon the capture of circulating tumor cells or circulating tumor DNA (ctDNA) in the bloodstream to serve as a noninvasive source for sequencing.[69] This information can then be used as a surrogate for analysis of the tumor itself.[70] Notably, ctDNA provides a real-time snapshot of the global somatic landscape for an individual cancer, which helps avoid the pitfalls of relying on a single primary or metastatic tumor as the source for tumor tissue. In 2008, Maheswaran et al demonstrated the ability to detect epidermal growth factor receptor (*EGFR*) mutations in circulating lung-cancer cells.[71] They showed that deleterious EGFR activating mutations could be detected in circulating tumor cells from 92% of patients and in 33% of matched free-plasma DNA. As was the case for tissue-based genomic assays, a number of commercially available ctDNA genomic assays—such as FoundationOne Liquid CDx and Guardant360 CDx—have been validated and deployed in CLIA-accredited clinical laboratory environments. In more recent years, circulating tumor cells and ctDNA-based mutation profiles have become surrogate markers in clinical trials.[72] In 2017, MDACC formed a multiyear partnership with Guardant Health, Inc, to develop an institutional ctDNA-based liquid biopsy. Currently, our institutional liquid biopsy assay targets the exons of 70 known cancer genes and has been deployed into clinical practice.

Routine clinical genomic testing has been integrated into the standard-of-care at MDACC in accordance with the guidelines and approvals set forth by the institutional Molecular Testing Evaluation Committee, which was established as a formal mechanism to critically appraise published literature to determine whether there is sufficient scientific *and* clinical interest for the routine use of any given genomic assay. In the case of either tissue-based or ctDNA-based somatic mutation profiling, individual providers interpret the results to determine which mutations, if any, may be actionable for the patient receiving care. This includes decision making with respect to standard-of-care therapies and also referral to biomarker-specific clinical trials. Notably, a number of tools have been developed in this setting to help guide clinical decision making. In 2017, an MDACC team lead by Meric-Bernstam published a novel resource called the Precision Oncology Decision Support (PODS),[73] which is an online tool (publicly available at www.personalizedcancertherapy.org) that reports functional annotation, relevant targeted therapies, and matched clinical trials for any given somatic alteration. Similar resources are available from the My Cancer Genome (http://mycancergenome.com) and OncoKB projects.[74,75]

PRECISION ONCOLOGY IN THE CANCER GENOMICS ERA

With the advent of NGS, as well as improvements in molecular biology (immunohistochemistry, fluorescent in situ hybridization, PCR), our ability to characterize tumors has improved. This expansion in our knowledge base has led to many breakthroughs in drug development of targeted agents. One of the first breakthroughs for targeted therapy was the discovery of the BCR-ABL translocation as the main driver for a majority of chronic myelogenous leukemia (CML) cases and a smaller subset of acute lymphoblastic leukemia.[76,77] In the 1990s, while performing a high-throughput screen for tyrosine kinase inhibitors, Novartis developed the compound STI-571 (imatinib). Druker et al conducted the first clinical trial of STI-571, demonstrating its ability to inhibit proliferation of BCR-ABL–positive CML.[78] This trial paved the way for imatinib's approval by the Food and Drug Administration (FDA) in 2001 for CML.

The success of imatinib marked an era of rapid targeted therapy development and regulatory approval. In 1998, the targeted monoclonal antibody trastuzumab was approved to treat metastatic breast cancer.[79] In 2011, the small-molecule inhibitor vemurafenib was approved by the FDA to treat metastatic melanoma.[80] These agents, and many more, are discussed in detail throughout the manual; they are highlighted here in Table 55–1, which includes a list of the FDA-approved targeted cancer therapies.[81] Note that this table does not include targeted immunotherapies, hormonal agents, or cell-cycle inhibitors discussed in other chapters.

Table 55–1 FDA-Approved Targeted Therapies

Agent	Target(s)	FDA-Approved Indication(s)
Ado-trastuzumab emtansine (Kadcyla)	HER2 (ERBB2/neu)	Breast cancer (HER2+)
Afatinib (Gilotrif)	EGFR (HER1/ERBB1), HER2 (ERBB2/neu)	Non–small cell lung cancer (EGFR exon 19 deletions or exon 21 substitution [L858R] mutations)
Axitinib (Inlyta)	KIT, PDGFRβ, VEGFR1/2/3	Renal cell carcinoma
Bevacizumab (Avastin)	VEGF ligand	Cervical cancer Colorectal cancer Ovarian and fallopian cancer Glioblastoma Non–small cell lung cancer Peritoneal cancer Renal cell carcinoma
Bosutinib (Bosulif)	ABL	Chronic myelogenous leukemia (Philadelphia chromosome–positive)
Cabozantinib (Cometriq)	FLT3, KIT, MET, RET, VEGFR2	Medullary thyroid cancer
Ceritinib (Zykadia)	ALK	Non–small cell lung cancer (ALK fusion)
Cetuximab (Erbitux)	EGFR (HER1/ERBB1)	Colorectal cancer (KRAS wild type) Squamous cell cancer of the head and neck
Crizotinib (Xalkori)	ALK, MET	Non–small cell lung cancer (ALK fusion)
Dabrafenib (Tafinlar)	BRAF	Melanoma (*BRAF* V600 mutation)
Dasatinib (Sprycel)	ABL	Chronic myelogenous leukemia (Philadelphia chromosome–positive) Acute lymphoblastic leukemia (Philadelphia chromosome–positive)
Erlotinib (Tarceva)	EGFR (HER1/ERBB1)	Non–small cell lung cancer Pancreatic cancer
Everolimus (Afinitor)	mTOR	Pancreatic neuroendocrine tumor Renal cell carcinoma Nonresectable subependymal giant cell astrocytoma associated with tuberous sclerosis Breast cancer (HR^+, $HER2^-$)
Gefitinib (Iressa)	EGFR (HER1/ERBB1)	Non–small cell lung cancer with known prior benefit from gefitinib (limited approval)
Ibrutinib (Imbruvica)	BTK	Mantle cell lymphoma Chronic lymphocytic leukemia Waldenström macroglobulinemia
Idelalisib (Zydelig)	PI3Kδ	Chronic lymphocytic leukemia Follicular B-cell non-Hodgkin lymphoma Small lymphocytic lymphoma
Imatinib (Gleevec)	KIT, PDGFR, ABL	Gastrointestinal stromal tumor (KIT^+) Dermatofibrosarcoma protuberans Multiple hematologic malignancies, including Philadelphia chromosome–positive ALL and CML
Lapatinib (Tykerb)	HER2 (ERBB2/neu), EGFR (HER1/ERBB1)	Breast cancer ($HER2^+$)
Lenvatinib (Lenvima)	VEGFR2	Thyroid cancer
Nilotinib (Tasigna)	ABL	Chronic myelogenous leukemia (Philadelphia chromosome–positive)
Olaparib (Lynparza)	PARP	Ovarian cancer (BRCA mutation)
Panitumumab (Vectibix)	EGFR (HER1/ERBB1)	Colorectal cancer (KRAS wild type)

(*Continued*)

Table 55–1 FDA-Approved Targeted Therapies *(Cont.)*

Agent	Target(s)	FDA-Approved Indication(s)
Pazopanib (Votrient)	VEGFR, PDGFR, KIT	Renal cell carcinoma
Pertuzumab (Perjeta)	HER2 (ERBB2/neu)	Breast cancer (HER2$^+$)
Ponatinib (Iclusig)	ABL, FGFR1-3, FLT3, VEGFR2	Chronic myelogenous leukemia Acute lymphoblastic leukemia (Philadelphia chromosome–positive)
Ramucirumab (Cyramza)	VEGFR2	Gastric cancer or gastroesophageal junction (GEJ) adenocarcinoma Non–small cell lung cancer
Regorafenib (Sitara)	KIT, PDGFRβ, BRAF, RET, VEGFR1/2/3	Colorectal cancer Gastrointestinal stromal tumors
Ruxolitinib (Jakafi)	JAK1/2	Myelofibrosis
Sorafenib (Nexavar)	VEGFR, PDGFR, KIT, RAF	Hepatocellular carcinoma Renal cell carcinoma Thyroid carcinoma
Temsirolimus (Torisel)	mTOR	Renal cell carcinoma
Trametinib (Mekinist)	MEK	Melanoma (BRAF V600 mutation)
Trastuzumab (Herceptin)	HER2 (ERBB2/neu)	Breast cancer (HER2$^+$) Gastric cancer (HER2$^+$)
Vandetanib (Caprelsa)	EGFR (HER1/ERBB1), RET, VEGFR2	Medullary thyroid cancer
Vemurafenib (Zelboraf)	BRAF	Melanoma (*BRAF* V600 mutation)
Vismodegib (Erivedge)	PTCH, Smoothened	Basal cell carcinoma
Ziv-aflibercept (Zaltrap)	PIGF, VEGFA/B	Colorectal cancer
Axitinib (Inlyta)	KIT, PDGFRβ, VEGFR1/2/3	Renal cell carcinoma

Recently, the FDA has required biomarker testing in conjunction with efficacy results for targeted therapy approval. One way to develop trials in line with new FDA standards is the creation of basket clinical trials, which are a relatively new clinical trial paradigm where, in principle, recruitment is based on the molecular aberration rather than the underlying tumor histology. In these trials, patients with multiple different tumor types may be receiving the same treatment. The MDACC Battle Umbrella trials have been conducted with a similar principle; patients with late-stage lung cancer were assigned to an arm of therapy based on their biomarker profile. This allowed for testing of multiple targeted therapies in a timelier fashion.

In 2015, the National Cancer Institute (NCI) launched the NCI-MATCH (Molecular Analysis for Therapy Choice) trial, with plans to initially enroll 1000 patients on targeted drug combination therapies based on molecular alterations by pathway rather than on tumor histology. Participants are randomly assigned to receive a drug specific for that genetic alteration or a treatment unknown to be particularly effective on that pathway.[82] Recently, the NCI-MATCH investigators have reported that 37.6% of 5954 patients enrolled in the study were found to have an actionable alteration, but only 17.8% could ultimately be assigned to participate in a matched drug arm.[83] These results add to a growing body of evidence showing that large-scale genomic-matched clinical trials are technically feasible, but further refinements are necessary to extend the benefits of this approach to a wider population of patients.

CONCLUSIONS

The cancer genomics era has yielded massive amounts of information and several key biological insights into the pathogenesis of many human cancers. Deep sequencing as well as single-cell sequencing has enabled us to better understand the clonal evolution of cancer, intratumoral heterogeneity, and mechanisms of resistance. Over time, this has translated into the identification of targetable somatic alterations and novel therapeutic approaches. Furthermore, decreasing costs and methodologic improvements over the past 10 years have also led to the robust integration of cancer genomics assays in clinical laboratory settings. The long-term feasibility and benefit(s) of tumor molecular profiling remain the subjects of intense study and debate. Yet ultimately the goal of this era remains true: to improve patient outcomes and quality of life.

MD ANDERSON PRACTICE TIPS

- Although the long-term benefits remain to be demonstrated, tissue- or liquid biopsy–based comprehensive tumor mutation profiling should be considered a standard-of-care for specific subsets of patients at MDACC.
- Decision-making tools such as PODS are freely available to help providers at MDACC interpret results and identify actionable alterations for individual patients.
- Tumor mutation profiles represent a snapshot of a complex and continually evolving molecular landscape. Repeat tissue biopsies and/or serial liquid biopsies may be indicated in specific settings where the loss or emergence of a biomarker (eg, a mutation conferring resistance) would lead to a change in therapy.
- Tumor mutation profiling should not be a substitute for germline genetic testing. Therefore, patients in whom a hereditary cancer syndrome is suspected should be referred for clinical genetic counseling and testing, if indicated.
- Basket trials or umbrella trials should be considered for patients found to have actionable mutations based on clinical tumor profiling.
- Cross-comparison of mutation profiles from different NGS assays should be done with extreme caution, because multiple factors (eg, exon coverage, sensitivity, preprocessing) can impact the detectability of any given mutation in one assay compared with another.

KEY CONCEPTS

- Immune checkpoint therapy (ICT) targeting cytotoxic T lymphocyte antigen-4 (CTLA-4) or programmed cell death protein 1 or programmed cell death ligand 1 (PD-L1) has changed the clinical course of many cancers, with some patients achieving survival benefit and durable responses lasting for years.
- The most commonly used biomarkers for ICT are tissue PD-L1 expression, tumor mutational burden, and mismatch repair deficiency or microsatellite instability.
- Significant efforts are underway to discover biomarkers for optimal patient selection and develop combinatorial strategies to improve response.
- Immune-related adverse events (irAEs) can affect any organ and require prompt recognition and early intervention is critical.
- Chimeric antigen receptor (CAR) T-cells are engineered with a synthetic antigen receptor with high affinity for a tumor antigen coupled with a T-cell signaling domain. There are now three CAR T-cell (CAR T therapeutics approved by the Food and Drug Administration for patients with hematologic malignancies). CAR T-cells have unique toxicities, including cytokine release syndrome and immune effector cell–associated neurotoxicity syndrome, which require a high index of suspicion.
- Future areas of investigation in cancer immunotherapy include rational targeting of other immune checkpoints, refinement of CAR T-cell therapies and other cellular therapies, testing of immunotherapy earlier in the disease state (eg, neoadjuvant), combinatorial strategies, improved understanding of irAEs, and development of predictive biomarkers for toxicities and response.

THE PROMISE OF IMMUNOTHERAPY

Although the ability of the immune system to recognize and eradicate cancer was first postulated in the 19th century, proof of principle remained elusive until the 20th century. As early as 1884, Anton Chekhov observed in a letter that: "It has long been noted that the growth of malignant tumors halts for a time when this disease [erysipelas] is present."[1] Beginning in the 1890s, William Coley developed a mixture of heat-killed bacteria (Coley's toxin) that was found to induce complete tumor regression in certain patients with sarcoma and subsequently studied in various types of cancer through the 1960s with mixed clinical benefit.[2] The concept of stimulating the immune system using bacterial elements was further validated with the development of intravesical bacillus Calmette–Guérin (BCG) for superficial bladder cancer, which promotes a nonspecific inflammatory immune response and clinical benefit.[3] Over time, the discovery of the major histocompatibility complex (MHC) and T-cell receptor (TCR) in the 1980s provided insight into T-cell function that led to a number of clinical trials.[4,5] Unfortunately, many early clinical trials failed because an incomplete understanding of T-cell function. As further research led to deeper understanding of mechanisms of T-cell function, including co-stimulation and co-inhibition, the field of cancer immunotherapy has expanded rapidly with the emergence of treatments that have yielded survival advantages for many patients, such as immune checkpoint therapies (ICTs) and chimeric

antigen receptor T-cell (CAR T) therapy. Immunotherapy is now firmly established as a pillar of cancer treatment, alongside chemotherapy, radiation, and surgery.

The basic principles that guide cancer immunology are (1) immune surveillance, (2) immune editing, and (3) immune tolerance.[6] *Immune surveillance* involves scanning and eliminating the transformed nascent cells by the immune system. Although it was shown that tumor-specific antigens could be recognized by cytotoxic T lymphocytes, it was increasingly understood that antigen recognition alone was insufficient to promote immunogenicity.[7] These findings gave rise to the concept of *immune editing*, which describes how tumor cells exploit different mechanisms to become less immunogenic and eventually evade immune recognition. Immune editing involves three phases: (1) an elimination phase similar to the original concept of immune surveillance, in which host immunity serves as an extrinsic tumor suppressor; (2) an equilibrium phase, in which tumor cells survive but are held in check by the immune system; and (3) and an escape phase, when tumor cells with reduced immunogenicity or the capacity to attenuate or subvert immune responses grow into clinically apparent cancers. Finally, the principle of *immune tolerance* argues that tumor cells may not only become less immunogenic themselves but exert changes in host immunity to induce a state of functional quiescence.

These principles have formed the bedrock of development for cancer immunotherapy, as insight has been gained into interactions between tumor and host immunity, as well as the mechanisms of regulation of T-cell function. Understanding of these immunologic principles led to clinical development of immunotherapeutic agents, which will be discussed in the following sections.

IMMUNE CHECKPOINT THERAPY

T-cell activation is finely balanced by co-stimulatory and co-inhibitory molecules to prevent excess activation and autoimmunity (Fig. 56–1) and requires two main signals.[8] The first signal of T-cell activation requires interaction of the TCR on naïve T-cells with MHC molecules on antigen-presenting cells (APCs).[9] The second co-stimulatory signal requires the binding of CD28 on T-cells with B7 (CD80/86) molecules on APCs.[9] Whereas the role of T-cell co-stimulation was well-recognized for many years, the discovery of the inhibitory checkpoint cytotoxic T lymphocyte antigen-4 (CTLA-4) heralded a paradigm shift in cancer immunotherapy by providing a pathway to release T-cell inhibition and promote antitumor immunity.[10] An array of ICTs targeting the inhibitory checkpoints CTLA-4, programmed cell death protein 1 (PD-1), and programmed cell death ligand 1 (PD-L1) have been approved for a wide variety of indications and continue to evolve rapidly as novel combinations and other checkpoints are explored. The current Food and Drug Administration (FDA)–approved landscape of ICTs is listed in Table 56–2. This section aims to provide a brief overview of FDA-approved ICTs across tumor types; full details for each cancer are available in their respective chapters.

Inhibitory Checkpoints: CTLA-4

CTLA-4 is expressed by activated T-cells and competes with the co-stimulatory molecule CD28 for binding to its ligands (B7, CD80/86), thereby serving as a negative regulator of T-cell responses. Preclinical studies in murine models demonstrated that inhibition of CTLA-4 enhanced antitumor immune responses, leading to durable regression of syngeneic tumors.[10] These results led to the development of ipilimumab, a fully human immunoglobulin (Ig) G1 monoclonal antibody (mAb) against CTLA-4, which has been approved by the FDA as monotherapy in patients with unresectable or metastatic melanoma and as adjuvant treatment for patients with melanoma with pathologic involvement of regional lymph nodes larger than 1 mm who have undergone complete resection (Table 56–2).

In a randomized phase III trial, patients with metastatic melanoma received either ipilimumab with or without a peptide (gp100) vaccine or vaccine treatment alone. Ipilimumab monotherapy improved median overall survival (OS), and approximately 20% of patients who received ipilimumab had long-term survival of greater than 3 years, which led to the initial FDA approval of ipilimumab.[11] Another phase III trial in previously untreated metastatic melanoma compared ipilimumab plus dacarbazine chemotherapy to dacarbazine alone and showed a survival advantage with ipilimumab.[12] In the adjuvant setting, ipilimumab was compared with placebo investigated in patients with high-risk stage III melanoma after complete resection and demonstrated median recurrence-free survival of 46.5% for ipilimumab versus 34.8% for placebo.[13] A pooled analysis of 10 prospective and two retrospective studies showed ipilimumab increased long-term survival of approximately 20% of patients, with survival of 10 years noted for some patients.[14] Ipilimumab is currently the only FDA-approved mAb against CTLA-4, although another humanized IgG2 mAb targeting CTLA-4, tremelimumab, is under active investigation.[15]

Inhibitory Checkpoints: PD-1 and PD-L1

PD-1 is another negative regulator of T-cell response that is mainly expressed by activated CD4 and CD8 T-cells as well as APCs.[16] PD-1 has two ligands, PD-L1 and PD-L2, with distinct expression profiles. The

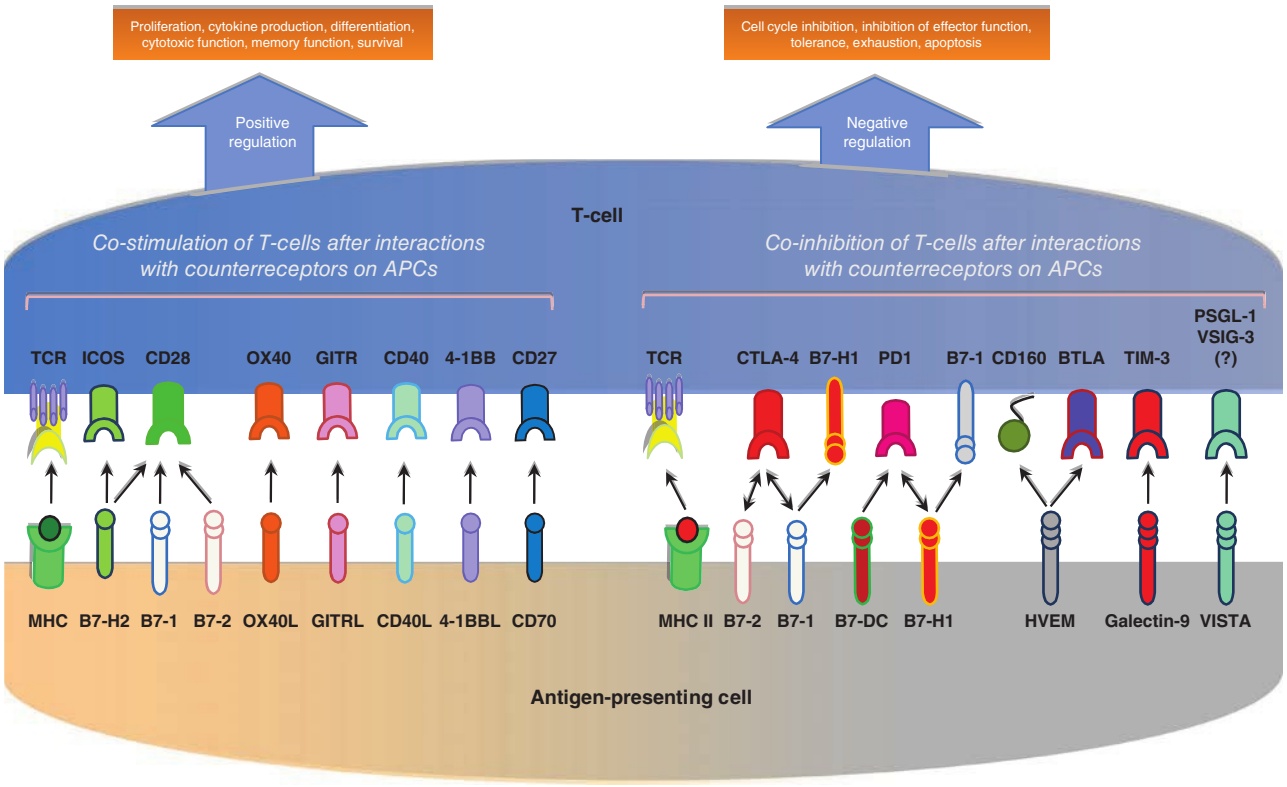

FIGURE 56–1 **T-cell activation begins with interaction of the T-cell receptor (TCR) on a T-cell with major histocompatibility complex (MHC) bound to antigen on an antigen-presenting cell (APC) (signal 1); activation of the T-cell requires additional signals that are provided by the interaction between CD28 and other co-stimulatory molecules (signal 2). T-cell activation is inhibited by co-inhibitory molecules such as cytotoxic T lymphocyte antigen-4 (CTLA-4) and programmed cell death protein 1 (PD-1). BTLA, B- and T-lymphocyte attenuator; CD40L, CD40 ligand; GITR, glucocorticoid-induced tumor necrosis factor receptor; GITRL, GITR ligand; HVEM, Herpesvirus entry mediator; ICOS, inducible T-cell co-stimulator; MHC, major histocompatibility complex; OX40, OX40 ligand; PSGL-1, P-selectin glycoprotein ligand-1; TIM-3, T-cell immunoglobulin and mucin-domain containing-3; VSIG-3, V-set and immunoglobulin domain containing 2.**

TABLE 56–1 Anti- and Protumor Arms of the Immune System

	Antitumor	Protumor
	Innate: Mature dendritic cell Tumor-associated macrophage (M1 phenotype) Tumor-associated neutrophil (N1)	Innate: Immature dendritic cell Tumor-associated macrophage (M2 phenotype) Tumor-associated neutrophil (N2)
Cellular compartment	NK cells Adaptive: CD8+ T-cells CD4+ T-cells: Th-1, Th-9, Th-17	Adaptive: CD4+ T-cells: Th-9, Th-17 T-regulatory cells
Soluble factors (cytokines)	Granzyme B, IL-1 a,b, IL-2, IL-6, IFN-g, IL-12, IL-17	TGF-b, IL-2, IL-4, IL-6, IL-10, IL-17, IL-23

IFN, interferon; IL, interleukin; NK, natural killer; TGF, transforming growth factor.

