

THE MD ANDERSON MANUAL OF MEDICAL ONCOLOGY

FOURTH EDITION

HAGOP M. KANTARJIAN
ROBERT A. WOLFF
ALYSSA G. RIEBER

Mc Graw Hill

The MD Anderson Manual of Medical Oncology

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Dedication

Emil J Freireich, MD
March 16,1927 – February 1, 2021

Dedication of the fourth Edition of "The MD Anderson Manual of Medical Oncology" to Emil J Freireich, a Legendary Trailblazer in Cancer and Leukemia Research and Therapy

Emil J Freireich was a founding father of modern cancer research, and leader of the world's first generation of cancer research pioneers.

Following his medical training at the University of Illinois College of Medicine at Chicago, and internal medicine training at Cook County Hospital and Presbyterian Hospital, he moved to the National Cancer Institute (1955-1965), where he made his first seminal discoveries: the benefit of platelet transfusions in reducing bleeding; the design of the first-ever continuous-flow blood cell separator that extracted platelets from whole blood; the development of multidrug regimens that paved the way for the cure of childhood acute lymphoblastic leukemia (ALL).

In 1965, Freireich moved to Houston and spent the next 55 years at MD Anderson, his real home. He was a founding member of the institution, which owed much of its early success and reputation to his work and that of his mentees. Freireich's name became synonymous with that of MD Anderson. He created a department of Developmental Therapeutics (DT), dedicated to medical cancer research and to developing novel cancer strategies. Over the next 15 years, he attracted hundreds of cancer researchers from all over the world who, like him, were convinced that cancer was curable and were determined to accomplish this. Many of the early chemotherapy drugs (cytarabine, Adriamycin, cisplatin, others) were developed during this period, and became building blocks for curative combinations. Together with Dr Gerald Bodey, Freireich discovered the association between neutropenia and increased risk of infections and developed the concept of empiric antibiotic therapy to prevent and treat fever and infections in patients with cancer. This, along with platelet transfusions, made cancer care safer and opened the research venues for intensive chemotherapy and stem cell transplantation in hematologic and solid tumors. The pheresis machines he helped to create were later used to collect stem cells for the purpose of transplantation.

In DT, and later as a senior leader at MD Anderson, Freireich trained and mentored hundreds of oncologists, many of whom later created their own legacies and helped hundreds of thousands of patients with cancer. He also created in 1966 the first training fellowship program in cancer and established clinical-translational research and care as a new critical discipline in oncology.

To the hundreds of us who trained under Freireich, he and his stories and education are indelibly cemented in our memories. In recognition of his massive contributions to education in cancer research and care, we dedicate this fourth edition to Emil J Freireich.

A Brief History of MD Anderson Cancer Center xxv

Foreword xxix

Preface xxxi

I LEUKEMIA

Section Editor: *William G. Wierda*

1. **Acute Lymphoblastic Leukemia 3**
   Hind Rafei, Sergej N. Konoplev, Sa A. Wang, Nicholas J. Short, Hagop M. Kantarjian, Elias J. Jabbour
2. **Adult Acute Myeloid Leukemia 23**
   Tapan M. Kadia, Joseph D. Khoury, Farhad Ravandi
3. **Chronic Lymphocytic Leukemia and Associated Disorders 49**
   Nitin Jain, Philip Thompson, Carlos Bueso-Ramos, Susan M. O'Brien, William G. Wierda
4. **Chronic Myeloid Leukemia 67**
   Koji Sasaki, Elias Jabbour, Jorge Cortes, Hagop Kantarjian
5. **Myelodysplastic Syndromes: The MD Anderson Cancer Center Approach 91**
   Kelly Chien, Carlos Bueso-Ramos, Guillermo Garcia-Manero
6. **Philadelphia Chromosome-Negative Myeloproliferative Neoplasms 119**
   Prithviraj Bose, Lucia Masarova, Hesham M. Amin, Srdan Verstovsek

II LYMPHOMA AND MYELOMA

Section Editor: *Nathan H. Fowler*

7. **Follicular Lymphoma 165**
   Paolo Strati, Jillian R Gunther, L. Jeffrey Medeiros, Loretta J. Nastoupil
8. **Marginal Zone and Other Small Cell Lymphomas 183**
   Melody Becnel, Felipe Samaniego
9. **Aggressive B-Cell Lymphomas 191**
   Raphael Steiner, Jason R. Westin, Sergej N. Konoplev, Luis E. Fayad, L. Jeffrey Medeiros
10. **Mantle Cell Lymphoma 227**
    Preetesh Jain, Michael Wang
11. **Nodal Peripheral T-Cell Lymphoma 253**
    Ranjit Nair, Francisco Vega, Swaminathan P. Iyer
12. **Cutaneous Lymphomas 269**
    Auris Huen
13. **Hodgkin Lymphoma 291**
    Collin K. Chin, L. Jeffrey Medeiros, Fredrick B. Hagemeister, Hun J. Lee
14. **Systemic Immunoglobulin Light Chain Amyloidosis 323**
    Gregory P. Kaufman, Muzaffar H. Qazilbash, Krina Patel, Sheeba Thomas, Robert Z. Orlowski, Hans C. Lee
15. **Waldenström Macroglobulinemia 333**
    Melody Becnel, Gregory P. Kaufman, Elisabet E. Manasanch, Krina Patel, Hans C. Lee, Robert Z. Orlowski, Sheeba Thomas
16. **Multiple Myeloma 341**
    Paul Lin, Gregory P. Kaufman, Hans C. Lee, Elisabet E. Manasanch, Melody Becnel, Sheeba Thomas, Donna Weber, Robert Z. Orlowski, Krina Patel
17. **Cellular Therapy for Lymphoma 363**
    Sairah Ahmed, Simrit Parmar, Sattva Neelapu

III STEM CELL TRANSPLANTATION

Section Editor: *Elizabeth J. Shpall*

18. **Autologous Hematopoietic Progenitor-Cell Transplantation 383**
    Neeraj Saini, Yago Nieto
19. **Allogeneic Transplantation 397**
    Rohtesh S. Mehta, Chitra Hosing
20. **Alternative Donor Transplants: Cord Blood Transplant 427**
    Hind Rafei, Amanda Olson, Rohtesh S. Mehta, Betul Oran, Katayoun Rezvani, Elizabeth J. Shpall

21. **Alternative Donor Transplants: Haploidentical Hematopoietic Stem Cell Transplantation 447**
Samer A. Srour, Richard E. Champlin, Stefan O. Ciurea

22. **Cellular Therapy in Allogeneic Hematopoietic Cell Transplantation 457**
Amanda Olson, Jeremy Ramdial, Uri Greenbaum, Paul Lin, Katayoun Rezvani, Partow Kebriaei

IV LUNG CANCER
Section Editor: *Bonnie S. Glisson*

23. **Small Cell Carcinoma of the Lung 475**
Jeremy A. Ross, Lauren A. Byers, Carl M. Gay

24. **Non–Small Cell Lung Cancer: General Principles, Management of Localized Disease, and Treatment of Metastatic Disease without Oncogene Drivers 495**
Mehmet Altan, Joshua M Gulvin, George Simon, Bonnie Glisson

25. **Targeted Therapies in Non–Small Cell Lung Cancer 535**
Yasir Y. Elamin, Don L. Gibbons, Marcelo V. Negrao

V HEAD AND NECK CANCER
Section Editor: *Bonnie S. Glisson*

26. **Head and Neck Cancer 555**
Ruth Sacks, David Boyce-Fappiano, Amy Moreno, Frank Mott