PD-L1 ligand is expressed not only on APCs but also on T-cells, B cells, and nonhematopoietic cells, including tumor cells. Expression of PD-L2 is largely restricted to APCs, including macrophages and myeloid dendritic cells (DCs), as well as mast cells. In preclinical studies, mAbs against PD-1 and PD-L1 resulted in reduction of tumor metastasis and growth in a number of experimental tumor models, which have led to an enormous array of clinical trials and a FDA approvals in various tumor types.[17,18] Currently, there are six mAbs against PD-1 (nivolumab, pembrolizumab, cemiplimab) and PD-L1 (durvalumab, atezolizumab, avelumab) FDA approved in a diverse array of cancers, including skin, genitourinary, lung, head and neck,

TABLE 56–2 List of Food and Drug Administration–Approved Immune Checkpoint Therapies as of September 1, 2020

Immune Checkpoint Therapy	Disease	Indications	References
Anti–CTLA-4			
Ipilimumab	Melanoma	Metastatic or unresectable	11,12,14
	Melanoma	High-risk stage III after complete resection (adjuvant)	13
Anti–PD-1			
Nivolumab	Colorectal cancer	Metastatic, MSI-H or dMMR, after treatment with a fluoropyrimidine, oxaliplatin, and irinotecan	65
	Esophageal cancer	Unresectable advanced, recurrent or metastatic esophageal squamous cell carcinoma after prior fluoropyrimidine- and platinum-based chemotherapy	196
	Head and neck cancer, squamous cell carcinoma	Recurrent or metastatic with progression on or after platinum-based therapy	57
	Hepatocellular carcinoma	After treatment with sorafenib	58
	Hodgkin lymphoma, classical	Relapsed or progressed after autologous hematopoietic stem cell transplant and brentuximab vedotin or after three or more lines of systemic therapy that included autologous transplant	67
	Melanoma	Metastatic or unresectable	19,20
	Melanoma	Lymph node involvement or metastatic disease after complete resection (adjuvant)	21
	Non–small cell lung cancer	Metastatic, progressive after platinum-based chemotherapy	42,43
	Renal cell carcinoma	Advanced, after antiangiogenic therapy	30
	Small cell lung cancer	Metastatic, progression after platinum-based chemotherapy and at least one other line of therapy	45
	Urothelial carcinoma	Locally advanced or metastatic with disease progression during or after platinum-containing therapy or disease progression within 12 months of neoadjuvant or adjuvant treatment with platinum-containing therapy	36
Pembrolizumab	Any solid tumor	Unresectable or metastatic MSI-H or dMMR solid tumors that have progressed after prior treatment with no satisfactory alternate treatment options	71,72
	Any solid tumor	Unresectable or metastatic TMB-H (≥10 mut/Mb) solid tumors that have progressed on prior treatment with no satisfactory alternative treatment options	73
	Cervical cancer	Recurrent or metastatic, with tumor PD-L1 CPS ≥1 and disease progression on *or* after chemotherapy	70
	Colorectal cancer	Unresectable or metastatic MSI-H or dMMR tumors that have progressed after treatment with fluoropyrimidine, oxaliplatin, and irinotecan *or* first-line treatment	66,197
	Cutaneous squamous cell carcinoma	Recurrent or metastatic cutaneous squamous cell carcinoma not curable by surgery or radiation	29
	Esophageal cancer	Recurrent locally advanced or metastatic squamous cell, with tumor PD-L1 CPS ≥10 and disease progression after one or more prior lines of systemic therapy	63,64
	Gastric cancer	Recurrent locally advanced or metastatic, with tumor PD-L1 CPS ≥1 and disease progression on or after two or more prior lines of therapy, including fluoropyrimidine- and platinum-containing chemotherapy, and if appropriate, HER2/neu-targeted therapy	61,62

TABLE 56–2 List of Food and Drug Administration–Approved Immune Checkpoint Therapies as of September 1, 2020 (*Cont.*)

Immune Checkpoint Therapy	Disease	Indications	References
	Head and neck cancer, squamous cell carcinoma	First-line treatment for metastatic or unresectable recurrent disease with tumor PD-L1 CPS ≥1 or subsequent treatment with disease progression on or after platinum-containing chemotherapy	54,55
	Hepatocellular carcinoma	After treatment with sorafenib	59,60
	Hodgkin lymphoma, classical	Relapsed or refractory after three or more prior lines of therapy	68
	Melanoma	Metastatic or unresectable	22,198
	Melanoma	Lymph node involvement after complete resection (adjuvant)	23
	Merkel cell carcinoma	Recurrent locally advanced or metastatic	24,25
	Non-small cell lung cancer	First-line stage III (not candidates for resection or definitive chemoradiation) or metastatic disease and with tumor PD-L1 expression TPS ≥1% without *EGFR* or *ALK* tumor alterations or metastatic with PD-L1 TPS ≥1% with disease progression on or following platinum-containing chemotherapy and EGFR or ALK-directed therapy if genomic alterations present	47,48
	Primary mediastinal B-cell lymphoma	Refractory disease or relapse after two or more lines of therapy	69
	Small cell lung cancer	Metastatic, with disease progression on or after platinum-based chemotherapy and at least one other prior line of therapy	49
	Urothelial carcinoma	High-risk, BCG-unresponsive, non–muscle-invasive bladder cancer with carcinoma in situ with or without papillary tumors, ineligible for or declined cystectomy	35
	Urothelial carcinoma	Locally advanced or metastatic disease ineligible for cisplatin-based chemotherapy with tumor PD-L1 CPS ≥10 or platinum ineligible regardless of PD-L1 status or patients with disease progression during or after platinum-based chemotherapy or within 12 months of neoadjuvant or adjuvant platinum-based chemotherapy	31,33,34
Cemiplimab	Cutaneous squamous cell carcinoma	Metastatic or locally advanced	27,28
Anti–PD-L1			
Atezolizumab	Non–small cell lung cancer	Metastatic disease, with progression during or after platinum-containing therapy (with progression on *EGFR*- or *ALK*-directed therapy if indicated) *or* frontline for tumors with PD-L1 tumor cells ≥50% or PD-L1 immune cells ≥10% without *EGFR* or *ALK* alterations	50–52
	Urothelial carcinoma	Locally advanced or metastatic disease ineligible for cisplatin-based chemotherapy with tumor PD-L1 immune cells ≥5% or patients with disease progression during or after platinum-based chemotherapy or within 12 months of neoadjuvant or adjuvant platinum-based chemotherapy	37,38

(*Continued*)

TABLE 56–2 List of Food and Drug Administration–Approved Immune Checkpoint Therapies as of September 1, 2020 (*Cont.*)

Immune Checkpoint Therapy	Disease	Indications	References
Avelumab	Merkel cell carcinoma	Metastatic disease	26
	Urothelial carcinoma	Locally advanced or metastatic, with disease progression during or after platinum-based chemotherapy or disease progression within 12 months of neoadjuvant or adjuvant platinum-based therapy	39
	Urothelial carcinoma	Maintenance treatment for locally advanced for metastatic UC that has not progressed with first-line platinum-containing chemotherapy	41
Durvalumab	Non–small cell lung cancer	Unresectable stage III disease after concurrent platinum-based chemotherapy and radiation therapy	53
	Urothelial carcinoma	Locally advanced or metastatic with disease progression during or after platinum-containing chemotherapy or disease progression within 12 months of neoadjuvant or adjuvant treatment with platinum-containing chemotherapy	40
Anti–CTLA-4 + anti–PD-1			
Ipilimumab + nivolumab	Colorectal cancer	Metastatic, MSI-H or dMMR, after treatment with fluoropyrimidine, oxaliplatin, and irinotecan	83
	Hepatocellular carcinoma	After treatment with sorafenib	81
	Melanoma	Metastatic or unresectable, previously untreated	77,78
	Non–small cell lung cancer	Metastatic or recurrent, without *EGFR* or *ALK* genomic tumor alterations	82
	Renal cell carcinoma	Advanced, intermediate, or poor risk, previously untreated	79,80
Anti–PD-(L)1 + targeted therapy			
Pembrolizumab + lenvatinib	Endometrial carcinoma	Advanced, non–MSI-H and dMMR with progression after prior systemic therapy and not candidate for curative surgery or radiation	94
Atezolizumab + vemurafenib + cobimetinib	Melanoma	BRAF V600 mutation-positive unresectable or metastatic melanoma	93
Pembrolizumab + axitinib	Renal cell carcinoma	Advanced, first line	91
Avelumab + axitinib	Renal cell carcinoma	Advanced, first line	92
Atezolizumab + bevacizumab	Hepatocellular carcinoma	Unresectable or metastatic hepatocellular carcinoma, first line	199
Anti–PD-(L)1+ chemotherapy			
Atezolizumab + nab-paclitaxel	Breast cancer	Unresectable locally advanced or metastatic, triple negative, with PD-L1 immune cells ≥1%	90
Atezolizumab + bevacizumab + paclitaxel + carboplatin	Non–small cell lung cancer	First line for metastatic, nonsquamous, without *EGFR* or *ALK* genomic tumor alterations	86
Atezolizumab + nab-paclitaxel/ carboplatin	Non–small cell lung cancer	Metastatic, without *EGFR* or *ALK* genomic tumor alterations	87

TABLE 56–2 List of Food and Drug Administration–Approved Immune Checkpoint Therapies as of September 1, 2020 (*Cont.*)

Immune Checkpoint Therapy	Disease	Indications	References
Atezolizumab + etoposide/ carboplatin	Small cell lung cancer	Extensive-stage, first-line treatment	88
Durvalumab + etoposide/ platinum	Small cell lung cancer	Extensive-stage, first-line treatment	89
Pembrolizumab + 5-FU/platinum	Head and neck cancer, squamous cell	First-line treatment for metastatic or unresectable recurrent disease	56
Pembrolizumab + pemetrexed/ platinum	Non–small cell lung cancer	Metastatic, nonsquamous, without *EGFR* or *ALK* genomic tumor alterations	84
Pembrollizumab + carboplatin/(nab) paclitaxel	Non–small cell lung cancer	Metastatic, squamous	85

ALK, anaplastic lymphoma kinase; BCG, Bacillus Calmette-Guerin; CPS, combined positive score; CTLA-4, cytotoxic T-cell lymphocyte antigen-4; dMMR, deficient mismatch repair; EGFR, epidermal growth factor receptor; 5-FU, fluorouracil; MSI-H, high microsatellite instability; PD-1, programmed cell death protein 1; PD-L1, programmed cell death ligand 1; TKI, tyrosine kinase inhibitor; TMB-H, high tumor mutational burden; TPS, tumor proportion score; UC, urothelial carcinoma.

lymphoma, gynecologic, gastrointestinal (GI), and select tumor-agnostic indications. These indications are summarized in Table 56–2.

Skin Cancers

Two phase III trials supported the approval of nivolumab in refractory unresectable or metastatic melanoma, as well as first-line treatment for patients with metastatic melanoma. A phase III study of nivolumab in advanced melanoma after ipilimumab achieved an objective response rate (ORR) of 31.7% for nivolumab versus 10.6% for chemotherapy alone.[19] Another trial in previously untreated metastatic melanoma without BRAF mutation showed an improved 1-year OS in patients treated with nivolumab (72.9%) compared with dacarbazine (42.1%), with a subgroup analysis showing survival advantage regardless of PD-L1 expression status on tumor cells.[20] In the adjuvant setting, a phase III study comparing nivolumab with ipilimumab demonstrated improved 12-month recurrence-free survival (70.5%; 95% confidence interval [CI], 66.1–74.5) compared with ipilimumab (60.8%; 95% CI, 56.0–65.2).[21]

Pembrolizumab has also been approved for melanoma in the metastatic or unresectable as well as the adjuvant setting. A randomized phase III trial of frontline pembrolizumab versus ipilimumab yielded 1-year estimates of survival of 74.1% for pembrolizumab and 58.2% for ipilimumab, with lower rates of high-grade toxicity with pembrolizumab.[22] A subsequent post-hoc analysis after a median follow-up period of 57.7 months reported a median OS of 32.7 months (95% CI, 24.5–41.6) for pembrolizumab versus 15.9 months (95% CI, 13.3–22.0) for ipilimumab. In the adjuvant setting for high-risk, completely resected stage III melanoma, 1 year of pembrolizumab was compared with placebo; at a median follow-up of period 15 months, the 1-year recurrence-free survival rate was 75.4% (95% CI, 71.3–78.9) with pembrolizumab versus 61.0% (95% CI, 56.5–65.1) with placebo.[23]

Immune checkpoint therapy (ICT) has transformed the care of other cutaneous malignancies for which the treatment landscape has historically been limited. In metastatic Merkel cell carcinoma, both the anti–PD-1 pembrolizumab (as well as in locally advanced disease) and the anti–PD-L1 avelumab are FDA approved.[24–26] Finally, the anti–PD-1 mAbs cemiplimab and pembrolizumab have been FDA approved in advanced cutaneous squamous cell carcinoma, a disease that previously lacked any approved systemic therapies.[27–29]

Genitourinary Cancers

As a single agent, nivolumab is approved for advanced or metastatic renal cell carcinoma (RCC) in the second-line setting after antiangiogenic therapy. In a phase III trial of nivolumab versus everolimus, OS was 25.0 months with nivolumab (95% CI, 21.8 to not estimable) versus 19.6 months with everolimus (95% CI, 17.6–23.1). Anti–PD-1 combinations with anti–CTLA-4 mAbs or tyrosine kinase inhibitors (TKIs) for RCC are discussed section later.[30]

For urothelial carcinoma, five anti–PD-(L)1 therapies have been approved. Pembrolizumab was initially approved in the second-line setting after

platinum-based chemotherapy. In a phase III study, patients with recurrent or progressive advanced urothelial carcinoma after platinum-based chemotherapy pembrolizumab demonstrated a survival advantage over investigator's choice chemotherapy (hazard ratio [HR] for death, 0.73; 95% CI, 0.37–0.88; $P = .005$).[31] Pembrolizumab also gained additional indications in the first line for locally advanced or metastatic, cisplatin-ineligible urothelial carcinoma with a PD-L1–expression combined positive score (CPS) of 10% or greater and for high-risk, non–muscle-invasive bladder cancer unresponsive to BCG with or without papillary tumor.[32–35] Nivolumab has also been approved in the second-line setting after platinum-based therapy.[36]

The anti–PD-L1 mAb atezolizumab is approved for patients with locally advanced and metastatic urothelial carcinoma who are cisplatin ineligible and whose tumors express PD-L1 (with PD-L1–infiltrating immune cells ≥5% of tumor area), in cisplatin-ineligible patients regardless of PD-L1 status, and in the second line after platinum-based chemotherapy. In a phase III trial of platinum-treated locally advanced or metastatic urothelial carcinoma, atezolizumab was compared with physician's choice chemotherapy with a primary endpoint of OS tested hierarchically in prespecified populations by PD-L1 expression status. No difference in OS was observed, although the safety profile for atezolizumab was favorable compared with chemotherapy.[37,38] Two other anti–PD-L1 mAbs, avelumab and durvalumab, have also been approved in second-line urothelial carcinoma.[39,40] More recently, avelumab garnered an indication for maintenance treatment after platinum-based first-line therapy on the basis of a phase III study demonstrating an OS of 21.4 months vs 14.3 months for best supportive care (HR, 0.56; 95% CI, 0.40–0.79; $P = .0003$).[41]

Lung Cancers

Whereas ICT was initially approved in non–small cell lung cancer (NSCLC), FDA indications have now expanded to include small cell lung cancer (SCLC) as well. ICT and chemotherapy combinations are discussed in subsequent sections. For nivolumab, phase III clinical trials in both squamous and nonsquamous NSCLC demonstrated survival advantage versus docetaxel chemotherapy after progression after first-line chemotherapy.[42,43] In these FDA approvals, patients with epidermal growth factor receptor (EGFR) or anaplastic lymphoma kinase (ALK) genomic tumor aberrations should have had disease progression on approved targeted therapy before receiving nivolumab. Notably, a phase III trial comparing first-line nivolumab with platinum-based chemotherapy in patients with PD-L1–positive (≥5%) NSCLC did not demonstrate a difference in progression-free survival (PFS).[44] Nivolumab has also been approved for metastatic SCLC in patients with progression after platinum-based therapy and at least one other line of therapy.[45]

Pembrolizumab monotherapy has been FDA approved for metastatic NSCLC in patients with tumors with PD-L1 expression tumor proportion score (TPS) 1% or greater, both in the first line and in subsequent lines after platinum-based chemotherapy (with targeted treatment for patients with EGFR or ALK aberrations as indicated), as well as in patients with stage III NSCLC who are not candidates for surgical resection or definitive chemoradiation. In a phase II/III study of pembrolizumab versus docetaxel in previously treated patients with advanced NSCLC (squamous and nonsquamous) with PD-L1 TPS of 1% or greater, improved survival with pembrolizumab was observed, including in patients with TPS of 50% or greater.[46] In the frontline setting, a phase III trial of pembrolizumab versus platinum doublet therapy in patients with PD-L1 TPS of 50% or greater showed a median OS was 30.0 months with pembrolizumab (95% CI, 18.3 to not reached) versus 14.2 months with chemotherapy (95% CI, 9.8–19.0) at a median follow-up period of 25.2 months.[47] Additionally, a phase III trial of frontline pembrolizumab versus platinum-based chemotherapy in patients with locally advanced or metastatic NSCLC with PD-L1 TPS of 1% or greater also demonstrated improvement in OS.[48] Pembrolizumab has also been approved by the FDA for patients with metastatic SCLC with progression on or after platinum-based therapy and at least one other line of therapy.[49]

Anti–PD-L1 therapies have also garnered approval in the treatment of patients with metastatic NSCLC. A phase III trial compared atezolizumab versus docetaxel and showed an OS benefit in the intention-to-treat population for atezolizumab (median OS, 13.8 months; 95% CI, 11.8–15.7 months) versus docetaxel (9.6 months; 95% CI. 8.6–11.2 months).[50,51] In the front line setting, a phase III trial of patients with metastatic NSCLC and PD-L1 expression on tumor or immune cells of 1% or greater demonstrated a statistically significant improvement in OS compared with platinum-chemotherapy in patients with high PD-L1 expression (20.2 months vs 13.1 months; HR, 0.59; 95% CI, 0.40–0.89; $P = .0106$).[52] Finally, the anti–PD-L1 mAb durvalumab carries a unique indication in patients with NSCLC as adjuvant treatment after concurrent chemoradiation for locally advanced, unresectable stage III disease that has not progressed after two to three cycles of chemoradiation. In a phase III study, consolidation therapy for 1 year (durvalumab vs placebo) after chemoradiation demonstrated a median PFS of 16.8 months in the durvalumab arm (95% CI, 13.0–18.1) versus 5.6 months in the placebo arm (95% CI, 4.6–7.8).[53]