VI GASTROINTESTINAL CANCER
Section Editor: *Robert A. Wolff*

27. **Gastric, Gastroesophageal Junction, and Esophageal Cancers 579**
Mariela Blum Murphy, Elena Elimova, Ahmed Abdelhakeem, Jaffer Ajani

28. **Pancreatic Cancer 619**
Jonathan D. Mizrahi, Anirban Maitra, Robert A. Wolff

29. **Biliary Tract Cancer 647**
Shalini Makawita, Sunyoung Lee, Yun Shin Chun, Millicent A. Roach, Eugene J. Koay, Milind Javle

30. **Hepatocellular Carcinoma 677**
Sunyoung S. Lee, Hao Chi Zhang, Hop S. Tran Cao, Sudha Kodali, Joshua D. Kuban, Eugene J. Koay, Rony Avritscher, Ahmed O. Kaseb

31. **Small Bowel Cancer and Appendiceal Tumors 707**
Pat Gulhati, John Paul Shen, Kanwal P. Raghav, Michael J. Overman

32. **Colorectal Cancer 733**
Arvind Dasari, Benny Johnson, Christine Parseghian, Kanwal P. Raghav, Scott Kopetz

33. **Anal Cancer 765**
Emma Holliday, Van Morris, Craig A. Messick

34. **Neuroendocrine Tumors 781**
Jessica E. Maxwell, James C. Yao, Daniel M. Halperin

VII BREAST CANCER
Section Editor: *Gabriel N. Hortobagyi*

35. **Early-Stage and Locally Advanced Breast Cancer 803**
Demetria Smith-Graziani, Mariana Chavez-MacGregor

36. **Metastatic Breast Cancer 829**
Haven R. Garber, Meghan S. Karuturi, Gabriel N. Hortobagyi

37. **Management of Locally Advanced Breast Cancer, Including Inflammatory Breast Cancer 863**
Bora Lim, Gabriel N. Hortobagyi

38. **Special Situations in Breast Cancer 875**
Rachel M. Layman

VIII GYNECOLOGIC MALIGNANCIES
Section Editor: *Karen H. Lu*

39. **Ovarian Cancer 897**
Roni Nitecki, Lauren P. Cobb, Amir A. Jazaeri, J. Alejandro Rauh-Hain

40. **Tumors of the Uterine Corpus 931**
Michaela A. Onstad, Shannon N. Westin, Karen H. Lu

41. **Tumors of the Uterine Cervix 955**
Gloria Salvo, Mila P. Salcedo, Sol Basabe, Pedro T. Ramirez

42. **Gestational Trophoblastic Disease 983**
Han T. Cun, Aaron Shafer

IX GENITOURINARY MALIGNANCIES
Section Editor: *Nizar M. Tannir*

43. **Renal Cell Carcinoma 1005**
Andrew W. Hahn, Jose A. Karam, Christopher G. Wood, Nizar M. Tannir

44. Bladder Cancer 1027
Alexander Y. Andreev-Drakhlin, Ashish M. Kamat, Arlene O. Siefker-Radtke

45. Prostate Cancer 1049
Patrick Pilié, Paul Viscuse, Christopher J. Logothetis, Paul G. Corn

46. Penile Cancer 1071
Jad Chahoud, Curtis A. Pettaway

47. Germ Cell Tumors 1081
Joseph A. Moore, Shi-Ming Tu

X NEUROLOGIC TUMORS
Section Editor: *John de Groot*

48. Tumors of the Central Nervous System 1105
Shiao-Pei Weathers, Barbara O'Brien, Ashley Aaroe, Debra Yeboa, Sujit Prabhu, John de Groot

XI MALIGNANT MELANOMA
Section Editor: *Michael A. Davies*

49. Melanoma 1133
Houssein Safa, Jane Mattei, Andrew J. Bishop, Emily Z. Keung, Sirisha Yadugiri, Michael A. Davies, Isabella C. Glitza Oliva

XII SARCOMAS
Section Editor: *Shreyaskumar Patel*

50. Soft Tissue and Bone Sarcomas 1159
J. Andrew Livingston, Anthony P. Conley, Ravin Ratan, Vinod Ravi, Shreyaskumar Patel

XIII OTHER TUMORS AND CANCER TOPICS OF INTEREST
Section Editor: *Alyssa G. Rieber*

51. Endocrine Malignancies 1189
Ha Nguyen, Mouhammed Amir Habra

52. The Acquired Immunodeficiency Syndrome–Related Cancers 1223
Adan Rios, Fredrick B. Hagemeister

53. Carcinoma of Unknown Primary 1253
Gauri R. Varadhachary, Kanwal P. Raghav, Ryan W. Huey

54. Pediatric Cancers 1271
Branko Cuglievan, Wafik Zaky, Richard Gorlick, Douglas Harrison

55. Cancer Genomics 1283
Jason A. Willis, Jennifer B. Goldstein, Zhijing Zhang, Andy Futreal

56. Immuno-oncology 1297
Bilal A. Siddiqui, Sangeeta Goswami, James P. Allison, Padmanee Sharma

57. Targeted Therapy in Cancer 1323
Rabih Said, Apostolia-Maria Tsimberidou

58. Viral Infections in Patients with Cancer 1345
Fareed Khawaja, Roy F. Chemaly

59. Fungal Infections in Patients with Cancer 1363
Bruno P. Granwehr, Dimitrios P. Kontoyiannis

60. Endocrine and Metabolic Complications of Cancer Therapy 1381
Rachael Hosein, Sara Bedrose, Rebecca Jeun, Jeena M. Varghese, Sonali N. Thosani

61. Oncologic Emergencies 1407
Sai-Ching Jim Yeung, Ellen F. Manzullo, Patrick Chaftari

62. Oncocardiology 1435
Elie Mouhayar, Danielle El-Haddad, Peter Kim, Kara Thompson, Cezar Iliescu, Abdulrazzak Zarifa

63. Pulmonary Complications of Cancer Therapy 1461
Audra J. Schwalk, Saadia A. Faiz, Horiana B. Grosu, Lara Bashora, Vickie R. Shannon

64. Cancer-Associated Thrombosis 1493
Kelly A. Casteel, Michael H. Kroll

XIV SUPPORTIVE AND PALLIATIVE CARE
Section Editor: *Eduardo Bruera*

65. Inpatient Supportive and Palliative Care 1509
Ahsan Azhar, Ali Haider, Eduardo Bruera

66. Integrated Outpatient Supportive Care 1519
Akhila Reddy, David Hui, Eduardo Bruera

67. Rehabilitation 1529
Brian Fricke, An Ngo-Huang, Ekta Gupta

68. Pain Management and Symptom Control 1553
Kaoswi K. Shih, Rony Dev, Shalini Dalal

XV BIOSTATISTICS

Section Editor: *Xuelin Huang*

69. Statistical Designs for Oncology Clinical Trials 1579

Xuelin Huang, Wei Qiao, Fang Xia, E Lin, Liang Zhu, Jing Ning

70. Big Data and Machine Learning in Oncology 1593

Peng Wei, Hai Shu

71. Value-Based Oncology 1603

Casey J. Allen, Aileen Chen, Ryan W. Huey, Ya-Chen Tina Shih

Index 1619

The fourth edition of *The MD Anderson Manual of Medical Oncology* is also available online as part of the excellent **accesshemonc.com** website, with direct links to a comprehensive drug therapy database and to other important medical texts that include *Hematology-Oncology Therapy*. The online edition of *The MD Anderson Manual of Medical Oncology* also includes PubMed links to journal articles cited in the references.

New in this edition is the online-only presentation of clinical cases, *The MD Anderson Manual of Medical Oncology Cases*, for readers to explore, with each case linked to the relevant chapter.