Head and Neck Cancers

Pembrolizumab was initially FDA approved for the recurrent or metastatic head and neck squamous cell carcinoma (HNSCC) with progression on chemotherapy in a phase 1b study.[54,55] In previously untreated patients, a phase III trial in recurrent or metastatic HNSCC randomized one to one to one to pembrolizumab versus pembrolizumab plus chemotherapy (platinum and fluorouracil) versus cetuximab plus chemotherapy with improvements in OS in both the pembrolizumab combination and single-agent pembrolizumab arms, leading to the approval of pembrolizumab alone or in combination for patients with PD-L1 CPS of 1 or greater.[56] Nivolumab has also been approved for platinum-refractory recurrent squamous cell carcinoma of the head and neck. A phase III trial of nivolumab versus single-agent systemic therapy after platinum-based chemotherapy demonstrated an OS of 7.5 months for nivolumab compared with OS of 5.1 months with standard single-agent therapy.[57]

Gastrointestinal and Hepatobiliary Cancers

In hepatocellular carcinoma (HCC), both nivolumab and pembrolizumab have been approved after prior sorafenib.[58,59] Notably, although a phase III trial of pembrolizumab versus placebo in second-line HCC showed improvement in OS (13.9; [95% CI, 11.6–16.0] vs 10.6 months; [95% CI, 8.3–13.5]), it did not reach the prespecified criteria for statistical significance.[60] In gastric cancer, pembrolizumab is approved for previously treated patients with recurrent locally advanced or metastatic gastric or gastroesophageal junction adenocarcinoma whose tumors express PD-L1 (CPS ≥1). In a phase III trial of first-line pembrolizumab or pembrolizumab plus chemotherapy versus chemotherapy in patients with PD-L1 CPS 1 or greater, HER-2–negative advanced gastric cancer, pembrolizumab was found to be noninferior to chemotherapy for OS per prespecified margins, although the combination was not superior to chemotherapy alone.[61,62] For esophageal cancer, pembrolizumab has been approved for recurrent locally advanced or metastatic squamous cell carcinoma with PD-L1 positivity (CPS ≥10) and disease progression after one or more prior lines of systemic therapy.[63] In a phase III trial of second-line pembrolizumab versus investigator's choice chemotherapy (paclitaxel, docetaxel, or irinotecan), pembrolizumab demonstrated an OS benefit in patients with CPS of 10 or greater (9.3 months vs 6.7 months; HR, 0.69; 95% CI, 0.52–0.93; $P = .0074$).[64] Finally, in colorectal cancer, to date, the benefit of anti–PD-1 therapy has been limited to the high microsatellite instability (MSI-H) and deficient mismatch repair (dMMR) population. Both nivolumab and pembrolizumab are approved for MSI-H and dMMR colorectal cancer that as progressed after treatment with fluoropyrimidine and oxaliplatin or irinotecan.[65,66]

Other Cancers and Tumor-Agnostic Indications

ICTs have made headway in certain hematologic malignancies, notably in Hodgkin lymphoma, in which Reed-Sternberg cells have frequent amplification of chromosome 9p24.1, leading to overexpression of PD-L1. A phase I study of nivolumab in relapsed or refractory Hodgkin lymphoma demonstrating an ORR of 87% led to the approval in classical Hodgkin lymphoma for patients who have relapsed or progressed after autologous hematopoietic stem cell transplant and brentuximab vedotin or after three or more lines of systemic therapy that included autologous stem cell transplant.[67] Pembrolizumab also demonstrated activity in heavily pretreated patients and has been approved for refractory or relapsed classical Hodgkin lymphoma after three or more prior lines of therapy.[68] In non-Hodgkin lymphoma, pembrolizumab demonstrated activity in primary mediastinal large B-cell lymphoma and has been approved for patients with refractory disease or who have relapsed after two or more prior lines of therapy.[69] In gynecologic malignancies, pembrolizumab has been FDA approved for recurrent or metastatic cervical cancer in patients who tumors express PD-L1 with a CPS of 1 or greater, with disease progression on or after chemotherapy.[70]

Finally, in 2017, pembrolizumab garnered the first tumor-agnostic approval of a cancer treatment based on a common biomarker for unresectable and metastatic solid tumors with dMMR. In a phase II trial, 41 patients with progressive metastatic carcinoma with or without dMMR were treated with pembrolizumab, with objective response rates of 40% for dMMR colorectal cancers, 71% for dMMR noncolorectal cancer, and 0% in mismatch repair proficient colorectal cancer.[71] In a subsequent study across 12 tumor types, objective responses were observed in 53% of patients, with complete responses (CRs) in 21% of patients.[72] Pembrolizumab has also been approved for patients with high tumor mutational burden (TMB), defined as 10 mutations/megabase, on the basis of a preplanned analysis of patients in a phase II basket study of advanced solid tumors, in which the ORR was 29% (95% CI, 21–39), with 4% complete response (CR) and 25% partial response (PR) rates.[73]

Combination Anti–CTLA-4 and Anti–PD-(L)1

Because anti–CTLA-4 and anti–PD-1 target distinct inhibitory pathways in T-cells, preclinical studies have shown that concurrent targeting of CTLA-4 and PD-1 can improve therapeutic efficacy when compared to

the monotherapies.[74–76] The combination of ipilimumab and nivolumab has now been FDA approved for patients with melanoma (metastatic or unresectable), HCC, RCC, and colorectal cancer (metastatic, microsatellite unstable, or dMMR).

In a phase III trial comparing ipilimumab, nivolumab, and the combination in patients with untreated, unresectable or metastatic melanoma, the combination demonstrated statistically superior survival.[77] In the long-term follow-up, the estimated 5-year OS was 52% for the combination versus 44% for nivolumab and 26% for ipilimumab.[78] In advanced or metastatic clear cell RCC (intermediate or poor risk), the combination of ipilimumab and nivolumab was compared with sunitinib. A median follow-up period of 25.2 months demonstrated an 18-month OS rate of 75% with nivolumab plus ipilimumab and 60% with sunitinib and ORR of 42% versus 27% with CR rate of 9% versus 1%.[79] These findings were confirmed with extended follow-up (median, 32.4 months).[80] In patients with HCC previously treated with sorafenib, ipilimumab plus nivolumab demonstrated activity with an ORR of 31% and 24 months OS of 40%.[81] In a phase III study of metastatic or recurrent NSCLC, ipilimumab plus nivolumab was compared with chemotherapy and demonstrated an OS of 17.1 months (95% CI, 15.2–19.9) with the combination versus 13.9 months (95% CI, 12.2–15.1) for chemotherapy.[82] Finally, the combination of ipilimumab and nivolumab has also been approved by the FDA for patients with previously treated MSI-H or dMMR metastatic colorectal cancer on the basis of a trial showing an ORR of 55%, with a disease control rate for 12 weeks or longer of 80%.[83] Combination anti–CTLA-4 and anti–PD-(L)1therapy is currently under active investigation for a range of tumor types.

Combination Immune Checkpoint Therapy and Chemotherapy

ICT in combination with chemotherapy has demonstrated benefit in at least four tumor types to date: NSCLC, SCLC, HNSCC, and triple-negative breast cancer. A phase III clinical trial tested chemotherapy (cisplatin or carboplatin with pemetrexed) with or without pembrolizumab as a first line in patients with PD-L1–unselected, nonsquamous NSCLC lung cancer without driver mutations and demonstrated a 12-month OS of 69.2% in the pembrolizumab-combination group versus 49.4% in the placebo-combination group (HR, 0.49; 95% CI, 0.38–0.64; P <.001).[84] Another phase III trial tested chemotherapy (carboplatin with either paclitaxel or nab-paclitaxel) with pembrolizumab or placebo in PD-L1–unselected patients with squamous NSCLC population. This trial demonstrated an improvement in the co-primary endpoints of OS and PFS for the combination arm (OS, 15.9 months vs 11.3 months, HR, 0.64; 95% CI, 0.49–0.85, P <.001; PFS, 6.4 months vs 4.8 months; HR for progression or death, 0.56; 95% CI, 0.45–0.70; P <.001), leading to approval.[85] Atezolizumab in combination with chemotherapy has also been studied in two phase III trials of patients with NSCLC. A phase III study of carboplatin, paclitaxel, and bevacizumab with and without atezolizumab in PD-L1–unselected nonsquamous NSCLC demonstrated improvements in PFS and OS (19.2 vs 14.7 months; HR for death, 0.78; 95% CI, 0.64–0.96) for the atezolizumab arm.[86] Additionally, a phase III trial comparing chemotherapy (carboplatin, nab-paclitaxel) with or without atezolizumab demonstrated improvement for the combination in OS (18.6 months [95% CI, 16.0–21.2] vs 13.9 months [95% CI, 12.0–18.7]) and PFS (7.0 months [95% CI, 6.2–7.3] vs 5.5 months [4.4–5.9]).[87]

In extensive-stage SCLC, a phase III study of atezolizumab with or without carboplatin–etoposide (induction phase) followed by a maintenance phase of atezolizumab or placebo demonstrated, at a median follow-up of period 13.9 months, median OSs were 12.3 months for atezolizumab and 10.3 months for placebo (HR for progression or death, 0.77; 95% CI, 0.62–0.96; P = .02), leading to the approval of this combination.[88] The anti–PD-L1 mAb durvalumab has also been approved for extensive-stage SCLC in combination with platinum chemotherapy and etoposide. In a phase III clinical trial, patients with untreated extensive-stage SCLC were randomized to platinum–etoposide and either durvalumab alone or in combination with the anti–CTLA-4 mAb tremelimumab. In a planned interim analysis, durvalumab plus platinum–etoposide prolonged median OS compared with chemotherapy alone (13.0 months [95% CI, 11.5–14.8] vs 10.3 months [95% CI, 9.3–11.2; HR, 0.73 95% CI, 0.59–0.91; P = .0047]).[89]

In triple-negative breast cancer, the combination of atezolizumab and nab-paclitaxel was approved in patients with PD-L1 tumor-infiltrating immune cell staining of 1% or greater on the basis of a phase III trial of nab-paclitaxel with or without atezolizumab showing significant improvement with the combination in PFS (7.2 vs 5.5 months, HR, 0.62; 95% CI, 0.49–0.78; P <.001) and an OS benefit in PD-L1 positive patients (25.0 vs 15.5 months; HR for death, 0.62; 95% CI, 0.45–0.86).[90] Finally, in HNSCC, the combination of pembrolizumab with fluoropyrimidine and platinum-based chemotherapy has been approved, as described earlier.[56]

Combination Immune Checkpoint Therapy and Targeted Therapy

ICT in combination with targeted therapy has been well-studied in patients with RCC, with two approvals for the TKI axitinib with either pembrolizumab or

avelumab. A phase III trial in first-line advanced RCC compared pembrolizumab plus axitinib versus sunitinib and demonstrated improved OS in the entire study population (18-month OS, 82% vs 72% with the combination), most notably in intermediate- or poor-risk disease.[91] On the other hand, when first-line avelumab in combination with axitinib was compared with sunitinib in a phase III trial, an improvement in PFS was observed with the combination (13.8 vs 8.4 months).[92] The combination of atezolizumab and bevacizumab has been studied in the frontline setting in a phase III trial versus sorafenib testing the co-primary endpoints of OS and PFS; the 12-month OS was 67.2% with bevacizumab versus 54.6% with sorafenib (HR, 0.58; 95% CI, 0.42–0.79; $P<.001$), and median PFS was 6.8 months versus 4.3 months, respectively (HR for progression or death, 0.59; 95% CI, 0.47–0.76; $P<.001$). Additionally, a major area of interest in melanoma is the combination of ICT with BRAF and MEK inhibition. In a phase III study of vemurafenib and cobimetinib with or without atezolizumab, the addition of atezolizumab prolonged PFS at a median follow-up period of 18.9 months: 15.1 months for atezolizumab versus 10.6 months for control (HR, 0.78; 95% CI, 0.63–0.97; $P = .025$).[93] Finally, in endometrial carcinoma, the combination of pembrolizumab with lenvatinib has demonstrated activity and earned FDA approval.[94]

Biomarkers of Response to Immune Checkpoint Therapy

Despite the substantial clinical success of immune checkpoint therapies, including durable responses in certain patients, only subsets respond to therapy. Therefore, considerable effort is underway to identify predictive biomarkers to optimize patient selection for therapy. Broadly speaking, categories of putative biomarkers under study include (1) target expression (eg, surface expression of PD-L1), (2) tumor-specific features (eg, TMB), (3) tumor microenvironment, and (4) host features (eg, the gut microbiome).[95]

With respect to target expression, the assay most often used is PD-L1 expression on tumor and/or immune cells by immunohistochemistry. Although a number of studies have demonstrated that PD-L1 expression on tumor cells correlates with clinical response across multiple tumor types (eg, urothelial cancer and NSCLC), other studies have demonstrated conflicting results, with significant response rates in certain patients with PD-L1–negative tumors.[38,96,97] Additionally, PD-L1 is not a static marker; therefore, variations in time and area of sampling may also influence the level of PD-L1 expression. Dynamic biomarker assessments, such as the observation that sustained inducible T-cell co-stimulatory (ICOS) expression on CD4 T-cells correlates with survival of melanoma patients treated with anti–CTLA-4 therapy represents one potential path forward.[98] Therefore, although these assays have been approved as companion diagnostics, differences in antibodies, tissue handling techniques, and thresholds have limited the uniform application of PD-L1 expression as a predictive biomarker for ICT.[95]

A number of tumor-intrinsic biomarkers have been explored, including TMB and neoantigen load, DNA damage repair (DDR) pathways, viral infections (eg, Merkel cell polyoma virus), MHC expression, and transcriptional signatures.[95] High TMB has been associated with response to ICT in several cancer types, including melanoma and NSCLC, potentially because of the formation of neoantigens that are recognized by the immune system and may be met with compensatory upregulation of inhibitory immune checkpoints by the tumor cell.[99,100] As described earlier, pembrolizumab has now been approved for TMB-high tumors across tumor types.[73] Intriguingly, however, certain tumor types with a low TMB have been associated with high response rates to ICT, such as clear cell RCC, implying that TMB must be considered in the context of other potential biomarkers.[101] Further areas of investigation into TMB as a predictive biomarker include validation of thresholds of TMB, assay development, and deeper understanding of the immunogenicity of different mutations.[95] Although a number of bioinformatics algorithms are available to predict potential immunogenic neoantigens from mutations and human leukocyte antigen (HLA) phenotype, these have not yet been shown to be clearly superior to TMB.[95] In addition, DDR pathways play a key role in response to ICT, as described earlier with the tumor-agnostic approval of pembrolizumab in dMMR and MSI-H patients.[72] Other repair defects associated with response to ICT that have been reported include the DNA polymerases POLE and POLD1[102,103] and those with defects in homologous-recombination DNA repair, such as BRCA1/2, in which the generation of double-stranded breaks and release of cytosolic DNA can lead to activation of cGAS-STING, promotion of type I interferon (IFN) signaling, and upregulation of PD-L1.[104–106]

The tumor microenvironment is also a critical avenue of exploration for biomarker development. Increased tumor-infiltrating lymphocytes (TILs) have been associated with response to ICT in melanoma and in breast cancer.[107,108] Notably, a spectrum of tumor-infiltrating T-cell populations have been identified, with evidence indicating that ICT targets specific subsets of these infiltrating cells.[75] Anti–PD-1 therapy has been demonstrate to induce expansion of specific tumor-infiltrating exhausted-like CD8 T-cell subsets, whereas anti–CTLA-4 therapy has been shown to induce expansion of ICOS+ Th1-like CD4 effector cells, as well as engaging subsets of exhausted-like CD8

T-cells.[75] Classification systems have been proposed incorporating PD-L1 expression and TILs, though these require clinical validation.[109] Beyond the T-cell compartment, B cells and tertiary lymphoid structures have also been found to be associated with response to ICT in patients with melanoma and RCC.[110] Several transcriptional signatures have also been identified that are associated with response to ICT, such as markers of IFN-γ signaling.[111,112]

Finally, host factors independent of the primary tumor are also emerging, including the gut microbiome, systemic immune elements, and germline genetic polymorphisms.[95] In one study of patients with melanoma, a significant association was observed between response to anti–PD-1 therapy and commensal microbial composition, including *Bifidobacterium longum, Collinsella aerofaciens,* and *Enterococcus faecium*.[113] A separate study similarly demonstrated significant differences in the diversity and composition of the gut microbiome in patients with melanoma who responded to anti–PD-1 versus those who did not.[114] These findings have raised the possibility that modulation of the gut microbiome, perhaps through fecal microbiota transplantation, may offer an avenue to improve response to ICT. Other elements of host immunity in circulating immune cells have been identified as possible biomarkers; in one study, distinct subsets of CD4 and CD8 memory T-cell subsets were associated with response to anti–CTLA-4.[115] Overall, biomarkers of response to ICT are a highly active area of investigation, and further understanding of mechanisms, genetic backgrounds and interactions of host and tumor immunity will inform future development to enable improved patient selection.

Other Inhibitory Checkpoints

Beyond CTLA-4 and PD-1/PD-L1, a range of other inhibitory checkpoints are under active investigation and are briefly discussed here. Lymphocyte activation gene 3 (LAG-3) is expressed on T-cell subsets, B cells, DCs, and natural killer (NK) cells and is co-expressed with PD-1 on activated T-cells, providing a potential rational for combination with PD-1–directed therapy. LAG-3 shares homology with CD4, and it is hypothesized that it interacts with MHC class I to regulate T-cell responses.[116] Early clinical studies of the anti–LAG-3 mAb relatlimab (BMS-986016) in combination with nivolumab in patients with melanoma previously treated with immunotherapy demonstrated encouraging responses and is currently being investigated in a phase III clinical trial (NCT03470922).[117] Anti–LAG-3 mAbs are currently being studied in a range of tumor types.[118]

V-domain Ig suppressor of T-cell activation (VISTA) is an immune checkpoint highly expressed on myeloid cells (eg, macrophages, DCs, monocytes, neutrophils) and moderately expressed on regulatory T-cells (Tregs).[119] VISTA suppresses T-cell activation, and in preclinical models, VISTA blockade has been shown to improve antitumor immunity.[120] Upregulation of VISTA on macrophages in response to anti–CTLA-4 therapy with ipilimumab has been identified as a possible mechanism of resistance to immunotherapy in prostate cancer.[121] Anti-VISTA mAbs are currently under clinical development, with early-phase trials underway.[122] T-cell Ig and mucin domain–containing-3 (TIM-3) is another inhibitory receptor expressed on T-cell subsets and DCs—TIM3+ T-cells have been shown to display an exhausted phenotype, and targeting TIM-3 can restore the activated T-cell phenotype.[123] In a phase I study of the anti–TIM-3 antibody LY3321367 with or without anti–PD-L1 therapy, drug activity was observed, including one patient with SCLC after PD-1 treatment who achieved a PR.[124] Anti–TIM-3 mAbs under active clinical development. B7-H3 (CD276) is an immune checkpoint expressed on APCs whose receptor has yet to be defined and was initially thought to be a co-stimulatory checkpoint, though recent findings have pointed to its co-inhibitory functions.[125] Expression of B7-H3 on tumor cells has been identified as a possible mechanism of resistance to PD-1 blockade, and anti–B7-H3 antibodies are being tested in early-phase clinical trials.[126] Other inhibitory checkpoints under active investigation include TIGIT (T-cell immunoglobulin and ITIM domain) and BTLA (B- and T-lymphocyte attenuator).[127,128] In a phase I study of the anti-TIGIT mAb tiragolumab with or without atezolizumab, clinical activity was observed with the combination.[129] A phase II study of patients with newly diagnosed locally advanced or metastatic NSCLC with 1% or greater PD-L1 tumor expression (without *EGFR* or *ALK* alterations) reported an ORR of 37% and median PFS of 5.6 months with the combination versus 21% and 3.9 months with atezolizumab alone.[130] This combination is now being tested in a phase III study in patients with PD-L1–selected NSCLC (NCT04294810).

Co-stimulatory Checkpoints

As described earlier, T-cell activation requires two signals: (1) TCR engagement on T-cells with MHC molecules and (2) binding of co-stimulatory molecules on T-cells (eg, CD28) to B7 proteins (eg, CD80/CD86) on APCs. Thus, co-stimulatory agonism has also been explored as a potential therapeutic avenue. Initially, however, in a phase I trial of the anti-CD28 mAb TGN142, six healthy young patients experienced massive cytokine storm and multiorgan failure secondary to uncontrolled T-cell activation.[131] Since then, more precise targeting of T-cell activation has been sought,

specifically seeking to target co-stimulatory receptors that are expressed when T-cells are activated rather than constitutively expressed.