A Brief History of MD Anderson Cancer Center

Houston's evolution into the fourth largest city in the United States was propelled by four seminal events. First was the Great Galveston Hurricane of 1900, which destroyed the city port of Galveston and led to the realization that Houston could become a viable and safer deep-water port; this led to the widening of the Ship Channel to offer direct access to Houston. Second was the discovery of oil at Spindletop in Beaumont, Texas in 1901. This prompted the development of the oil industry in Texas and transformed Houston from a small town into a large city. Third was (of course) the commercialization of air conditioning in 1950's, which made Houston (and many Southern cities of the United States) more livable. And lastly, the allocation of land for the Texas Medical Center created the largest medical center in the world with one of the highest densities of clinical facilities for patient care, basic science, and translational research. The Texas Medical Center is a major contributor to Houston's economy and growth.

Several additional factors contributed to the creation of The University of Texas MD Anderson Cancer Center in Houston and its development into one of the most important cancer centers in the world. First was the generous philanthropy of visionary Texans such as Monroe Dunaway Anderson (Fig. 1) (his nephew died of leukemia in 1936) and his partner Will Clayton, who founded the charitable MD Anderson Foundation, which helped create the Texas Medical Center in 1945.

FIGURE 1.

FIGURE 2.

The charter of the Anderson Foundation did not specify how the money should be used, but Mr. Anderson's trustees and close friends—Colonel William Bates, John Freeman and Horace Williams—leaned strongly in favor of health care. Soon after taking possession of the estate from its executors, the trustees turned to Dr. Ernest Bertner (Fig. 2) for advice. Dr. Bertner was a prominent Houston surgeon and gynecologist who was well known to the trustees because of his care for cancer patients, despite inadequate facilities and treatment options (he was later called the "father of the Texas Medical Center").

The trustees and Dr. Bertner noted that the 1941 Texas legislature authorized the University of Texas to create a hospital for cancer research and treatment, allocating $500,000 for the purpose. Today, that figure would be approximately $8 million. The Anderson trustees, with Dr. Bertner's guidance, seized the opportunity and offered to match the $500,000 legislative appropriation, if the hospital was to be named for Monroe Dunaway Anderson and located in Houston. The legislature accepted their offer. The trustees then purchased 134 acres of mosquito-infested land to create the Texas Medical Center, stating that the new cancer hospital would be located there. They made it known that the new state hospital should be an academic institution. In fact, MD Anderson was the first comprehensive cancer hospital to be associated with a major university as an independent free-standing unit.

In 1942, The University of Texas Board of Regents appointed Dr. Bertner as the director of the new hospital. A 6-acre property near downtown was purchased from the estate of Captain James A. Baker, grandfather of former Secretary of State James Baker III, and became the first campus of the hospital. An empty carriage house became the office and stables were the research laboratories. Twelve surplus army barracks were procured for patient clinics (Figs. 3A-C). With the addition of 22 leased beds at Hermann Hospital, the dream became realityA small faculty of physicians and scientists was recruited from the University

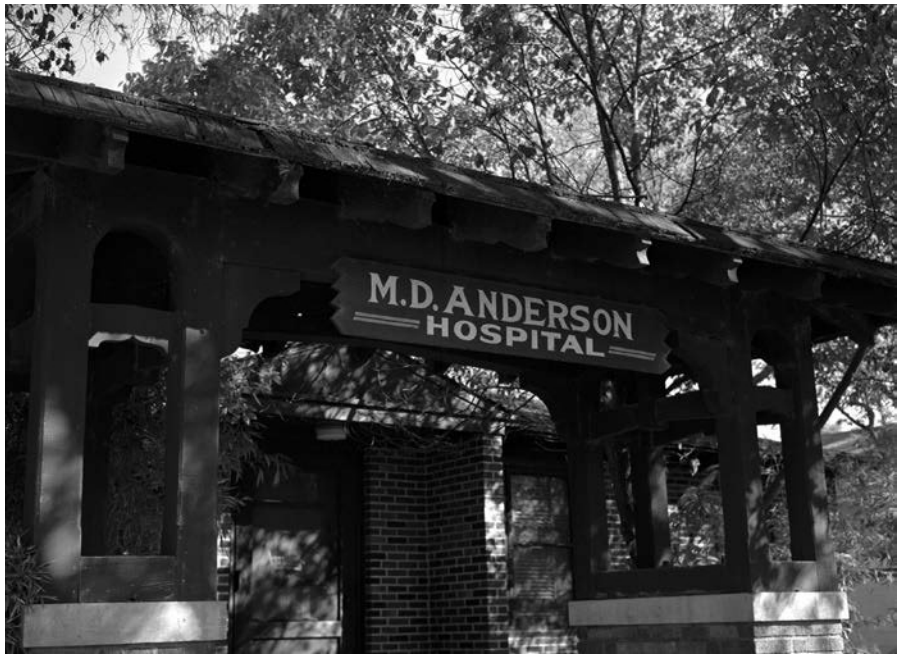

FIGURE 3A.

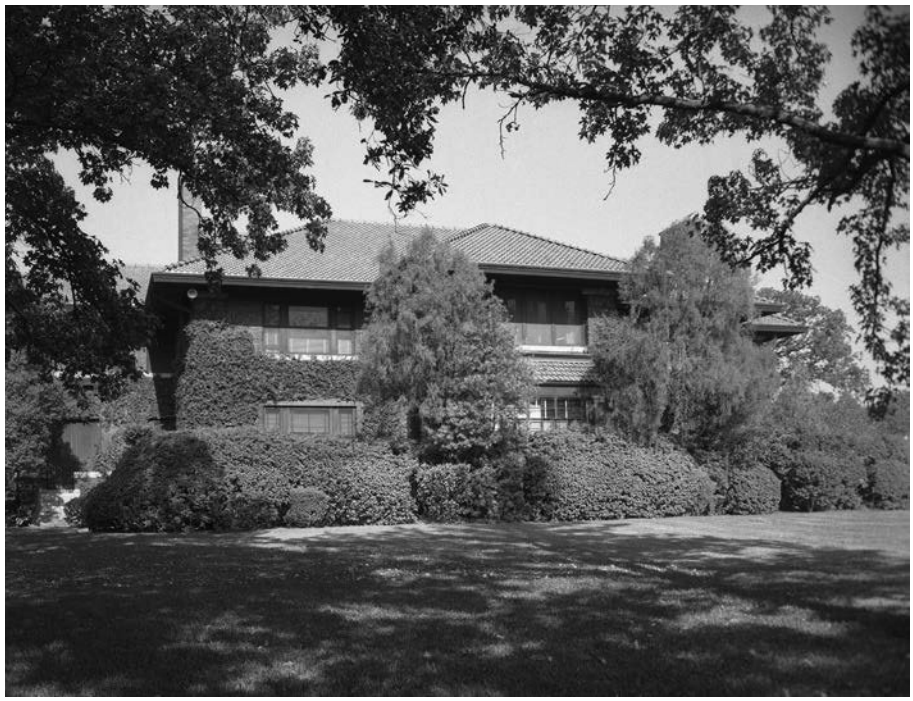

FIGURE 3B.

FIGURE 3C.

of Texas Medical Branch in Galveston, and cancer patients finally had a home. The name proposed in 1941 was the "Texas State Cancer Hospital and the Division of Cancer Research", which was changed to "M.D. Anderson Hospital for Cancer Research of The University of Texas" (to acknowledge the donation of M.D. Anderson). The name was again changed in 1955 to "The University of Texas M.D. Anderson Hospital and Tumor Institute at Houston" (to avoid the word "cancer" which elicited fear and avoidance). In 1988 the name was finally changed to its current "The University of Texas MD Anderson Cancer Center".