4-1BB/CD137 is an inducible co-stimulatory receptor that is expressed on activated T- and NK cells, promotes upregulation of antiapoptotic genes and protection from activation-induced cell death, and demonstrated promising preclinical efficacy.[132] In phase I trials, whereas the anti-CD137 antibody urelumab was associated with significant transaminitis, another anti-CD137 antibody, utomilumab, demonstrated a well-tolerated safety profile but an overall ORR of 3.8% across solid tumors.[133,134] Whereas OX40 is a late co-stimulatory receptor expressed transiently on activated CD4 and CD8 T-cells, the ligand OX40L is expressed on activated DCs, B cells, macrophages, activated T-cells, and endothelial cells.[135] OX40 functions to regulate T-cell survival, prevent T-cell tolerance, and inhibit regulatory T-cells. An antimouse OX40 demonstrated promising preclinical efficacy, and a phase Ib dose-escalation study of an OX40 agonist in combination with atezolizumab demonstrated acceptably safety but limited efficacy.[136,137] CD27 is expressed constitutively on naïve T-cells and has also been described on NK and B cells; its ligand is CD70.[138] The role of the CD27–CD70 axis in antitumor immunity has been identified—approximately one third of patients with germline deficiencies in CD27 or CD70 present with Hodgkin lymphoma or diffuse large B-cell lymphoma (DLBCL), and somatic alteration in CD27 or CD70 are often observed in patients with DLBCL or Burkitt lymphoma.[138] Varlilumab is an antihuman CD27 mAb that induced CD8 T-cell–dependent tumor rejection in human-CD27 transgenic mice and has demonstrated activity in a phase I clinical trial.[138] Glucocorticoid-induced tumor necrosis factor receptor (TNFR) (GITR) is constitutively expressed at high levels on Tregs and low levels on naïve and memory T-cells; T-cell activation leads to increased GITR expression on both regulatory and effector T-cells.[139] The GITR ligand is predominantly expressed by APCs, including DCs, macrophages, and activated B cells.[139] A phase I trial of a GITR agonist (TRX518) demonstrated limited efficacy as monotherapy, although it was found to reduce circulating and intratumoral Treg cells and increase effector T cell (Teff)-to-Treg ratio, prompting a subsequent study in combination with PD-1 inhibition.[140,141]

Finally, ICOS is a member of the CD28 and CTLA-4 family expressed on activated T-cells. ICOS interacts with its ligand (ICOSL) on APCs to provide a co-stimulatory signal for proliferation and activation.[142] In murine models of melanoma and prostate cancer, concomitant CTLA-4 blockade and ICOS engagement enhanced antitumor immune resposnes.[143] Anti–CTLA-4 therapy was shown to result in higher frequency of ICOS expressing CD4 T-cells in nonmalignant and malignant prostate tissue.[144] Moreover, in ipilimumab-treated patients with melanoma, persistent ICOS upregulation on CD4 T-cells was associated with improved clinical outcomes.[145] Multiple clinical trials are currently testing ICOS agonist alone and in combination with anti–CTLA-4 or anti–PD-1 therapy.[146,147] Overall, targeting co-stimulatory checkpoints represents a promising avenue in cancer immunotherapy, which will require careful patient selection and biomarker development.

Response Assessment with Immune Checkpoint Therapy

The distinct mechanisms of action of ICT compared with chemotherapy have required evolution in assessment of tumor responses. In the initial trials of ICT, patterns of response were observed that resembled traditional tumor flare but then subsequently developed deep and durable responses, a phenomenon deemed pseudoprogression.[148] These observations have led to the development of modified criteria for response assessment, such as immune-related response criteria (irRC),[149] immune-modified Response Evaluation Criteria in Solid Tumours (imRECIST)[150] and immune response evaluation criteria in solid tumors (iRECIST).[148] A pooled FDA analysis of lesion measurements for 7920 patients receiving ICT or chemotherapy from 14 randomized controlled trials demonstrated that patients with initial progressive disease per standard RECIST v1.1 can have prolonged stability or reduction in tumor burden per iRECIST, which can be associated with improved OS.[151] Similarly, a retrospective evaluation of atezolizumab data from clinical trials of NSCLC, RCC, melanoma, and urothelial carcinoma demonstrated that imRECIST captured a 1% to 2% greater best overall response, 8% to 13% greater disease control rate, and 0.5- to 1.5-month longer median PFS versus RECIST v.1.1.[150] Emerging techniques in imaging for immunotherapy include volumetric imaging, dynamic contrast imaging, and quantitative imaging biomarkers that may be able to identify T-cell infiltration of tumors.[152]

Immune-Related Adverse Events

Although ICT induces T-cell–mediated antitumor responses, they also carry the risk of breach of immune self-tolerance mechanisms, leading to inflammation of normal tissue, termed *immune-related adverse events (irAEs)*. These irAEs can affect a wide spectrum of organs, most commonly the skin, GI tract, lungs, and endocrine system (thyroid, adrenal, pituitary), but can also have musculoskeletal, renal, ocular, cardiovascular, neurologic, and hematologic effects (Fig. 56–2). These effects can range from sufficiently mild that ICT can be continued, to severe, requiring hospitalization,

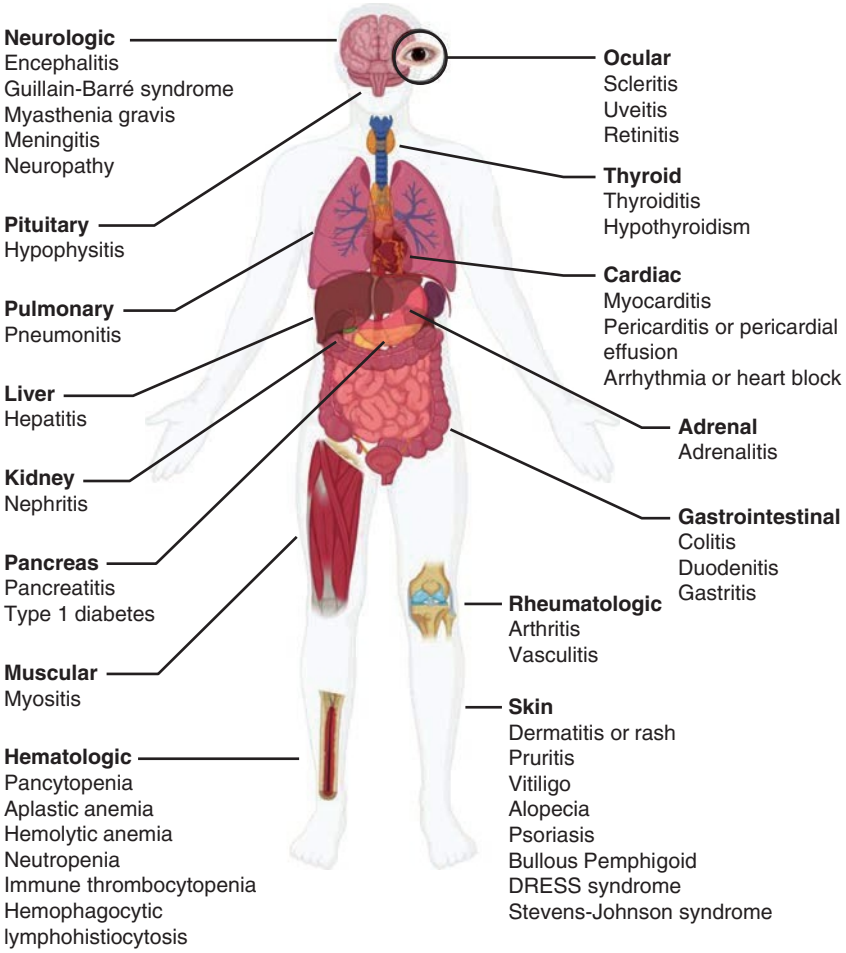

FIGURE 56–2 **Distribution of immune-related adverse events. DRESS, drug rash with eosinophilia and systemic symptoms.**

and even fatal. Prompt recognition and early intervention for irAEs, with close multidisciplinary collaboration is essential. Management of irAEs is an active area of investigation, with a number of studies underway investigating ICT rechallenge, identification of biomarkers to predict toxicity, and determining immunological mechanisms of irAEs, including the possibility of decoupling antitumor immunity from autoimmune toxicity.[153,154]

General principles of irAE management and an overview of selected toxicities are outlined here; detailed clinical guidelines for each toxicity are reviewed elsewhere.[155] Overall, a high index of suspicion is key in recognizing the emergence of irAEs. For most grade 1 events (as defined by the Common Terminology Criteria for Adverse Events v. 5.0), ICT is able to be continued, with the exception of certain cardiac, neurologic, and hematologic toxicities.[155] Grade 2 toxicities usually warrant interrupting ICTs and treatment with corticosteroids (at an initial dosage of 0.5–1 mg/kg/day of prednisone or equivalent), with resumption of ICT when the toxicity returns to grade 1 or greater.[155] Grade 3 toxicities warrant high-dose corticosteroids in addition to withholding ICT and often involve specific therapies (briefly described later). Although many guidelines advocate for prolonged steroid taper over 4 to 6 weeks, prolonged corticosteroids are associated with iatrogenic side effects, including myopathy, hyperglycemia, and infection risk; therefore, steroid-sparing approaches are under active investigation. Grade 4 toxicities usually warrant permanent cessation of ICT, with the exception of certain endocrinopathies that are controlled with hormone replacement.[155] Intriguingly, in a retrospective study of 346 patients at MD Anderson Cancer Center (MDACC) with metastatic melanoma, the occurrence of any grade GI irAEs was associated with improved OS, independent of immunosuppression, highlighting the careful balance between immune activation and tolerance inherent in ICT.[156]

ICT-associated enterocolitis most commonly presents as watery diarrhea, associated with abdominal pain, blood or mucous in stool, distension, nausea, vomiting, and fever, with a spectrum of severity that can range from self-limited, nonbloody diarrhea to perforation and even death.[157] Although the typical presentation of enterocolitis occurs approximately 5 to 10 weeks after initiation of ICT, the range is wide and can occur after the first dose or more than 6 months after cessation of ICT and can be acute or gradual.[157,158] Treatment of patients with ICT-associated enterocolitis generally matches the principles outlined earlier, with interruption of ICT for grade 2 or greater toxicity and introduction of corticosteroids. In more severe cases, adjunctive treatments in addition to corticosteroids have been studied, including the anti–tumor necrosis factor-α (TNF-α) mAb infliximab and the anti-$\alpha_4\beta_7$ integrin mAb vedolizumab; early introduction of targeted immunosuppression has been associated with favorable clinical outcomes compared to those who received targeted therapy more than 10 days after onset of toxicity, including fewer hospitalizations, shorter course of steroids, lower rate of steroid taper failure, and shorter duration of symptoms.[159] For refractory cases, fecal microbiota transplantation is emerging as a promising therapeutic approach.[160]

ICT-associated myocarditis is a feared complication of therapy that can result in fulminant cardiomyopathy, hemodynamic instability, and cardiac arrest.[161] The reported incidence of ICT-associated myocarditis is less than 1%; however, this may be an underestimation because of the possibility of subclinical cases of myocarditis.[162] A safety database report of 20,594 patients who received ipilimumab, nivolumab, or both reported an incidence of severe myocarditis in 0.09% of patients, with a rate of 0.27% in patients who received combination therapy.[161] The median time to developing myocarditis after the first treatment has been reported at 17 days but may range from 2 to 32 weeks after initiation of threatment.[162] The clinical spectrum of cardiotoxicity includes myocarditis and frank cardiomyopathy but also pericarditis and pericardial effusion, QTc prolongation and advanced heart block, and hypertension.[162] Notably, case series have identified an overlap syndrome of cardiac and neuromuscular toxicities encompassing myositis and myasthenia gravis in addition to myocarditis.[163–165] Guidelines for the management of myocarditis currently recommend holding ICT for grade 1 toxicity and permanent discontinuation if greater than grade 1, given the high risk of progression to fulminant toxicity and death.[155] Initial management remains high-dose corticosteroids.[162] In refractory cases, addition of adjunct immunosuppression has been explored, including infliximab.[162] Additionally, case reports have demonstrated success in refractory cases with the CTLA-4 Ig fusion protein abatacept as well as anti-CD52, alemtuzumab.[166,167]

CELLULAR THERAPY

Because immune effector cells, such as CD8 T-cells, are some of the primary mechanisms of tumor killing, cellular therapy seeks to directly harness these cells to recognize and eliminate tumor cells. This section briefly reviews adoptive cellular therapy with tumor-infiltrating lymphocytes and CAR T-cells, as well as highlighting emerging areas of research, including CAR NK cells.

Adoptive T-Cell Therapy

Adoptive T-cell therapy (ACT) involves transfer of autologous TILs to the tumor-bearing host.[168,169] Preparation of cells involves isolation and ex vivo rapid expansion of TILs from tumor followed by infusion of large numbers of expanded autologous TILs as depicted in Figure 56–3. TIL therapy has demonstrated objective response rates ranging from 40% to 70%, with durable CRs reported in certain heavily pretreated patients with metastatic melanoma.[169,170] The efficacy of TIL therapy is boosted through combination with interleukin-2 (IL-2) and through the development of preconditioning chemotherapy regimens, such as those incorporating cyclophosphamide and fludarabine. ACT has encountered challenges in clinical practice, including factors relating to difficulties in generating appropriate products for adoptive transfer, factors relating to host or tumor resistance to transferred populations, and off-tumor toxicity with associated treatment-related morbidity and mortality. Furthermore, TIL therapy has been shown to be particularly beneficial in patients pretreated with other immunotherapy agents such as IL-2 or checkpoint blockade such as anti–CTLA-4.[169]

Chimeric Antigen Receptor T-Cells

CAR T-cells are engineered to increase the affinity of T-cell to the tumor antigen and contain a synthetic antigen receptor with specificity to a tumor cell marker coupled with T-cell signaling domain, resulting in high-affinity recognition of the tumor antigen.[171] Therefore, CAR T-cells are particularly effective against tumors in which the tumor antigen is well-defined. The manufacturing process for CAR T-cells involves leukapheresis for collection and enrichment of CD3 T-cells, transduction with viral CAR construct and ex vivo CAR T-cell expansion, conditioning chemotherapy (most

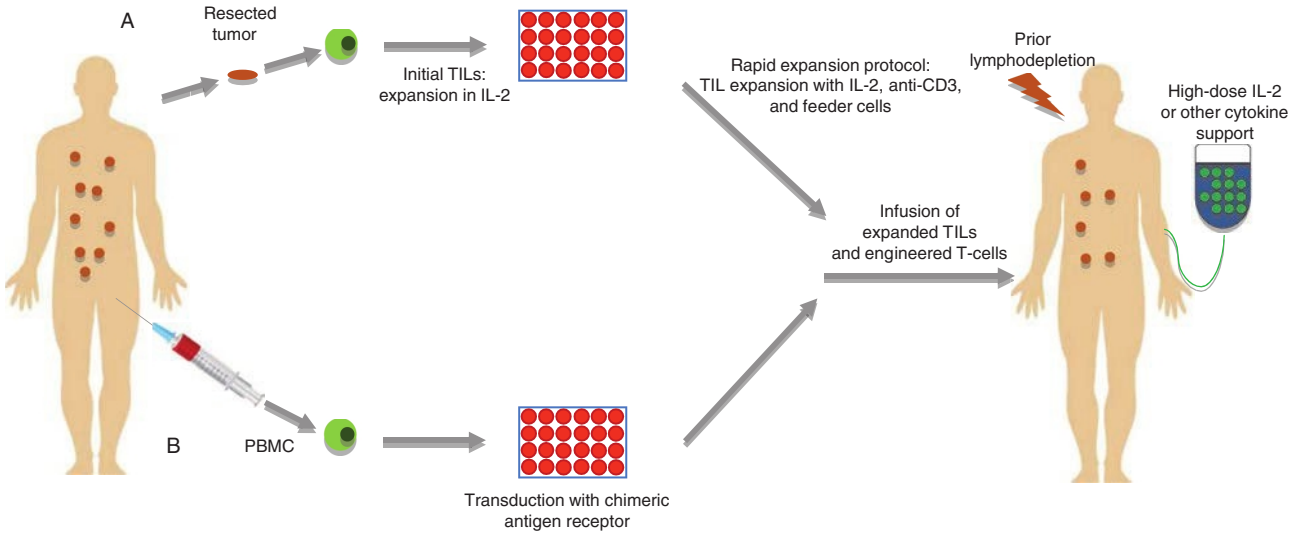

FIGURE 56–3 Adoptive T-cell therapy. There are currently two major sources of T-cells used in adoptive cell therapy for melanoma and other cancers. A. The first form of therapy uses tumor-infiltrating lymphocytes (TILs) expanded ex vivo from surgically resected metastatic tumors. The TILs are initially expanded ex vivo using anti-CD3 activation in the presence of irradiated peripheral blood mononuclear cell (PBMC) feeder cells and interleukin-2 (IL-2). The final product is infused into the patient. B. The second major approach for adoptive T-cell therapy uses T-cells expanded from autologous PBMCs that undergo one of three possible manipulations to enrich the cells for tumor antigen-specific T-cells.

commonly with cyclophosphamide and fludarabine), and finally infusion into the patient. CAR T-cells have had particularly respect in hematologic malignancies, with approvals of three CD19-directed CAR T-cell therapies, axicabtagene ciloleucel, tisagenlecleucel, and brexucabtagene autoleucel.

Axicabtagene ciloleucel is a CD19-directed autologous CAR T-cell composed of a murine single-chain antibody fragment recognizing CD19, fused with the co-stimulatory domain CD28 and the signaling domain CD3-zeta. This agent is approved by the FDA for relapsed or refractory large B-cell lymphoma after two or more lines of systemic therapy. In the phase II trial that led to its approval, 111 patients with DLBCL, primary mediastinal B-cell lymphoma, or transformed follicular lymphoma with refractory disease experienced an ORR of 82% with a CR rate of 54%.[172] At a 2-year follow-up, the duration of response was 11.1 months, and the median OS was not reached.[173]

Tisagenlecleucel is a CD19-directed autologous CAR T-cell transduced with a lentivirus encoding a murine single-chain antibody fragment recognizing CD19 fused to the co-stimulatory domain 41-BB (CD137) and signaling domain CD3 zeta. This CAR T product is FDA approved for B-cell precursor acute lymphoblastic leukemia (ALL) that is refractory or in second or later relapse in patients younger than the age of 25 years and for relapsed or refractory large B-cell lymphoma after two or more lines of systemic therapy. In a multicenter phase II study of pediatric and young adult patients with CD19+ relapsed or refractory B-cell ALL, the overall remission rate within 3 months was 81%.[174] In a phase II trial of adults with relapsed or refractory DLBCL, tisagenlecleucel achieved an ORR of 52%.[175]

Brexucabtagene autoleucel is a CD19-directed CAR T-cell therapy, recently approved for the treatment of relapsed or refractory mantle cell lymphoma (MCL). In a single-arm, open-label, multicenter phase II study of 74 patients with relapsed or refractory MCL who had previously been treated with chemotherapy (anthracycline or bendamustine-based), CD20-directed treatment, and Bruton's tyrosine inhibitor, patients were treated with a single infusion of brexucabtagene autoleucel.[176] Of 60 patients in the primary efficacy analysis, the ORR was 93% (95% CI, 53–78), with a 67% CR rate.[176] In the intention-to-treat analysis of all 74 patients, the ORR was 85%.[176] Grade 3 or high cytokine release syndrome (CRS) occurred in 15% and neurologic events in 31%, with two grade 5 infectious adverse events reported.[176]

CAR T-cell approaches are currently being explored in a wide array of tumors, including solid cancers, although this has been challenging, in part because of the multiplicity of tumor-associated antigens. Finally, additional cell populations are being explored, such as NK cells, which offer the possibility of allogeneic cell transfer. In a phase I/II study of HLA-mismatched, cord blood–derived anti-CD19 CAR NK cells, 11 patients with relapsed or refractory CD19-positive cancers (non-Hodgkin lymphoma or chronic lymphocytic leukemia) achieved a 73% response rate.[177]

Chimeric Antigen Receptor T-Cell Toxicity

CAR T-cell therapy is associated with unique toxicities arising from its mechanism of action: CRS and immune effector cell–associated neurotoxicity syndrome (ICANS). These toxicities are reversible. Less common toxicities include B-cell aplasia, tumor lysis syndrome, hemophagocytic lymphohistiocytosis, and anaphylaxis.[178] CRS is a common inflammatory syndrome associated with massive cytokine release (eg, IFN-γ, TNF-α, and IL-6, among others), triggering an inflammatory cascade, which can manifest with fever, hypotension, rigors, tachycardia, hypoxia, and in severe cases, multiorgan failure.[178] These symptoms occur earlier in CAR T-cells transduced with CD28 co-stimulatory domains (median time to onset with axicabtagene ciloleucel, 2 days) compared with those with 4-1BB domains (median time to onset with tisagenlecleucel, 3 days).[178] The reported incidences of CRS were 93% with axicabtagene ciloleucel (with grade ≥3 in 13%) and 58% with tisagenlecleucel (with grade ≥3 in 22%).[173,175]

Management of patients with CRS requires prompt recognition and multidisciplinary evaluation; consensus guidelines have been developed for standardized grading of toxicities.[179] Patients with grade 1 CRS may be managed supportively with antipyretics, fluids, and empiric antibiotics as indicated.[178] For grade 2 CRS, defined as fever with temperature 38°C or greater, hypotension not requiring vasopressors, or hypoxia requiring low-flow nasal cannula, treatment involves IL-6 blockade.[178] Tocilizumab, a humanized mAb against IL-6 is FDA approved for this indication. Siltuximab, a chimeric mAb, has also been used off-label in the management of patients with CRS. For cases refractory to IL-6 blockade, corticosteroids are used, with dexamethasone 10 to 20 mg every 6 hours in grade 3 toxicity and methylprednisolone up to 1000 mg/day for grade 4 toxicity.[178] The median time to resolution is 7 to 8 days.[178]

ICANS was reported in 64% (grade ≥3 in 32%) of patients with axicabtagene ciloleucel and in 39% (grade ≥3 in 12%) of patients with tisagenlecleucel.[172,175] The early manifestations of ICANS can be subtle and include decreased attention or impaired handwriting and can subsequently progress to confusion, agitation, somnolence, tremors, or aphasia, with the most severe cases associated with seizure, obtundation, weakness, increased intracranial pressure, and cerebral edema.[178] ICANS can clinically progress in two phases, with a first phase concurrently with CRS and a second phase without CRS.[178] Similar to CRS, management involves aggressive supportive care, IL-6 blockade, and corticosteroids in a closely monitored multidisciplinary setting.