In 1946, Dr. Bertner persuaded Dr. Randolph Lee Clark, a native Texan, to become president of what was to become The University of Texas MD Anderson Cancer Center. Dr. Clark, a widely recognized surgeon, concentrated on recruiting an excellent surgical faculty and then set upon acquiring all the basic and clinical scientists and clinicians. From the outset, all efforts, whether administrative, clinical or research, were focused on developing excellence in research-driven cancer care. Forty-six patients were receiving treatment in these early quarters when the hospital moved to its current site in March 1954 (Figs. 4A and B).

FIGURE 4A.

FIGURE 4B.

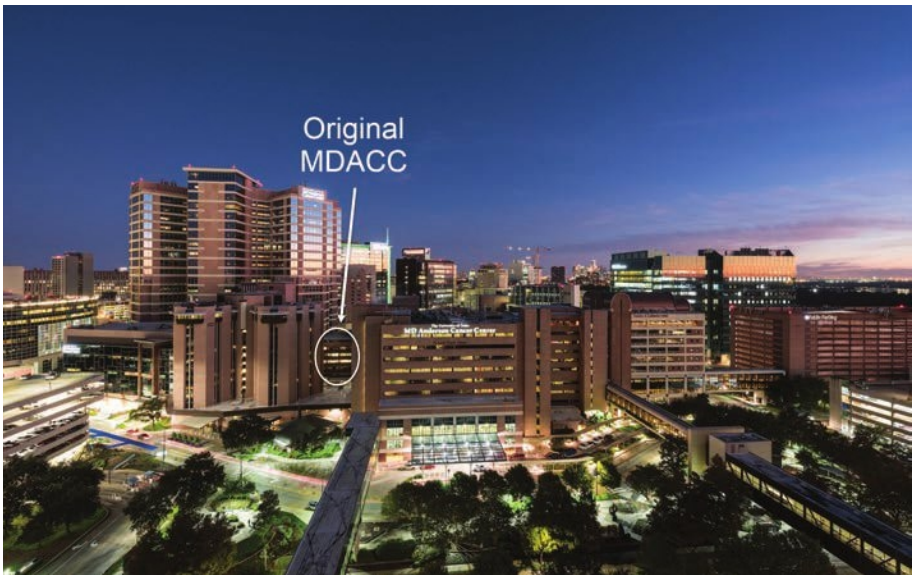

FIGURE 5.

FIGURE 6A.

FIGURE 6B.

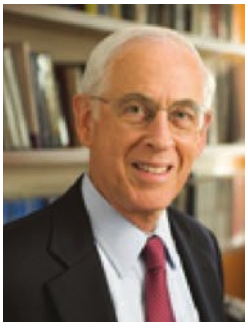

FIGURE 6C.

Additional resources to expand the MD Anderson infra-structure (Fig. 5) and research capacities came from several venues: (1) generous donations from the oil industry; (2) the visionary research and administrative leadership under its five presidents, Drs. Randolph Lee Clark (1946–1978) (Fig. 6A), Charles A. LeMaistre (1978–1996) (Fig. 6B), John Mendelsohn (1996–2011) (Fig. 6C), Ronald DePinho (2011–2017) (Fig. 6D), and Peter WT Pisters (2017-present) (Fig. 6E); (3) the recruitment of world-renowned cancer research pioneers (some of the early legends included Drs. Emil J. Freireich, Emil Frei, Gilbert Fletcher, James Butler, Felix Rutledge, Gerald Dodd, and Sidney Wallace); and (4) the relentless research efforts of the cancer experts on the MD Anderson's faculty.

Today, MD Anderson is one of the largest cancer centers in the world, with more than 21,000 employees and 1800 faculty; serving more than 150,000 patients with cancer in Houston every year; operating a 700-bed cancer hospital; and being ranked as

FIGURE 6D.

FIGURE 6E.

the No. 1 hospital for cancer care by the *U.S. News and World Report* in 11 of the past 14 years. The MD Anderson Cancer Center research has resulted in numerous discoveries that became standards of care across many types of cancers, and that have saved the lives and/or improved survivals and outcomes of millions of patients with cancer around the world.