Overall, cellular therapy continues to evolve, with significant efforts underway to optimize the CAR structure, develop suicide switches to abort toxicity, and develop allogeneic cells such as CAR NK described above.

CANCER VACCINES

Because tumors express a variety of antigens, cancer vaccines have been studied as a means of activating a tumor antigen-specific lymphocyte population, leading to eradication of cell expressing this antigen. This is in contrast to preventative cancer vaccines, such as the recombinant human papillomavirus vaccine. Although therapeutic cancer vaccines demonstrated significant antitumor activity in animal models and early-phase clinical trials, the clinical impact has been minimal.[180]

To date, only one therapeutic cancer vaccine has been approved for human use, sipuleucel-T, for metastatic, castration-resistant prostate cancer. Sipuleucel-T is an autologous DC vaccine prepared from a patient's peripheral blood mononuclear cells pulsed with a fusion protein of granulocyte-macrophage colony-stimulating factor (GM-CSF) and the prostate cancer antigen prostatic acid phosphatase. Sipuleucel-T was FDA approved on the basis of a phase III clinical trial that demonstrated a 4.1-month improvement in OS compared with placebo.[181] Notably, no effect on time to disease progression was observed.[181] A similarly promising vaccine in prostate cancer was (PROSTVAC) or PSA-TRICOM, composed of vaccinia and fowlpox vectors containing transgenes for prostate-specific antigen and three co-stimulatory molecules, B7.1, leukocyte function-associated antigen 3, and intercellular adhesion molecule 1, known as TRICOM. Despite early signals of benefit, a phase III clinical trial did not demonstrate an OS benefit.[182]

In light of the proof of principle demonstrated by sipuleucel-T, investigation continues into the design of cancer vaccines, including combinatorial approaches with ICT to boost immunogenicity.

OTHER IMMUNOTHERAPIES

Cytokine-Based Therapies

Cytokine-based therapies have a long history in the treatment of certain cancers, particularly melanoma and RCC. The use of high-dose IL-2 was approved for metastatic RCC by the FDA in 1992, with studies from the NCI showing a 20% objective response rate and durable response observed in certain patients.[183] High-dose IL-2 is associated with cytokine-related

toxicities, including capillary leak and hypotension, and with the growth of treatment options for these disease, notably ICT, high-dose IL-2 has been reserved for highly selected situations. Novel cytokine approaches are under investigation, including a pegylated form of IL-2 that is being studied in combination with ICT.

Oncolytic Viruses

Oncolytic viruses function through selective tumor killing as well as induction of antitumor immunity. Talimogene laherparepvec (T-VEC) is a genetically modified attenuated herpes simplex 1 virus that has been FDA approved for local treatment of unresectable cutaneous, subcutaneous, and nodal lesions in patients with recurrent melanoma after initial surgery. In a phase III clinical trial of intratumoral T-VEC versus subcutaneous GM-CSF, the median OS was 23.3 months with T-VEC versus 18.9 months with GM-CSF, although these analyses were descriptive.[184] The objective response rate was 31.5%.[184] Oncolytic viruses are being studied for use in the neoadjuvant setting and as part of combination therapy in melanoma as well as other tumor types.

Bispecific Antibodies

Bispecific antibodies are antibody constructs that ligate an anti-CD3 domain to a tumor-associated antigen-recognizing domain and have been postulated to promoted redirected T-cell killing of tumor cells. Currently, the only FDA-approved bispecific antibody is blinatumomab, a CD19-directed agent approved for relapsed or refractory B-cell precursor ALL and treatment of B-cell precursor ALL in first or second complete remission with minimal residual disease 0.1% or greater. In a study of 405 pretreated patients with relapsed or refractory Philadelphia chromosome positive B-cell ALL versus chemotherapy, an OS benefit of 7.7 versus 4.0 months as well as complete remission with full hematologic recovery of 34% versus 12%.[185] Bispecific antibodies are now being explored in solid tumors as well as other hematologic malignancies.

Dendritic Cell–Based Immunostimulatory Agents

DCs are professional APCs that are critical for effective T-cell stimulation. Both DCs and T-cells possess an array of stimulatory molecules that are necessary for sustained and durable immune response, making them potential therapeutic targets.

Toll-like receptors (TLRs) are a group of 13 receptors present in DCs that have distinct ligands, and the receptor–ligand interaction leads to the activation of DCs, inducing the expression of type I IFNs, cytokines (eg, IL-12), and co-stimulatory molecules (eg, CD80, CD86, and CD40) that are critical for T-cell activation.[186,187] Clinical trials with TLR agonists have shown promise, particularly in combination with other therapeutic modalities. The imidazoquinoline imiquimod ligates TLR7; in several clinical trials, topical application resulted in an 80% to 90% clearance rate for superficial basal cell carcinoma.[188,189] Systemic administration of TLR7 and TLR9 agonist as monotherapy in melanoma and RCC had a strong immune response but failed to demonstrate objective clinical response.[190,191]

Another attractive target for enhancing DC function is CD40, which is present on APCs, including DCs, and ligation of CD40 with its ligand CD40L present on T-cells is critical for T-cell priming.[192] CD40 targeting agents as monotherapy showed modest clinical benefit in non-Hodgkin lymphoma and melanoma.[193] To increase its efficacy, one approach used electroporation to introduce mRNA encoding CD40 ligand, constitutively active TLR4, CD70, and multiple melanoma tumor antigens into autologous DCs (TriMix-DC). Tumor regressions were observed in 6 of 17 patients who had received IFN-α-2b in combination with TriMix-DC.[194] Furthermore, combination of anti-CD40 antibody and the chemotherapy agent gemcitabine showed tumor regression in both humans and mice.[195]

FUTURE DIRECTIONS

Immunotherapy is firmly established as a mainstay of cancer treatment. Current areas of active research include (among many others) the discovery and validation of additional checkpoints as rational targets, refinement of CAR T-cell therapies and the emergence of allogeneic cellular therapies, testing of immunotherapy earlier in the disease state (eg, neoadjuvant), continuing exploration of combination treatments (including chemotherapy and radiation therapy), improved understanding of immune-related adverse events, and development of predictive biomarkers for toxicities and response. As the field of cancer immunotherapy continues to develop, continued focus will be toward improving patient selection to minimize toxicities and maximize efficacy.

MD ANDERSON PRACTICE TIPS

- ICT has transformed the care of many cancers, providing subsets of patients with durable responses and survival benefit, but many patients do not respond. To increase ORR, multiple clinical trials are ongoing with combinatorial strategies. At MDACC, we advise patients to be treated on clinical trials when possible.
- ICT can have unique patterns of response resembling traditional tumor flare that subsequently develops into deep and durable responses, termed *pseudoprogression*. For this reason, modified criteria for response assessment have been developed, including immune-related response criteria irRC, imRECIST, and iRECIST.
- irAEs require prompt recognition and early intervention because these events can be fatal. Although corticosteroids are the mainstay of management, prolonged steroid courses carry morbidity, and there is growing evidence for the use of selective immunosuppression. At MDACC, patients with irAEs are managed with close multidisciplinary collaboration with expertise in advanced immunosuppression, and patients should be managed in specialized centers when feasible.
- The most commonly used biomarkers for ICT are tissue PD-L1 expression, TMB, and dMMR and MSI-H. These have utility in specific circumstances (and are required for certain indications), but they have limitations, and development of more sophisticated biomarkers is an active area of investigation.
- CAR T-cell therapy is associated with unique toxicities: CRS and ICANS. These toxicities are reversible and can be managed supportively (fluids, antipyretics, vasopressors) or with IL-6 blockade and corticosteroids in severe cases. Consensus guidelines have been developed for standardized toxicity grading. A high index of suspicion is warranted, and patients should be treated in experienced centers with expertise in these therapies.

57 Targeted Therapy in Cancer

Rabih Said
Apostolia-Maria Tsimberidou

KEY CONCEPTS

- The therapeutic approach for patients with metastatic cancer includes multigene tissue genomic analysis and assessment of immune markers that include programmed cell death-ligand 1, microsatellite instability (MSI) status, tumor mutational burden, neurotrophic tyrosine kinase receptor (NTRK) fusion, human *epidermal growth factor* receptor 2 (HER2) amplification, and cell-free DNA analysis to identify drivers of carcinogenesis. The use of targeted therapy against molecular alterations in individual patients has been associated with improved clinical outcomes.
- Patients with advanced cancer may have tumor molecular alterations in one or more of the following genes and pathways: RAS-RAF-MEK, PI3K-AKT-mTOR, EGFR, HER-2, BRCA, HER2, RET, ROS-1, KIT, CDK4/6, PDGFR, VEGFR1/2/3, PDGFRα, NTRK, METex1h4, FGF, Trop-2 CSF1R, AR, ER, and other genes. (See text for abbreviations.)
- Larotrectinib and entractinib are novel NTRK inhibitors indicated for patients whose tumor has a NTRK fusion, irrespective of tumor type.
- Treatment with pembrolizumab (a programmed cell death protein 1 inhibitor) is indicated for patients with MSI-H mismatch repair deficient tumors irrespective of tumor type.
- The combination of targeted therapy with either chemotherapy or immunotherapy has shown promising results in various tumors. Prospective trials are warranted to provide biomarkers associated with response or resistance to immunotherapeutic agents.
- Novel drug development, complete understanding of mechanisms of carcinogenesis, innovative clinical trials, and harmonization of policy and practice will accelerate the implementation of personalized medicine.

The Human Genome Project has enabled sequencing of human DNA and led to advancements in technologies that detect genomic, transcriptional, proteomic, and epigenetic changes. The application of these technologies and novel drug development have accelerated the implementation of personalized medicine. Personalized medicine uses concepts of the genetic and environmental bases of disease to individualize prevention, diagnosis, and treatment.[1,2] Optimization of treatment by incorporating targeted therapy—the use of molecules that target specific enzymes, growth factor receptors, and signal transducers to interfere with a variety of oncogenic cellular processes—and other strategies made possible by advancements in the field of translational medicine hold the promise of improving patient care.[3] In recent years, immunotherapy has revolutionized the field of personalized medicine, and many drugs have been approved for the treatment of patients with specific tumor types and for patients whose tumors express specific immune markers. These drugs are now included in the targeted therapy arsenal.

This chapter focuses on the evolution of targeted therapy in cancer therapeutics and is organized according to the key drivers of carcinogenesis in humans, focusing on the novel agents designed to target those drivers. It also summarizes the current state-of-the-art applications of personalized medicine.

RAS-RAF-MEK PATHWAY INHIBITORS

The mitogen-activated protein kinase (MAPK) cascades contribute to carcinogenesis with upregulation of the MAPK cascades rapidly accelerated fibrosarcoma (RAF) and MAPK/extracellular signal-regulated kinase

(ERK) (MEK). Cell-surface molecules activate the RAS family (KRAS, NRAS, and HRAS), which are GTPases that activate downstream RAF protein kinases [rapidly accelerated fibrosarcoma homolog B (BRAF); rapidly accelerated fibrosarcoma homolog C (CRAF); rapidly accelerated fibrosarcoma homolog A (ARAF)]. The most important substrates of RAF kinases are MEK1 and MEK2, the MAPK/ERK kinases. MEK kinases have one main substrate, ERK. Activation of ERK leads to gene expression modifications, mediated by transcription factors that control cell cycle progression, differentiation, metabolism, survival, migration, and invasion. This pathway regulates apoptosis through the posttranslational phosphorylation of apoptotic regulatory molecules, including Bad, Bim, Mcl-1, and caspase 9. RAS is a downstream effector of epidermal growth factor receptor (EGFR). ERK activation promotes upregulated expression of EGFR ligands and an autocrine loop critical for tumor growth.

BRAF mutations are found in 62% to 72% of patients with metastatic melanoma[4] and are less frequent in radial growth phase (10%) and in situ (5.6%) melanomas. *NRAS* mutations occur in 5.2% of melanomas.[5] In conjunctival melanoma, *BRAF* and *NRAS* mutations were identified in 29% and 18% of patients, respectively. KIT alterations were found in 36% and 39% of patients with acral and mucosal melanoma, respectively. GNAQ and GNA11 alterations were found in 45% and 32% of patients with uveal melanoma, respectively. The Food and Drug Administration (FDA)–approved drugs by molecular target are listed in Table 57–1 and Figure 57–1.

BRAF Inhibitors

Vemurafenib

Vemurafenib was the first FDA-approved inhibitor of BRAF for metastatic melanoma with a *BRAF* V600E mutation (Table 57–2). A phase III trial demonstrated a 3.7-month improvement in progression-free survival (PFS) in the vemurafenib arm compared with the dacarbazine arm (median, 5.3 months and 1.6 months, respectively).[6] A 5-year follow-up analysis demonstrated the superiority of vemurafenib in prolonging overall survival OS; 13.6 vs 9.7 months; hazard ratio [HR], -.81; $P = .03$).[7]

Dabrafenib

Dabrafenib is indicated for patients with unresectable or metastatic melanoma with a *BRAF* V600E mutation. A phase III study demonstrated longer PFS in the dabrafenib arm compared with the dacarbazine arm (median, 5.1 vs 2.7 months, respectively).[8] Both vemurafenib[9] and dabrafenib[10] have antitumor activity in patients with melanoma and brain metastases. However, adjuvant treatment with vemurafenib for 1 year did not increase disease-free survival (DFS) compared with observation in patients with stage IIC to IIIC melanoma with *BRAF* V600E and V600K mutation.[11]

Encorafenib

Encorafenib is an adenosine triphosphate (ATP)–competitive RAF kinase inhibitor that leads to the decrease of ERK phosphorylation and the down-regulation of cyclin D1, ultimately arresting the cell cycle at phase G1 and causing cell senescence.[12] Encorafenib in combination with binimetinib is indicated for the treatment of patients with advanced melanoma with *BRAF* V600E and V600K mutations on the basis of a phase III study in this setting that compared encorafenib versus vemurafenib versus encorafenib plus the MEK inhibitor binimetinib and demonstrated longer PFS in the combination arm.[13] The median PFSs were 9.6 months, 14.9 months, and 7.3 months, respectively.[13]

MEK Inhibitors

Trametinib

Trametinib, a MEK1/MEK2 kinase inhibitor, is indicated as monotherapy or in combination with dabrafenib for unresectable or metastatic melanoma with a *BRAF* V600E or V600K mutation. The FDA approval of trametinib was based on the results of a randomized trial, which demonstrated longer PFS with trametinib than with chemotherapy consisting of either dacarbazine or paclitaxel in patients with stage IIIc to IV melanoma and a *BRAF* V600E or V600K mutation.[14] The median PFS durations were 4.8 and 1.5 months in the trametinib and chemotherapy arms, respectively (HR, 0.47; $P < .0001$). The 6-month OS rates were 81% and 67%, respectively.[14] A long-term follow-up analysis of the patients who received trametinib plus dabrafenib demonstrated that the OS rate was 37% at 4 years and 34% at 5 years.[15] Of 563 patients, 109 (19%) had a complete response (CR) and improved long-term outcomes, and the 5-year OS rate was 71%.[15] Cutaneous squamous cell carcinoma (SCC), an adverse event noted in patients treated with BRAF inhibitors, was less common in the dabrafenib plus trametinib group than in the dabrafenib monotherapy group (7% vs 19%, respectively).

Cobimetinib

Cobimetinib, an oral highly selective inhibitor of MEK, is indicated in combination with vemurafenib for the treatment of unresectable or metastatic melanoma with a *BRAF* V600E or V600K mutation on the basis of improvement in PFS with this combination compared with vemurafenib monotherapy (9.9 months vs 6.2 months; $P < .001$).[16] Binimetinib is another orally bioavailable selective inhibitor of MEK1/2.[17] As

TABLE 57–1 Food and Drug Administration–Approved Drugs by Molecular Target

Target	Drug	Target	Drug
BRAF	Dabrafenib	ALK	Ceritinib

mentioned earlier, the combination of binimetinib and encorafenib was approved by the FDA for the treatment of patients with melanoma harboring *BRAF* V600E and V600K mutations.[13]

Up to 4% of patients with non–small cell lung cancer (NSCLC) have *BRAF* mutations. Molecular alterations in *EGFR*, *ALK*, *ROS1*, *NRAS*, and *KRAS* also contribute to the pathogenesis of lung cancer. In phase II trials, vemurafenib or dabrafenib monotherapy has demonstrated efficacy in *BRAF*-mutant NSCLC, with response rates of 42% and 33%, respectively.[18,19] However, two subsequent phase II trials demonstrated higher response rates (63% and 64%) with the combination of dabrafenib and trametinib.[20,21] Thus,

TABLE 57–2 Targets of Food and Drug Administration–Approved and Investigational Therapy in Selected Tumor Types

Tumor Type	FDA-Approved Therapy Targets	Investigational Therapy Targets
NSCLC	EGFR, ALK, ROS-1, BRAF, MET^{ex14}, PD-1/PDL-1, CTLA-4, NTRK	RET, HER-2
Breast	ER, HER-2, PI3K, PD-1/PDL-1, NTRK, BRCA, DDR	AKT, mTOR
Colorectal carcinoma	RAS, BRAF, MMR/MSI, NTRK	HER-2
Gastroesophageal carcinoma	HER-2, MSI, PDL-1, NTRK	
Melanoma	BRAF, MEK, PD-1, NTRK, MSI	RAS, KIT, ALK, ROS-1
Ovarian carcinoma	VEGF, BRCA, DDR, ER, MSI/MMR, NTRK	MEK
Prostate adenocarcinoma	AR, MSI/MMR, NTRK	PD-1/PDL-1, BRCA
Bladder cancer	PDL-1, FGFR, NTRK	VEGF, Nectin-4

ALK, anaplastic lymphoma kinase; AR, androgen receptor; AXL, anexelekto; BRAF, rapidly accelerated fibrosarcoma homolog B; BRCA, breast cancer type 1; CDK4/6, cyclin-dependent kinase 4 and 6; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; EGFR, epidermal growth factor receptor; FGF, fibroblast growth factor; DDR, DNA damage repair; HER2, human epidermal growth factor receptor 2; KIT, tyrosine-protein kinase of CD117 (cluster of differentiation 117); MEK, mitogen-activated protein kinase; MET^{ex14}, mesenchymal-epithelial transition exon 14 deletion; mTOR, mammalian target of rapamycin; NTRK, neurotrophin receptor kinase; PD-1, programmed cell death protein 1; PD-L1, programmed death-ligand; PDGFR, platelet-derived growth factor receptor; PI3K, phosphoinositide 3-kinases; RAF, rapidly accelerated fibrosarcoma; RET, receptor tyrosine kinase; ROS-1, c-ros oncogene 1; Trop-2, trophoblast antigen 2; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

the combination of dabrafenib and trametinib was approved by the FDA for patients with advanced or metastatic NSCLC with *BRAF* V600E mutation. *KRAS* mutations are more common in smokers, and in metastatic NSCLC, they are associated with a worse prognosis than *EGFR* mutations.[22]

PI3K-AKT-mTOR PATHWAY INHIBITORS

The phosphatidylinositol 3-kinase (PI3K) signaling pathway is among the most critical in cancer, affecting the survival, growth, metabolism, motility, and progression of cancer.[23] Of the proteins in the PI3K family, only class IA signaling aberrations are involved in human cancers. The class IA PI3Ks are composed of heterodimers of regulatory subunits (p85α, p85β, p50α, p55α, and p55γ) and catalytic subunits (p110α, p110β, and p110δ). Three genes encode the regulatory subunits: *PIK3R1* encodes p85α, and *PIK3R2* and *PIK3R3* encode the p85β and p55γ isoforms of the p85 regulatory subunit, respectively. *PIK3CA*, *PIK3CB*, and *PIK3CD* encode the highly homologous p110 catalytic subunit isoforms p110α, p110β, and p110δ and share a similar five-domain structure. At the amino (N) terminus, there is an adaptor-binding domain that interacts with the p85 regulatory subunit followed by a RAS-binding domain that mediates interaction with RAS. The class I PI3Ks can phosphorylate the 3¢ position of the phosphatidylinositols PI-4-P and PI-4,5-P_2, through PI-4,5-P_2, to generate phosphatidylinositol (3,4,5) triphosphate (PIP_3). Cytosolic proteins, such as the AKT family of protein-serine/threonine kinases, bind to PIP_3 and localize to the plasma membrane in response to PI3K activation. In the absence of stimulated growth conditions, PIP_3 levels in the plasma membrane are undetectable in mammals and regulated by the tumor suppressor phosphatase and tensin homolog (PTEN), whose lipid phosphatase activity converts PIP_3 back to PI-4,5-P_2. The loss of PTEN function—owing to inactivating mutations, deletion, chromosomal translocation, or epigenetic silencing—is second only to p53 mutation as a driver of cancer initiation.

Mutations or amplifications of the PI3K catalytic subunits p110α (*PIK3CA*) and p110β (*PIK3CB*), the PI3K regulatory subunits p85α (*PIK3R1*) and p85β (*PIK3R2*), and AKT (*AKT1*) can activate the PI3K pathway. Mutations, deletions, or epigenetic changes in negative regulators of the PI3K axis (PTEN and inositol polyphosphate-4-phosphatase, type II) may modify tumor cell sensitivity to chemotherapy or targeted therapies.[24] AKT is the main effector of PI3K activation and has three isoforms: AKT1, AKT2, and AKT3. AKT signaling plays a significant role in cell hypertrophy, survival, hyperplasia, and metabolism. The mammalian target of rapamycin (mTOR) is the catalytic subunit of mTOR complex 1 (mTORC1) and mTORC2, which are distinguished by their respective accessory proteins, regulatory-associated protein of mTOR and rapamycin-insensitive companion of mTOR.

Several studies focus on targeting the PI3K-AKT-mTOR pathway. Rapamycin analogs (rapalogs) have antitumor activity in several tumor types and are frequently combined with other anticancer agents.[25] Everolimus is approved for the treatment of subependymal giant cell astrocytoma; hormone receptor (HR)–positive, human epidermal growth factor

receptor 2 (HER2)–negative breast cancer (in combination with exemestane); neuroendocrine pancreatic tumors; tuberous sclerosis-associated subependymal giant cell astrocytoma; and renal cell carcinoma (sunitinib- or sorafenib-refractory). Temsirolimus is approved for patients with renal cell carcinoma.

PI3K Inhibitors

The first generation of class I pan-PI3K inhibitors, including Wortmannin and LY294002, targeted PI3Kα, PI3Kβ, PI3Kγ, and PI3Kδ but had limited activity. New pan-PI3K inhibitors that have improved pharmacokinetic profiles and target specificity are being evaluated in ongoing studies. The antitumor activity of these inhibitors is primarily cytostatic. Novel agents that inhibit both PI3K and mTOR may result in greater antitumor activity than either agent alone.

Pictilisib

Pictilisib is a selective, oral, class I PI3K inhibitor; it is also an mTOR inhibitor at high concentrations. Several studies were unsuccessful owing to lack of efficacy or neuropsychiatric and gastrointestinal (GI) toxicity.

Buparlisib

Several clinical studies of buparlisib, an oral pyrimidine-derived pan-PI3K inhibitor with activity against all class I PI3K isoforms, demonstrated limited antitumor activity in phase I studies in patients with various tumor types and in phase II/III studies in patients with postmenopausal, HR-positive, HER2-negative, advanced breast cancer.[26] The use of buparlisib was associated with hyperglycemia, rash, nausea, fatigue, and mood alterations.

Idelalisib

Idelalisib, a highly selective inhibitor of PI3Kδ is indicated for the treatment of patients with relapsed follicular B-cell non-Hodgkin lymphoma or relapsed small lymphocytic lymphoma (SLL) previously treated with two or more prior systemic therapies. In a phase 2 study in this setting, idelalisib was associated with an objective response rate (ORR) of 57%, the median duration of response (DOR) was 12.5 months, and the median PFS was 11 months. The most common grade 3 to 4 adverse events were neutropenia, increase in liver enzymes, and diarrhea.[27]

Duvelisib

Duvelisib, an oral dual PI3Kδγ inhibitor, is indicated for adult patients with relapsed or refractory chronic lymphocytic leukemia (CLL) or SLL after two or more prior therapies. In a phase 3 trial in patients with relapsed or refractory CLL or SLL, duvelisib was associated with longer PFS than ofatumumab. The median PFS durations were 13.3 and 9.9 months for duvelisib and ofatumumab, respectively (HR, 0.52; P <.0001).[28] Similar benefit was noted in patients with high-risk chromosome 17p13.1 deletion or TP53 mutations (HR, 0.40; P = .0002). The ORR was significantly higher in the duvelisib arm compared with the ofatumumab arm (74% vs 45%, respectively; P <.0001) regardless of del(17p) status.[28]

Copanlisib

Copanlisib, a pan-class I PI3K inhibitor with activity against PI3Kα, PI3Kβ, PI3Kδ, and PI3Kγ, is indicated for the treatment of adult patients with relapsed follicular lymphoma treated with two or more prior systemic therapies. In a phase II trial, the use of copanlisib was associated with an ORR of 43.7% and 27.1% in indolent and aggressive lymphoma, respectively. The median PFS and DOR in indolent lymphoma were 9.8 and 13 months, respectively. Common adverse events included hyperglycemia, hypertension, and diarrhea.[29]

Dactolisib

Dactolisib an oral, selective inhibitor of PI3K and TORC1/2, was investigated in phase I/II clinical trials in patients with advanced solid malignancies alone or combined with other agents, in metastatic breast cancer with PI3K/PTEN alterations, in patients with advanced pancreatic neuroendocrine tumors, and in prostate cancer. The development of dactolisib was terminated because of limited antitumor activity and poor safety profile that included nausea, diarrhea, and elevated transaminases.

Alpelisib

Alpelisib, a p110a isoform-specific inhibitor, is indicated in combination with fulvestrant for postmenopausal women and men with HR-positive, HER2-negative, *PI3KCA*-mutated advanced or metastatic breast cancer after progression on or after an endocrine-based therapy. The FDA approval of alpelisib was based on results of a phase III trial; alpelisib combined with fulvestrant was compared with placebo with fulvestrant in patients with HR-positive, HER2-negative breast cancer previously treated with endocrine therapy and stratified on the basis of their *PIK3CA* mutational status. In the *PIK3C*-mutated cohort, the median PFSs were 11.0 months with alpelisib treatment and 5.7 months in the placebo groups (P <.001). No difference in PFS was noted in the wild-type *PIK3CA* cohort.[30]

AKT Inhibitors

AKT inhibitors may induce the PI3K-stimulating receptor tyrosine kinase HER3 in breast cancer cell lines and may increase insulinlike growth factor (IGF) 1R and the insulin receptor, thereby leading to the development of escape pathways and resistance mechanisms. Combination therapies that block the feedback response may overcome resistance to AKT inhibitors. Various AKT inhibitors were investigated in clinical trials, including MK2206, GSK2141795, and BAY1125976, as single agents or in combination with other agents, but their clinical efficacy was limited. A clinical trial with MSC2363318A, a dual p70S6K/AKT inhibitor, has been completed (NCT01971515).

In summary, molecular alterations in the PI3K/AKT/mTOR pathway have been identified in several different tumor types, emphasizing the critical role of this pathway in tumorigenesis and disease progression. Resistance to PI3K/AKT/mTOR inhibitors occurs via several escape mechanisms, and to overcome these mechanisms, PI3K, AKT, or mTOR inhibitors in combination with other targeted or cytotoxic agents are being investigated in clinical trials. In our experience, among patients referred for phase I clinical trials who were treated with targeted therapies, those with molecular alterations in the PI3K/AKT/mTOR pathway had shorter OS than patients with alterations in the RAS/RAF/MEK or EGFR/HER/other pathways.[31] This difference may be attributed at least partially to limited efficacy of targeted agents against tumors driven by PI3K/AKT/mTOR pathway alterations.

Carefully designed clinical trials with novel effective drugs, and the elucidation of mechanisms of response and resistance to PI3K/AKT/mTOR pathway inhibitors, including protein and phosphoprotein expression with signatures of sensitivity or resistance, may improve clinical outcomes.

EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS

EGFR (ErbB1; HER1) is a cell-surface transmembrane receptor that belongs to the EGF family of extracellular protein ligands. It is a member of the ErbB receptor family, which consists of four receptor tyrosine kinases: EGFR, HER2 (ErbB2), HER3 (ErbB3), and HER4 (ErbB4). EGF binds to EGFR, stimulating ligand-induced dimerization, receptor dimerization, and signaling through tyrosine kinase activity, leading to activation of multiple pathways involved in cell proliferation, survival, metastases, and neoangiogenesis. EGFR-targeted therapies include tyrosine kinase inhibitors (TKIs) and monoclonal antibodies.

Erlotinib

Erlotinib targets the EGFR tyrosine kinase and is indicated for first-line treatment of patients with metastatic NSCLC with tumor *EGFR* exon 19 deletions or exon 21 (L858R) substitution mutations, maintenance therapy of patients with NSCLC and no evidence of disease progression after four cycles of platinum-based first-line chemotherapy, treatment of patients with NSCLC after one or more failed chemotherapy regimens, and first-line treatment of patients with locally advanced or metastatic pancreatic cancer in combination with gemcitabine.

In NSCLC, erlotinib demonstrated a significant improvement in median PFS and OS compared with placebo.[32] *EGFR* kinase domain mutations predicted response to EGFR-TKIs.[33,34] In patients with *EGFR* alterations, the response rate to EGFR-TKIs ranges from 48% to 90%.[35,36] Randomized trials demonstrated that the use of gefitinib or erlotinib is associated with longer PFS compared with platinum doublets in patients with lung adenocarcinoma and activating *EGFR* mutations. No OS benefit was noted,[37–41] perhaps partially because of crossover after disease progression. In a randomized study of erlotinib versus placebo as maintenance therapy in patients with advanced NSCLC who had an objective response or stable disease after four cycles of a platinum-based doublet, erlotinib was associated with superior PFS in patients with adenocarcinoma or SCC. Survival benefit was noted only in SCC.[42]

Gefitinib

Gefitinib, an EGFR inhibitor, is indicated as first-line treatment in patients with metastatic NSCLC whose tumors have EGFR exon 19 deletions or exon 21 (L858R) substitution mutations. It selectively binds to its tyrosine kinase domain, which prevents the binding and blocking of ATP to subsequent receptor autophosphorylation and results in inhibition of signal transduction. Gefitinib was the first FDA-approved selective EGFR inhibitor in 2003 for NSCLC, but in 2005, the FDA withdrew this approval for use in new patients because it did not improve OS compared with placebo in previously treated patients.[43] In a phase III trial, patients with metastatic NSCLC and *EGFR* mutations were randomized to receive either gefitinib or carboplatin plus paclitaxel.[39] In the interim analysis, PFS (primary endpoint) was longer in the gefitinib group than in the chemotherapy group (median, 10.8 months vs 5.4 months, respectively; HR, 0.30; $P < .001$). No difference in OS was noted between the two arms.[39]

Afatinib

Afatinib, a selective, oral inhibitor of EGFR/ErbB1, HER2, and HER4, is indicated for patients with

metastatic NSCLC whose tumors have EGFR exon 19 deletions or exon 21 (L858R) substitution mutations. In a phase III study of afatinib or cisplatin plus pemetrexed in patients with metastatic lung adenocarcinoma with EGFR mutations, afatinib was associated with longer PFS compared with standard doublet chemotherapy (11.1 months vs 6.9 months, respectively; $P = .001$).[44] In patients with exon 19 deletions or L858R mutations, the median PFS with afatinib was 13.6 months. Development of resistance to afatinib was attributed to additional *EGFR* (T790M on exon 20, 50% of patients)[45] or *PIK3CA* mutations, *MET* or *HER2* amplification, epithelial-to-mesenchymal transformation, or transformation to small cell lung cancer.

Dacomitinib

Dacomitinib, a second-generation pan-EGFR inhibitor, is indicated for the first-line treatment of patients with metastatic NSCLC with EGFR exon 19 deletion or exon 21 L858R substitution mutations. In a phase III study, in treatment-naïve patients with advanced NSCLC and *EGFR* mutation, the median PFS durations (primary endpoint) were 14.7 months and 9.2 months in the dacomitinib and the gefitinib arms, respectively (HR, 0.59; $P < .0001$). Grade 3 and 4 adverse events were more frequent with dacomitinib than with gefitinib and included dermatitis acneiform, diarrhea, and increase in alanine aminotransferase (ALT) levels. The median OS durations were 34.1 months and 26.8 months in the dacomitinib and the gefitinib arms, respectively (HR, 0.76; $P = .044$).[46]

Osimertinib

Osimertinib, an oral, third-generation EGFR inhibitor, is indicated for the treatment of patients with metastatic EGFR-T790M mutation-positive NSCLC whose disease has progressed on or after EGFR-TKI therapy and for the first-line treatment of patients with metastatic NSCLC whose tumors have EGFR exon 19 deletions or exon 21 L858R mutations. Osimertinib covalently binds to and inhibits the activity of mutant forms of EGFR, including the acquired EGFR resistance mutation T790M, thereby preventing EGFR-mediated signaling that ultimately both induces cell death and inhibits tumor growth.[47] In a phase III study, patients with T790M-positive advanced NSCLC whose disease progressed after first-line EGFR-TKI therapy were randomized to receive osimertinib or pemetrexed plus either carboplatin or cisplatin.[48] PFS was longer in the osimertinib arm compared with the chemotherapy arm (median, 10.1 months vs 4.4 months; HR, 0.30; $P < .001$), and it was also longer in patients with central nervous system (CNS) metastases (8.5 months vs 4.2 months, respectively; HR, 0.32). Grade 3 and 4 adverse events were less frequent with osimertinib arm (23%) compared with chemotherapy (47%).[48] In a phase III study, previously untreated patients with advanced NSCLC and an EGFR deletion in exon 19 or L858R mutation, PFS was longer in the osimertinib arm compared with the standard EGFR-TKI (gefitinib or erlotinib) arm (median, 18.9 months vs 10.2 months, respectively; HR, 0.46; $P < .001$). At 18 months, the OS rates were 83% and 71%, respectively (HR, 0.63; $P = .007$), and osimertinib was better tolerated than the standard EGFR-TKIs (grade 3–4 adverse events, 34% vs 45%, respectively).[49]

Cetuximab

Cetuximab is a chimeric mouse–human immunoglobulin (Ig) 1 monoclonal antibody (mAb) against EGFR. It is indicated for the treatment of patients with advanced SCC of the head and neck combined with radiation therapy, recurrent or metastatic SCC of the head and neck combined with platinum-based therapy with 5-fluorouracil (5-FU), and recurrent or metastatic SCC of the head and neck that progresses after platinum-based therapy. Cetuximab with FOLFIRI (infusional fluorouracil, leucovorin, and irinotecan) is indicated for the first-line treatment of patients with *KRAS* wild-type, EGFR-positive metastatic colorectal cancer (CRC); cetuximab with irinotecan is indicated for irinotecan-refractory patients. Cetuximab monotherapy is also indicated for patients with oxaliplatin- and irinotecan-refractory CRC or patients with irinotecan intolerance.

Because EGFR mutations and overexpression are frequent in patients with CRC, in patients with irinotecan-refractory CRC, cetuximab demonstrated antitumor activity as monotherapy (ORR, 10.8%; median time to progression [TTP], 1.5 months; median OS, 6.9 months) or combined with irinotecan (ORR, 22.9%; median TTP, 4.1 months; median OS, 8.6 months).[50] In a phase III study, cetuximab was associated with improved OS compared with best supportive care in patients with refractory metastatic CRC (6.1 months vs 4.6 months).[51] In another phase III study, first-line treatment with cetuximab plus FOLFIRI reduced the risk of progression compared with FOLFIRI alone in patients with metastatic CRC, but the benefit of cetuximab was limited to patients with *KRAS* wild-type tumors.[52] In patients with previously untreated metastatic CRC, cetuximab plus FOLFOX-4 (oxaliplatin, leucovorin, and FU) was associated with a higher ORR compared with FOLFOX-4 alone (43% vs 36%).[53] In patients with KRAS wild-type CRC, cetuximab plus FOLFOX-4 compared with FOLFOX-4 alone was associated with a higher ORR (61% vs 37%; $P = .01$) and a lower risk of disease progression (HR, 0.57; $P = .02$). This study established KRAS mutational status as

a selection criterion for the addition of cetuximab to FOLFOX-4 in this setting.[53]

Panitumumab

Panitumumab, a fully humanized IgG2 anti-hEGFR antibody, is indicated for the treatment of patients with wild-type *KRAS* (exon 2 in codons 12 or 13) metastatic CRC as first-line therapy in combination with FOLFOX or monotherapy in fluoropyrimidine-, oxaliplatin-, and irinotecan-refractory patients. In a phase III study of panitumumab with FOLFOX4 versus FOLFOX4 alone as first-line therapy in patients with wild-type *KRAS* metastatic CRC, the addition of panitumumab to FOLFOX4 resulted in higher ORR (57% vs 48%; $P = .02$), PFS (10 months vs 8.6 months; $P = .01$), and OS (HR, 0.83; $P = .03$).[54] In a randomized study of panitumumab versus cetuximab in patients with chemotherapy-refractory wild-type *KRAS* exon 2 metastatic CRC, panitumumab was not inferior to cetuximab, and the OS benefit was similar (median OS, 10.4 months vs 10 months, respectively; HR, 0.97).[55]

Necitumumab

Necitumumab, a second-generation, recombinant, human IgG1 EGFR mAb, is indicated in combination with gemcitabine and cisplatin for the first-line treatment of patients with locally advanced or metastatic squamous NSCLC.[56] Necitumumab binds to EGFR with high affinity, competing with ligands leading to the inhibition of receptor activation and downstream signaling. In a phase III study in patients with previously untreated stage IV squamous NSCLC, the use of necitumumab plus gemcitabine and cisplatin was associated with longer OS compared with gemcitabine and cisplatin (median, 11.5 months vs 9.9 months; HR, 0.84; $P = .01$]). Grade 3 and 4 adverse events were more frequent in the necitumumab arm (72% vs 62%).[56]

c-KIT PATHWAY INHIBITORS

The receptor tyrosine kinase protein KIT (c-Kit or CD117) is encoded by the *KIT* gene. KIT regulates cell differentiation and proliferation, resists cell apoptosis, and plays an important role in tumorigenesis and migration by activating downstream signaling molecules following interaction with stem cell factor (SCF). Complete loss of KIT activity results in in utero or perinatal death; KIT "loss of function" leads to failure of particular stem cell populations to migrate and survive.

Activating mutations of *KIT* occur in almost all patients with systemic mastocytosis. In gastrointestinal stromal tumors (GISTs), activating mutations of KIT occur in more than 80% of patients; two thirds of *KIT* mutations occur in exon 11, resulting in dysfunction of the intracellular autoinhibitory juxtamembrane domain. The majority of these mutations are indels. Deletion of exon 11 is associated with shorter PFS and OS in patients with GIST. Approximately 10% to 15% of *KIT* mutations in GIST occur in the extracellular region encoded by exon 9 (primarily in intestinal GIST). KIT mutations occur in core binding factor leukemias (17% of acute myeloid leukemia), in up to 26% of patients with testicular seminomas, and in 30% of patients with unilateral ovarian dysgerminomas. Activating *KIT* mutations and amplifications have been reported in 5% of patients with melanoma. In melanoma, more than 90% of these mutations are missense mutations and their distribution is as follows: exon 9 (5%), exon 11 (45%), exon 13 (25%), exon 17 (10%), and exon 18 (15%). KIT inhibition is an effective therapeutic strategy in patients with tumor aberrations of the SCF/c-KIT signaling pathway.

In the pre-imatinib era, the median survival time of patients with advanced GIST was less than 1.5 years. The use of imatinib in patients with advanced GIST is associated with a median survival period of approximately 5 years.[57] Imatinib binds directly to the ATP-binding site within KIT, competitively inhibiting ATP binding and stabilizing the kinase in the inactive conformation. In the adjuvant setting, imatinib was associated with decreased risk of relapse after surgery with curative intent.[58] The reintroduction of imatinib after disease relapse is associated with results inferior to those for continued imatinib therapy, suggesting that imatinib treatment should not be interrupted.[57] Primary resistance to imatinib is noted in 10% of patients with GIST and is attributed to the type of KIT mutation (threefold higher risk of resistance with exon 9 mutations than with exon 11 mutations) or to suboptimal dose in patients with *KIT* exon 9 mutations.[59] Secondary resistance is attributed to acquired mutations in the ATP-binding site (exons 13/14) that interfere with imatinib binding or in the activation loop (exons 17/18) that stabilize the active conformation of KIT.[60]

In patients with imatinib-resistant GIST tumors, sunitinib (anti–vascular endothelial growth factor [VEGF] TKI) demonstrated significant improvement in the median TTP compared with placebo, leading to FDA approval for this indication.[61] The efficacy of sunitinib in patients with imatinib-secondary resistance is attributed to its structural and enzymatic characteristics and to targeting additional tyrosine kinases.[62] Regorafenib is also indicated for patients with TKI-resistant GIST. In a phase III study, regorafenib was associated with longer PFS than placebo (median PFS, 4.8 months vs 0.9 months, respectively; $P < .0001$).[63]

Ripretinib

Ripretinib, a synthetic kinase inhibitor that targets a wide range of KIT mutants, is for the treatment of adults with GIST who have received therapy with three or more kinase inhibitors, including imatinib. DP-5439, the active metabolite of ripretinib, is a type II inhibitor of KIT and platelet-derived growth factor receptor (PDGFR) A.[64] In a phase III study in patients with GIST previously treated with imatinib, sunitinib, and regorafenib, the ORR was 9% with ripretinib versus 0% with placebo; the median PFS was 6.3 months versus 1.0 month, respectively (HR, 0.15; P <.0001); and the median OS was 15.1 months versus 6.6 months, respectively (HR, 0.36). The most common adverse events were GI symptoms, alopecia, fatigue, myalgia, and palmar-plantar erythrodysesthesia. KIT inhibitors have been combined with other targeted agents in the hope of improving the outcomes of patients with KIT alterations and overcoming resistance.

Avapritinib

Avapritinib, a selective kinase inhibitor with broad activity against oncogenic KIT/PDGFRA mutants, is indicated for the treatment of adults with unresectable or metastatic GIST harboring PDGFRA exon 18 mutations, including D842V mutations. In a phase II study in 43 patients with advanced GIST harboring PDGFRA mutations in exon 18, the ORR was 86%.[65]

HUMAN EPIDERMAL GROWTH FACTOR RECEPTOR 2 PATHWAY INHIBITORS

HER2 is involved in the regulation of proliferation and survival of epithelial cells. HER1, HER3, and HER4 receptors have ligands and form homodimers or heterodimers upon ligand binding. HER2 can heterodimerize with any of the other receptors and is the preferred dimerization partner, leading to autophosphorylation of tyrosine residues within the cytoplasmic domain of the receptors and initiating signal transduction via the PI3K/AKT and RAS/MAPK pathways. In breast cancer, amplification and overexpression of the HER2 oncogene occurs in approximately 15% to 20% of patients. HER2 is overexpressed in various tumor types, including gastroesophageal junction adenocarcinoma and colorectal, gallbladder, and lung tumors.

Trastuzumab

Trastuzumab is a recombinant DNA-derived humanized mAb that selectively binds with high affinity to the extracellular domain of HER2 protein. The antibody is an IgG1κ that contains human framework regions with the complementarity-determining regions of a murine antibody that binds to HER2. Trastuzumab is indicated as monotherapy for patients with metastatic breast cancer whose tumors overexpress HER2 protein and who have had one or more chemotherapy regimen and combined with paclitaxel for patients with metastatic breast cancer whose tumors overexpress HER2 protein and who have not received chemotherapy for their metastatic disease. Approximately 15% of patients develop disease recurrence after trastuzumab therapy. Resistance to trastuzumab has been attributed to altered receptor–antibody interaction, activation of the downstream pathways by increased signaling from other members of the HER family or other receptors, or constitutive activation of downstream elements.

Lapatinib

Lapatinib, a dual TKI of EGFR and HER2, is indicated in combination with capecitabine for patients with advanced or metastatic breast cancer whose tumors overexpress HER2 and who have received prior therapy, including anthracycline, taxane, and trastuzumab therapy; it is also indicated in combination with letrozole for postmenopausal women with HR-positive metastatic breast cancer that overexpresses the HER2 receptor and for whom hormonal therapy is also indicated.

Ado-Trastuzumab Emtansine

Trastuzumab emtansine (ado-trastuzumab emtansine, T-DM1), an antibody–drug conjugate consisting of trastuzumab linked to the cytotoxic agent mertansine, is indicated as monotherapy for patients with HER2-positive, metastatic breast cancer previously treated with trastuzumab with or without a taxane. Trastuzumab binds to HER2, and mertansine enters and destroys cells by binding to tubulin. In patients with HER2-positive, trastuzumab-resistant breast cancer, trastuzumab emtansine improved survival by 5.8 months compared with lapatinib and capecitabine combination therapy.[66] Trastuzumab emtansine is also indicated for the adjuvant treatment of patients with HER2-positive early breast cancer who have residual invasive disease after neoadjuvant taxane and trastuzumab-based treatment.[67] In a phase III study in this setting, the rates of invasive disease or death were 12.2% with trastuzumab emtansine versus 22.2% with trastuzumab. Invasive DFS was significantly higher in the trastuzumab emtansine group (HR, 0.5; P <.001).[67]

Pertuzumab

Pertuzumab, a humanized mAb that binds to the HER2 receptor and inhibits the interaction between HER2 and HER1, HER3, and HER4, is indicated in combination with trastuzumab and docetaxel as a neoadjuvant treatment for patients with HER2-positive breast cancer and as a treatment for patients with HER2-positive metastatic breast cancer. In a phase III trial, patients with node-positive or high-risk node-negative HER2-positive, operable breast cancer were randomized to receive pertuzumab or placebo added to standard adjuvant chemotherapy plus 1 year of treatment with trastuzumab.[68] The rates of disease recurrence were 7.1% versus 8.7% in the pertuzumab and the placebo groups, respectively (HR, 0.81; $P = .045$), and the 3-year rate of invasive DFS was lower in the node-positive group treated with pertuzumab compared with placebo (HR, 0.77; $P = .02$).[68]

Neratinib

Neratinib, an irreversible small-molecule TKI of HER1, HER2, and HER4, is indicated for the extended adjuvant treatment of adult patients with early-stage HER2-overexpressed or amplified breast cancer to follow adjuvant trastuzumab-based therapy. In a phase III trial in patients with stage 1-3c HER2-positive, operable breast cancer who had completed neoadjuvant and adjuvant chemotherapy plus trastuzumab with no evidence of disease recurrence or metastatic disease at study entry, the events of invasive DFS were lower with 1 year of neratinib compared with placebo (116 vs 163 events; HR, 0.73; $P = .0083$).[69] The most common adverse events were GI, mainly diarrhea. Neratinib is also indicated in combination with capecitabine for adult patients with advanced or metastatic HER2-positive breast cancer who have received two or more prior anti-HER2-based regimens in the metastatic setting.[70] In a phase III study in this setting, PFS was longer with neratinib and capecitabine than with lapatinib and capecitabine (at 1-year, 37.8% vs 14.8%, respectively), and the 1-year OS rates were 87.5% and 66.7%, respectively (HR, 0.88; $P = .21$).[70]

Fam-Trastuzumab Deruxtecan-Xki

Trastuzumab deruxtecan, is an antibody–drug conjugate of a humanized mAb that targets HER2, a cleavable tetrapeptide-based linker, and topoisomerase I inhibitor (cytotoxic drug). It is indicated for the treatment of patients with unresectable or metastatic HER2-positive breast cancer who have received two or more prior anti-HER2-based regimens in the metastatic setting.[71] In a phase 2 study in 184 patients with HER2-positive metastatic breast cancer who had previously received trastuzumab emtansine, trastuzumab deruxtecan was associated with response duration of 14.8 months and PFS of 16.4 months. The most common adverse events grade 3 or greater were neutropenia, anemia, and nausea.[72]

CDK 4/6 INHIBITORS

The cell cycle progression from G1 to mitosis is controlled by many proteins, including CDKs, cyclins, and the retinoblastoma (Rb)-E2F signaling pathway. These cyclins are the downstream effectors of many upstream activating complex networks, including ER/PR/androgen receptor (AR), nuclear factor κB (NF-κB), MAPKs, signal transducers and activators of transcription (STATs), WNT/β-catenin, and PI3K/AKT/mTOR.[73] In many cancer cells, CDK4 and CDK6 mediate cell cycle control. CDK inhibitors include the first-generation inhibitors (eg, flavopiridol) and the newer, more selective inhibitors (eg, palbociclib, ribociclib, and abemaciclib) (Fig. 57–2).

Flavopiridol

Flavopiridol is a pan-CDK inhibitor that targets CDK 1, 2, 4, 6, 7, and 9, has modest antitumor activity in patients with CLL.

Palbociclib

Palbociclib, an oral selective CDK4/6 inhibitor, is indicated in combination with an aromatase inhibitor for the initial endocrine-based therapy of postmenopausal women with HR-positive, HER2-negative, advanced or metastatic breast cancer. This indication was expanded to include men based on data from electronic health records. In a phase III trial in postmenopausal women with ER-positive, HER2-negative, previously untreated breast cancer, the median PFS was 24.8 versus 14.5 months in the palbociclib plus letrozole arm and in the placebo plus letrozole arm, respectively (HR, 0.58; $P < .001$). Grade 3 and 4 adverse events were more frequent in the combination arm (neutropenia, 66.4% vs 1.4%; leukopenia, 24.8% vs 0%).[74]

Palbociclib is also indicated in combination with fulvestrant for the treatment of patients with HR-positive, HER2-negative advanced or metastatic breast cancer in women with disease progression after endocrine therapy on the basis of results of a phase III study in this setting that demonstrated longer OS with palbociclib plus fulvestrant group than with placebo plus fulvestrant (median, 34.9 vs 28 months, respectively; HR, 0.81; $P = .09$). The median time to initiation of subsequent chemotherapy at the time of disease progression was 17.6 versus 8.8 months in the palbociclib

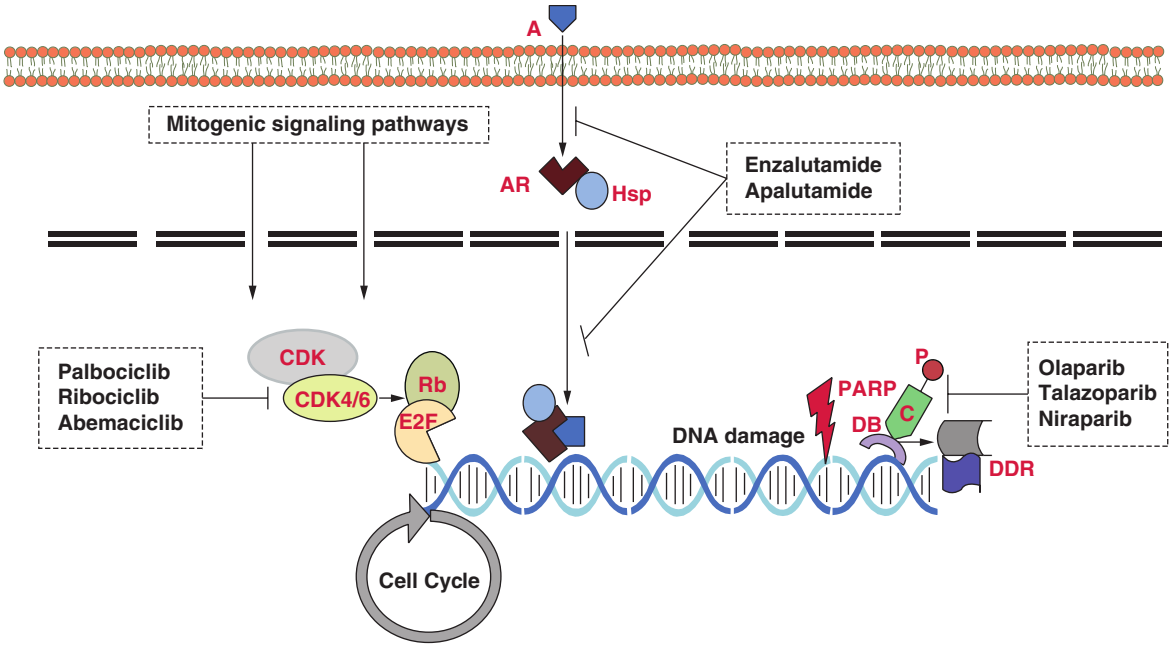

FIGURE 57–2 Major targeted intranuclear cancer pathways and associated approved targeted agents. A, androgen; AR, androgen receptor; CDK, cyclin-dependent kinase; DB, DNA binding domain; DDR, DNA damage response; E2F, eukaryote factor 2; Hsp, heat shock protein; PARP, poly (ADP-ribose) polymerase; P, phosphorylated; C, catalytic domain, Rb, retinoblastoma protein.

plus fulvestrant group and the placebo plus fulvestrant group, respectively (HR, 0.58; P <.001).[75]

Ribociclib

Ribociclib, an oral CDK4/6 inhibitor that blocks the phosphorylation of the Rb protein that leads to the inhibition of cell cycle progression and induces G1 phase arrest, is indicated in combination with an aromatase inhibitor as initial endocrine-based therapy for treatment of postmenopausal women with HR-positive, HER2-negative advanced or metastatic breast cancer. In a phase III study in postmenopausal women with HR-positive, HER2-negative recurrent or metastatic breast cancer with no previous systemic therapy, PFS (primary endpoint) was longer with ribociclib plus letrozole than with placebo plus letrozole (HR, 0.56; $P = 3.29 \times 10^{-6}$). At 18 months, the PFS rate was 63.0% vs 42.2% in the ribociclib versus the placebo group, respectively. Grade 3/4 neutropenia occurred in 59.3% of patients in the ribociclib arm and 0.9% in the placebo arm.[76] In another phase III trial in premenopausal or perimenopausal women with HR-positive, HER2-negative advanced breast cancer, the addition of ribociclib to endocrine therapy (goserelin adose and either a nonsteroidal aromatase inhibitor or tamoxifen) was associated with a longer OS than endocrine therapy alone (3.5-year OS rates, 70.2% vs 46.0% in the ribociclib vs placebo groups, respectively, HR, 0.71; P = .0097).[77] Therefore, the FDA expanded the approval of ribociclib to include pre- and perimenopausal women. In another phase III study, men and postmenopausal women with HR-positive, HER2-negative advanced breast cancer (metastatic or locoregionally recurrent disease not amenable to curative treatment) were randomized to receive ribociclib plus fulvestrant or placebo plus fulvestrant.[78] The 3.5-year OS (primary endpoint) rates were 57.8% vs 45.9% in the ribociclib and the placebo groups, respectively (relative risk of death, 28%; HR, 0.72; P = .0045).[78]

Abemaciclib

Abemaciclib is a selective inhibitor of CDK4/6 with higher potency against CDK4/cyclin D1 than CDK6/cyclin D6 and a lower IC_{50} compared with other available CDK4/6 inhibitors. Abemaciclib is indicated as monotherapy for women and men with HR-positive, HER2-negative advanced or metastatic breast cancer with disease progression following endocrine therapy and prior chemotherapy in the metastatic setting and in combination with fulvestrant for women with HR-positive, HER2-negative advanced or metastatic breast cancer with disease progression after endocrine therapy. In a phase III study in women with HR-positive, HER2-negative advanced breast cancer whose disease had progressed while receiving prior endocrine therapy, abemaciclib plus fulvestrant significantly extended PFS (primary endpoint) versus fulvestrant alone (median, 16.4 vs 9.3 months; HR, 0.55; P

<.001). The most common adverse events in the abemaciclib versus placebo arms were diarrhea (86.4% vs 24.7%), neutropenia (46.0% vs 4.0%), nausea (45.1% vs 22.9%), and fatigue (39.9% vs 26.9%).[79]

In another phase III study in postmenopausal women with HR-positive, HER2-negative advanced breast cancer with no prior systemic therapy in the advanced setting of abemaciclib or placebo plus a nonsteroidal aromatase inhibitor, the median PFS (primary objective) was significantly prolonged in the abemaciclib arm (HR, 0.54; $P = .000021$).[80] Adverse events were more common in the abemaciclib arm and included diarrhea (all grades, 81.3%; grade 1, 44.6%), neutropenia (grades 3–4, 21.1% vs 1.2%) and leukopenia (grades 3–4, 7.6% vs 0.6%).[80]

ANDROGEN RECEPTOR PATHWAY INHIBITORS

The AR, a member of the nuclear receptor superfamily, shares similar structure with estrogen receptor (ER), progesterone receptor (PR), and the thyroid hormone and glucocorticoid receptors. The gene that encodes for AR consists of eight exons and is located on chromosome X. Testing of AR by immunohistochemistry in normal prostate results in strong staining of luminal cells, fibromuscular stromal cells, and endothelial cells but not basal cells. In normal prostate tissue, AR plays a major role in protein secretion and prostate growth, and the functions of AR in prostate cancer include prostate-specific antigen synthesis and lipid metabolism regulation. Androgen deprivation is a key treatment option for patients with prostate cancer. Some patients develop castration-resistant prostate cancer (CRPC) status via various mechanisms that include AR point mutation, amplification, variants or cofactor variations, and androgen biosynthesis variations.

Enzalutamide

Older antiandrogens (bicalutamide and flutamide) bind to the ligand-binding domain (LBD) of AR and result in the inhibition of androgen binding to LBD, leading to growth inhibition of prostate cancer cells. Second-generation nonsteroidal antiandrogens, such as enzalutamide, have greater affinity for the LBD of AR.[81] Enzalutamide is indicated for the treatment of patients with metastatic or nonmetastatic CRPC as first-line therapy and for patients with metastatic castration-sensitive prostate cancer.

Abiraterone

Abiraterone is a selective inhibitor of androgen biosynthesis mainly via blocking cytochrome P450 c17 (CYP17), a critical enzyme in testosterone synthesis, and blocking androgen synthesis in the adrenal glands, testes, and the prostate tumor. Abiraterone is indicated in combination with prednisone for the treatment of patients with metastatic CRPC and for metastatic high-risk castration-sensitive prostate cancer. Adverse events include mineralocorticoid excess, adrenocortical insufficiency, and hepatotoxicity.

Apalutamide

Apalutamide, a nonsteroidal antiandrogen agent, binds directly to the LBD of the AR, leading to the inhibition of AR translocation to DNA binding and subsequently blocking AR-mediated transcription and inhibition of prostate cancer cell growth. Apalutamide is indicated for the treatment of patients with nonmetastatic CRPC and for metastatic castration-sensitive prostate cancer.

PARP INHIBITORS

BRCA1 and BRCA2 are key proteins in DNA damage response (DDR). Hereditary BRCA1/2 mutations, by leading to impaired double-strand DNA repair, are associated with an increased risk of breast and ovarian cancer. Poly (ADP-ribose) polymerase (PARP) is a family of proteins that play a key role in various cellular processes that include DNA repair, chromatin modulation, and replication stress response. PARP1 and PARP2, through multiple DDR pathways, play critical roles in DNA strand break repair that help maintain cell survival. Thus, the use of PARP inhibitors in tumors with deleterious BRCA1/2 mutations or other DDR alterations renders the cells unable to efficiently repair DNA and makes them vulnerable to apoptosis.

PARP inhibitors in clinical testing include olaparib, talazoparib, niraparib, rucaparib, and velaparib as single agents or in combination with other agents.

Olaparib

Olaparib, an oral PARP inhibitor, that induces synthetic lethality in BRCA-deficient cells, is indicated for the treatment of patients with deleterious or suspected deleterious germline BRCA-mutated (gBRCAm), HER2-negative metastatic breast cancer previously treated with chemotherapy either in the neoadjuvant, adjuvant, or metastatic setting. In a phase II trial, maintenance treatment with olaparib in patients with platinum-sensitive, relapsed, high-grade serous ovarian cancer who had received two or more platinum-based regimens significantly improved PFS but not OS.[82] In a phase III trial in patients with a gBRCAm and HER2–negative metastatic breast cancer with two or fewer previous chemotherapy regimens for metastatic disease,

olaparib was associated with longer PFS than single-agent chemotherapy per physician's choice (median, 7.0 months vs 4.2 months; HR, 0.58; P <.001).[83]

Another indication of olaparib is for the treatment of adult patients with deleterious or suspected deleterious gBRCAm or somatic BRCA-mutated (sBRCAm) advanced epithelial ovarian, fallopian tube, or primary peritoneal cancer who are in CR or PR after first-line platinum-based chemotherapy as maintenance treatment. This approval was based on results of a phase III trial in this setting that demonstrated that after a median follow-up period of 41 months, the risk of disease progression was 70% lower in the olaparib arm compared with the placebo arm (60% vs 27%, HR, 0.3; P <.0001).[84]

Olaparib is also indicated for the maintenance treatment of adult patients with deleterious or suspected deleterious gBRCA-mutated metastatic pancreatic adenocarcinoma whose disease has not progressed on 16 weeks or longer of a first-line platinum-based chemotherapy regimen, on the basis of a phase III study that demonstrated longer PFS in this setting in patients treated with olaparib compared with placebo (median, 7.4 vs 3.8 months, respectively; HR, 0.53; P = .004).[85]

Talazoparib

Talazoparib a PARP inhibitor with strong catalytic inhibition of TRAP in addition to potential for PARP trapping, is indicated for patients with deleterious or suspected deleterious gBRCAm, HER2-negative locally advanced or metastatic breast cancer. In a phase III study in this setting, talazoparib was associated with longer PFS compared with the standard of care (SOC) (capecitabine, eribulin, gemcitabine, or vinorelbine) physician's choice (8.6 vs 5.6 months, respectively, HR, 0.54; P <.001). The most common grade 3 and 4 adverse event was anemia (55%).

Niraparib

Niraparib, a selective inhibitor of PARP 1/2, is indicated for patients with advanced ovarian, fallopian tube, or primary peritoneal cancer treated with three or more prior chemotherapy regimens and whose cancer is associated with homologous recombination deficiency (HRD)–positive status, defined as a deleterious or suspected deleterious BRCA mutation or genomic instability in patients with disease progression for longer than 6 months after response to the last platinum-based chemotherapy. In a phase III trial in patients with platinum-sensitive, recurrent ovarian cancer, niraparib was associated with longer PFS compared with placebo (21.0 vs 5.5 months in the gBRCA mutation cohort; HR, 0.27; and 9.3 months vs 3.9 months in the overall non-gBRCA cohort; HR, 0.45; P <.001 for both comparisons).[86] In another phase III trial, in patients with newly diagnosed advanced ovarian cancer, in the HRD group, the median PFS was 21.9 months versus 10.4 months in the niraparib versus the placebo arms, respectively (HR, 0.43; P <.001); and in the overall population, the median PFS was 13.8 months versus 8.2 months (HR, 0.62; P <.001).[87]

Rucaparib

Rucaparib is indicated for the treatment of patients with deleterious gBRCAm mutation or somatic BRCAm-associated advanced ovarian cancer who have been treated with two or more chemotherapies, on the basis of results of two multicenter, single-arm clinical trials that demonstrated an ORR of 54% (CR, 9%) and response duration of 9.2 months in this setting.

c-MET PATHWAY INHIBITORS

c-MET (or MET) is a receptor tyrosine kinase with specificity for a single ligand, the hepatocyte growth factor (HGF). HGF binding to MET leads to receptor dimerization and autophosphorylation of MET on its intracellular kinase domain and subsequent phosphorylation of its C-terminal docking site and juxtamembrane domain. These phosphorylation events enable activation of multiple downstream effector proteins such as the adaptor proteins Grb2 and Gab1, leading to activation of the PI3K, RAS/RAF/MEK/ERK, PLC-γ, STATs, and FAK signaling pathways. c-MET plays a role in promoting the proliferation, survival, motility, and invasion of normal and tumor cells. c-MET and phospho-c-MET have been associated with poor clinical outcomes in various tumors. c-MET mutations are usually a result of sporadic somatic alterations acquired during cancer development.

Cabozantinib

Cabozantinib, a small-molecule inhibitor that inhibits c-MET, VEGFR2, AXL, and RET (receptor tyrosine kinase), is indicated for medullary thyroid cancer,[88] for renal cell carcinoma as first- and second-line therapy after TKI treatment and as second-line therapy after sorafenib in advanced hepatocellular carcinoma.

Capmatinib

Capmatinib, a selective MET inhibitor is indicated for the treatment of adult patients with metastatic NSCLC whose tumors have a mutation that leads to $MET\Delta^{ex14}$ as detected by an FDA-approved test on the basis of an ORR of 68%, response duration of 9.7 months, and manageable toxicity in this subset of patients.[89] Phase

II/III studies of other c-MET inhibitors (rilotumumab, ficlatuzumab, onartuzumab, tivantinib) were discontinued owing to the lack of clinical efficacy.[90] Clinical trials of selective c-MET inhibitors are ongoing. Most clinical trials with MET inhibitors were inconclusive, likely owing to differences in function of MET alterations, suboptimal validation of biomarker analysis, and limited antitumor activity of most inhibitors.[91]

ANAPLASTIC LYMPHOMA KINASE PATHWAY INHIBITORS

Crizotinib

ALK gene rearrangements occur in 2% to 7% of patients with NSCLC. Crizotinib, a small-molecule inhibitor of ALK, ROS1, and c-MET, is indicated for the treatment of patients with ALK-positive NSCLC. In these patients, crizotinib as first-line therapy was associated with longer PFS and less toxicity compared with chemotherapy.[92,93] Novel ALK inhibitors were developed to overcome resistance to crizotinib, which is attributed to secondary mutations within the ALK-TK domain; EML4-ALK amplification; bypass activation of the alternative signaling pathways EGFR, c-KIT, KRAS, and IGF-1 receptor; and progression or occurrence of CNS metastases.

Ceritinib

Ceritinib, an ATP-competitive ALK inhibitor, is indicated for the treatment of patients with ALK-positive metastatic NSCLC who have shown disease progression on or are intolerant to crizotinib. In a phase III study, patients with stage IIIB/IV ALK-rearranged nonsquamous NSCLC who were randomized to receive ceritinib had longer PFS than those randomized to receive platinum-based chemotherapy (16.6 vs 8.1 months, respectively; HR, 0.55, P <.00001). GI toxicity was commonly reported in the ceritinib group.[94]

Alectinib

Alectinib, another second-generation ALK inhibitor, is indicated for the treatment of patients with metastatic ALK-positive NSCLC. In a phase III study in patients with previously untreated, advanced ALK-positive NSCLC, alectinib was associated with longer PFS compared with crizotinib (HR, 0.47; P <.001).[95] After a median follow-up period of 1.5 years, disease progression or death occurred in 41% versus 68% of the alectinib and crizotinib groups, respectively. CNS progression was noted in 12% versus 45% of the alectinib and crizotinib groups, respectively (HR, 0.16; P<.001). Grade 3 to 5 adverse events were less frequent with alectinib compared with crizotinib (41% vs 50%).[95]

Brigatinib

Brigatinib, an inhibitor of ALK and mutant EGFR, is indicated for the treatment of patients with metastatic ALK-positive NSCLC who have progressed on or are intolerant to crizotinib. In a phase III study in patients with advanced ALK-positive NSCLC who had not previously received ALK inhibitors, PFS was longer with brigatinib than with crizotinib (1-year PFS, 67% vs 43%; HR, 0.49; P <.001).[96] The ORR and intracranial response rates both favored brigatinib over crizotinib.[96]

Lorlatinib

Lorlatinib is a new, reversible, ATP-competitive, small-molecule, third-generation, highly selective inhibitor of ALK and the ROS1, that retains potency against all known ALK-resistant mutants.[97] Lorlatinib is indicated for patients with ALK-positive metastatic NSCLC whose disease has progressed on crizotinib and one or more other ALK inhibitor for metastatic disease or whose disease has progressed on alectinib or ceritinib as the first ALK inhibitor therapy for metastatic disease. In a phase II study, patients with ALK-positive or ROS1-positive, advanced NSCLC, with or without CNS metastases, were treated with lorlatinib.[98] The primary endpoints were ORR and intracranial tumor response. The treatment groups were as follows: ALK positive and treatment naive (EXP1); ALK positive and prior crizotinib without chemotherapy (EXP2); ALK positive and prior crizotinib with chemotherapy (EXP3A); ALK positive, one prior non-crizotinib ALK inhibitor with or without chemotherapy (EXP3B); ALK positive, two prior ALK inhibitors with or without chemotherapy (EXP4); ALK positive, three prior ALK inhibitors with or without chemotherapy (EXP5); and ROS1 positive with any previous treatment (EXP6). In treatment-naïve patients (EXP1), the ORR was 90%, and the objective intracranial response rate was 67%. In ALK-positive patients with one or more previous ALK TKI (EXP2–5), the ORR was 47%, and the objective intracranial response rate was 63%. The ORR rates were 69.5% in patients previously treated with crizotinib (EXP2–3A), 32.1% in patients previously treated with a non-crizotinib ALK TKI (EXP3B), and 38.7% in patients with two or more previous ALK TKI treatments (EXP4–5). The objective intracranial response rates were 87% in EXP2–3A, 55.6% in EXP3B, and 53% in EXP 4–5.[98]

NTRK PATHWAY INHIBITORS

The neurotrophic tyrosine kinase receptor (NTKR) genes encode for a family of kinase membrane-bound receptors that, upon neurotrophin binding,

phosphorylate themselves (autophosphorylation) and members of the MAPK pathway. Gene fusions of NTRK1, NTRK2, or NTRK3 that encode the neurotrophin receptors TRKA, TRKB, and TRKC, respectively, are oncogenic drivers of various adult and pediatric tumor types. NTRK fusions are rarely identified in head and neck (0.5%), lung (0.1%–3.3%), colon (0.2%–2.7%), or thyroid (2.4%) cancers; glioblastoma (0.6%–1.2%); and sarcoma (0.2%–1.0%). Their frequency is higher in pediatric high-grade glioma (7%), papillary thyroid cancer (25.9%), and infantile fibrosarcoma and mammary analogue secretory carcinoma of the salivary gland (> 90%). The treatment of patients with NTRK fusion-positive cancers with larotrectinib or entrectinib, the first-generation TRK inhibitors, is associated with high response rates (>75%), regardless of tumor histology. Development of resistance to these inhibitors is attributed to the acquisition of NTRK kinase domain mutations. Second-generation NTRK inhibitors, such as LOXO-195 and TPX-0005, are currently being explored in clinical trials.

Larotrectinib

Larotrectinib, a potent and highly selective small-molecule inhibitor of NTRK1, NTRK2, and NTRK3 proteins, is FDA approved for adult and pediatric patients with solid tumors that have a NTRK gene fusion without a known acquired resistance mutation, that are either metastatic or where surgical resection is likely to result in severe morbidity, and who have no satisfactory alternative treatments or whose cancer has progressed after treatment. In patients aged 4 months to 76 years with 17 different tumor types and a TRK fusion, the ORR was 75%.[99] The PFS rate at 1 year was 55%. Drug-related grade 3 or 4 adverse events were reported in fewer than 5% of patients.[99] In patients with TRK fusion-positive cancer treated included in phase I and II trials of larotrectinib, the ORR rate was 79% (CR, 16%) and grade 3 or 4 adverse events were increased ALT (3%), anemia (2%), and neutropenia (2%).[100]

Entrectinib

Entrectinib, a potent inhibitor of TRKA, TRKB, TRKC, ROS1, and ALK, is specifically designed to cross the blood brain barrier (BBB) in addition to its systemic activity. It is indicated for the treatment of adults and patients 12 years of age or older with solid tumors with NTRK gene fusions without a known acquired resistance mutation, with metastatic disease or when surgical resection is contraindicated, and with progression after treatment or without satisfactory standard therapy. In three phase I to II trials in adults with advanced, metastatic NTRK fusion-positive solid tumors, the ORR was 57% (CR, 7%), and the median response duration was 10 months.[101] Grade 3 and 4 adverse events were increased weight (10%), anemia (12%), and nervous system disorders (4%).[101]

ROS PROTO-ONCOGENE 1 RECEPTOR TYROSINE KINASE PATHWAY INHIBITORS

ROS1 is a pivotal transmembrane receptor protein tyrosine kinase that regulates apoptosis, survival, differentiation, proliferation, cell migration, and transformation. ROS1 rearrangements were reported in 1% to 2% of patients with NSCLC and, is involved in various malignancies, including glioblastoma, colorectal cancer, gastric adenocarcinoma, inflammatory myofibroblastic tumor, ovarian cancer, and angiosarcoma. ROS1 and ALK share 49% sequence homology in their primary structures.

Crizotinib is indicated for the treatment of patients with metastatic NSCLC whose tumors are ROS1 positive. Crizotinib was superior to standard chemotherapy in patients with advanced NSCLC with *ALK* rearrangement in a phase III study.[92] In a phase II study in advanced NSCLC with *ROS1* rearrangement, crizotinib was associated with an ORR of 72% (CR, 6%), and the median DOR and PFS were 17.6 months and 19.2 months, respectively.[102]

NOTCH PATHWAY INHIBITORS

Notch was first identified as an oncogene in T-cell acute lymphoblastic leukemia (T-ALL) in which the t(7;9) chromosomal translocation fuses the N-terminal region of the T-cell receptor β (TCR-β) to the C-terminus of Notch1. The truncated Notch1 protein lacks the extracellular subunit and is constitutively active. The intracellular forms of all four Notch proteins are capable of transforming normal cells. Deregulated expression of Notch proteins, ligands, and targets has been described in various solid tumors and hematologic malignancies. Notch contributes to carcinogenesis by inhibiting differentiation, inhibiting apoptosis, or promoting proliferation. The intracellular forms of Notch induce transformation when it is expressed with oncoproteins that disable the G1-S checkpoint, such as adenovirus E1A, human papillomavirus E6 and E7, RAS, Myc, or SV40 large T-antigen. Notch also can activate the expression of several oncogenic pathways via induction of cyclins D1 and D3, cyclin A, SKP2, or c-Myc or via activation of PI3K-AKT-mTOR, NF-κB and NF-κB2, β-catenin,

or signal transducer and activator of transcription-3 (STAT3); it cooperates with oncogenic pathways such as WNT or HER2/Neu. In addition, it is involved in tumor–stroma interactions and has a tumor suppressor effect in the epidermis. Notch activity has been reported in cancer stem–like cells, a small subset of self-sustaining cancer cells that enhance resistance to chemotherapy and radiotherapy.

Neutralizing monoclonal antibodies directed against Notch 1–3 have been used in clinical trials. The development of the humanized mAb tarextumab was terminated due to lack of efficacy. Clinical trials of novel inhibitors are ongoing (eg, AL101, CB-103). Nonselective γ-secretase inhibitors (GSIs) are also known as "Notch inhibitors." Nirogacestat, an oral GSI, demonstrated encouraging results in phase I and II studies in patients with desmoid tumors with most common adverse events diarrhea, skin disorders, and hypophosphatemia. A grade 3 or 4 3 trial comparing nirogacestat with placebo in adults with progressing desmoid tumors is ongoing.

FIBROBLAST GROWTH FACTOR RECEPTOR PATHWAY INHIBITOR

The fibroblast growth factor receptor (FGFR) family comprises four main members (*FGFR1-FGFR4*) and encodes membrane tyrosine kinase receptors involved in signaling by interacting with fibroblast growth factors.[103] *FGFR3*- and *FGFR4*-activating mutations exist,[104,105] but amplification of *FGFR3* and *FGFR4* has been described rarely in cancer. *FGFR1* amplification occurred in 3.4% of 10,648 patients found in found in lung cancer, SCC of the head and neck, esophageal SCC, breast cancer, and pancreatic cancer. *FGFR2* amplification occurred in 0.9% of 8,352 patients[106] and were found in gastric and breast cancer and NSCLC.

In a phase II study of brivanib, an oral, multitargeted TKI with activity against VEGF and FGFR, in recurrent or persistent endometrial cancer, the ORR was 18.6%.[107] Dovitinib, a TKI that inhibits FGFR, VEGFR, and PDGFR, had limited antitumor activity in metastatic renal cell carcinoma and breast cancer.

Erdafitinib

Erdafitinib, an oral potent TKI of FGFR1–4, is indicated for patients with locally advanced or metastatic urothelial carcinoma, with susceptible FGFR3 or FGFR2 genetic alterations, that has progressed during or after platinum-containing chemotherapy, including within 12 months of neoadjuvant or adjuvant platinum-containing chemotherapy. In a phase II study, in this patient setting, the ORR was 40% (CR, 3%).[108] In patients with prior immunotherapy, the ORR was 59%. The median duration of PFS and OS were 5.5 months and 13.8 months, respectively.[108]

Pemigatinib

Pemigatinib is another oral inhibitor of FGFR1-3 that is indicated for the treatment of adults with previously treated, unresectable locally advanced or metastatic cholangiocarcinoma with a FGFR2 fusion or other rearrangement based. The FDA approval was based on favorable results of a phase II study that demonstrated an ORR rate of 35.5% in patients with this disease. Grade 3 and 4 adverse events occurred in 64% of patients and included hypophosphatemia and arthralgia.[109]

Other FGFR inhibitors that are being investigated in clinical trials.

P53 MDM2 PATHWAY/INHIBITORS

The P53-MDM2 interaction has a major role in maintaining the cellular normal function.[110] Direct interaction between P53 and MDM2 blocks the activity of P53 through diverse mechanisms. Inhibition of the P53-MDM2 pathway are an interesting target in cancer drug development. Ongoing clinical trials that include MDM-2 inhibitors are evaluating their safety and efficacy.

SACITUZUMAB GOVITECAN-HZIY

Sacituzumab govitecan-hziy is an antibody drug–conjugate that includes the topoisomerase I inhibitor SN-38 (irinotecan active metabolite), the humanized antitrophoblast cell-surface antigen 2 (Trop-2) mAb hRS7 IgG1κ, and the cleavable CL2A linker. The transmembrane calcium signal transducer Trop-2 is overexpressed in up to 85% in various carcinomas and has a stimulatory growth impact. When bound to Trop-2, hRS7 is internalized and delivers SN-38 into the tumor cell. SN-38, because of the characteristics of the cleavable linker, is released in the microenvironment with therapeutic concentrations in the bystander cells, enabling tumor cell death by extracellular release of SN-38. Sacituzumab govitecan-hziy is indicated for adult patients with metastatic triple-negative breast cancer with two or more prior therapies for metastatic disease. In a phase I/II trial, in patients with these characteristics treated with sacituzumab govitecan-hziy the ORR was 33.3%, and the median response duration was 7.7 months.[111] Grade 3 and 4 adverse events, noted in more than 10% of the patients, included severe neutropenia and diarrhea.[111]

RET PATHWAY INHIBITORS

Selpercatinib, a RET inhibitor, is indicated for the treatment of NSCLC, medullary thyroid cancer, and other types of thyroid cancers in patients whose tumors have a RET mutation or fusion. This is the first therapy approved specifically for patients with cancer and RET gene alterations. The approval was based on favorable ORR and response duration in patients with NSCLC with RET fusion, RET mutated medullary thyroid cancer, and other solid tumors with RET alterations treated with selpercatinib in a phase I/II study.

COLONY-STIMULATING FACTOR 1 RECEPTOR INHIBITOR

Pexidartinib

Pexidartinib, an oral small-molecule TKI of CSF1R, KIT, and FLT3-internal tandem duplication, is indicated for the treatment of adult patients with symptomatic tenosynovial giant cell tumor associated with severe morbidity or functional limitations and not amenable to improvement with surgery.[112] In a phase III trial in patients with advanced tenosynovial giant cell tumor, the ORR was 39% in patients (n = 61) randomized to receive pexidartinib compared with 0% in those randomized to the placebo arm (n = 59; P <.0001). Common adverse events included hair color changes, fatigue, and hepatotoxicity.

CHECKPOINT BLOCKADE PATHWAY INHIBITORS

A large family of costimulatory molecules (eg, programmed cell death protein 1 [PD-1] and PDL-1 and CTLA-4) modulate TCR signaling via phosphorylation cascades, leading to a crucial role in the regulation of the immune response (Table 57–3). These molecules represent remarkable targets for drug development and opened the era of antitumoral immunotherapy since 2011. Currently, there are seven FDA-approved checkpoint inhibitors in various tumors and indications: ipilimumab, pembrolizumab, nivolumab, avelumab, cemiplimab, durvalumab, and atezolizumab. The approval of these molecules is based on their favorable ORR and durable CRs in selected patients. Immunooncology (IO) drugs are associated with unique patterns of response and toxicity.[113]

Multiple trials have been or are being conducted to evaluate IO therapies and biomarkers that may be associated with response or toxicity to immunotherapy. High microsatellite instability (MSI-H) and PDL-1 expression are used to select patients who may benefit from immunotherapy.[114–118] Ongoing IO trials evaluate the association of high tumor mutational burden and other biomarkers with patient outcomes.

FUTURE PERSPECTIVES

Breakthroughs in technology and the discovery of effective drugs have led to epic advances in the war against cancer. We first demonstrated that in early-phase clinical trials across tumor types, tumor molecular profiling, and selection of matched targeted therapy were associated with high rates of response, PFS, and survival in patients with one targetable molecular alteration.[1,3,31,119,120] Progress in next-generation sequencing to identify alterations in tumor and cell-free DNA, profiling of immune markers, proteomics, and transcriptomics optimize treatment selection as standard of care or for selection of clinical trials. Current research focuses on understanding complex mechanisms of tumorigenesis, their dynamic changes and tumor plasticity, and the role of the immune system and microenvironment for identification of clinically significant biomarkers and effective drug discovery (Fig. 57–3). Optimization of bioinformatic analyses and use of artificial intelligence and overcoming regulatory and financial challenges will improve patient access to promising drugs and will improve patient outcomes.

TABLE 57–3 Tissue-agnostic approved targeted agents in cancer

Drug	Targeted Biomarker	Patient Population	Year	Trials
embrolizumab (Keytruda)	MSI-H/dMMR	Adults, children	2017	NCT01876511 (phase 2)
Larotrectinib (Vitrakvi)	NTRK	Adults, children	2018	NCT02122913 (phase 1) NCT02637687 (phase 1/2) NCT02576431 (phase 2)
Entrectinib (Rozlytrek)	NTRK	12 years or older	2019	NCT02097810 (phase 1) NCT02097810 (phase 1) NCT02568267 (phase 2)

dMMR, mismatch repair deficient; high MSI-H, microsatellite instability; NTRK, neurotrophic tyrosine receptor kinase.

As the number of FDA-approved drugs continues to increase, ongoing clinical trials with adaptive design such as Initiative for Molecular Profiling and Advanced Cancer Therapy 2 (IMPACT2), Investigation of Serial Studies to Predict Your Therapeutic Response through Imaging and Molecular Analysis 2 (I-SPY 2), National Cancer Institute Molecular Analysis for Therapy Choice (NCI MATCH), and Targeted Agent and Profiling Utilization Registry (TAPUR) hold the promise of accelerating the implementation of precision medicine using targeted anticancer therapy. Innovative clinical trials with immunotherapy and adoptive cell therapy that include tumor-infiltrating lymphocytes, chimeric antigen receptor T-cells, engineered TCRs, and natural killer cells have improved the clinical outcomes of selected patients and will elucidate the role of immunotherapy in the therapeutic approach of patients with cancer.

MD ANDERSON PRACTICE TIPS

- Early-phase clinical trials of investigational agents in patients with advanced, metastatic cancer and various tumor types have shown that matched therapy based on patients' molecular profiling is associated with higher rates of response, PFS, and OS compared with nonmatched targeted therapy.
- Improvement in bioinformatic analysis, tumor boards, and multidisciplinary conferences help optimize the selection of targeted therapies.
- Current research focuses on understanding complex mechanisms of tumorigenesis, their dynamic changes and tumor plasticity, and the role of the immune system and microenvironment for identification of clinically significant biomarkers of response or resistance to drugs and associated toxicity.
- Circulating tumor DNA analysis emerged as a useful molecular diagnostic approach for patients whose tumor is not accessible to tumor biopsies, tumor biopsies are deemed unsafe, or for monitoring of molecular signatures.
- Adaptive trial design, such as the design of the IMPACT 2 study and American Society of Clinical Oncology (ASCO) TAPUR, hold the promise to accelerate the implementation of precision medicine using targeted anticancer therapy.
- Innovative clinical trials with immunotherapy and adoptive cell therapy have improved the clinical outcomes of selected patients and will elucidate the role of immunotherapy in the therapeutic approach of patients with cancer.