One component of MD Anderson's mission is to spread its knowledge about cancer research and discoveries across the globe. This educational mission is furthered by the hematology/oncology fellowship that currently trains more than 40 medical hematology-oncology cancer specialists on its premises. *The MD Anderson Manual of Medical Oncology*, created as part of our educational mission, is often written by our fellows as first authors (many of whom later join the MD Anderson faculty) and supported in depth by senior tumor specialty faculty as co-authors. We envision this fourth edition expanding into a continuously updated electronic version that educates and spreads knowledge and discoveries in cancer research and therapy rapidly and widely.

Hagop M. Kantarjian, MD
Robert A. Wolff, MD
Alyssa G. Reiber, MD

Foreword

The MD Anderson Manual of Medical Oncology, fourth edition, articulates the personalized, multidisciplinary approach to cancer management pioneered by The University of Texas MD Anderson Cancer Center. Our unique perspective has evolved from decades of clinical practice and research with more than 1.6 million patients turning to MD Anderson for care. We are expanding our reach, making it easier for the patients and communities we serve to access our expertise. We are enabling high-impact discovery and introducing novel therapies through a leading clinical trials network. And we are setting new standards for high-touch, high-value cancer care.

This book is designed to bring a pragmatic approach to cancer management that may serve as a guide for oncologists around the world. The text reflects how MD Anderson currently operates, including many patient care practices that would not have been recognized by practitioners just a decade ago. Since the first edition, MD Anderson's experts have improved our ability to identify biomarkers that are predictive for survival, a major triumph in medical oncology that is demonstrated throughout the text.

Reflecting new advances in our research and our approach to cancer management, the fourth edition of *The MD Anderson Manual of Medical Oncology* features a wealth of new material. The sections on Lymphoma and Myeloma and Gastrointestinal Cancer contain additional chapters focused on recently defined subsets of disease and their treatment modalities. New targeted therapies are described in Lung Cancer. Additional Cancer Topics of Interest chapters detail updated knowledge in viral and fungal infections, for example, as well as oncocardiology and thrombosis. Biostatistics now has its own section, underscoring the extraordinary wealth of information brought about by big data analytics and its application to influence value-based oncology care. Supportive and Palliative Care content reflects current approaches in advanced symptom management concurrent with a patient's entire cancer journey, starting at diagnosis.

Every chapter includes abundant tables and diagrams, including algorithms and decision trees developed at MD Anderson for specific cancers or disease subtypes; promising novel therapy targets and the latest clinical trial phase of drugs targeting them; and new molecular therapies recommended to overcome resistance to previously effective therapies.

Emphasis on safety is even more relevant now than in prior editions of this book. MD Anderson's core value of Safety drives our colleagues each day, and this was especially highlighted during the COVID-19 pandemic when we came together with diligence, determination and evidence-based protocols to ensure the safest possible environment for our immunocompromised patients. Additionally, we remain laser focused on survivorship, as advances in cancer care have increased the number of people who are cancer free or who are living with cancer as a chronic condition rather than a fatal one. We remain dedicated to our bold aspiration of maximizing our impact on humanity through research-driven patient care, education, prevention and science that contribute to Making Cancer History®.

Peter WT Pisters, MD, MHCM
President, The University of Texas MD Anderson Cancer Center
Houston, Texas

Preface

When we first envisioned *The MD Anderson Manual of Medical Oncology*, we hoped that it would fill an important void in oncology reference material by serving as a hands-on resource for the practicing oncologist. The first edition, published in 2006, was written exclusively by our faculty and fellows with the idea of giving a bird's-eye view of how multidisciplinary care was practiced at our institution. We were proud of that initial effort and pleased that the book received positive reviews from several high-impact journals, including *JAMA*, *The Lancet*, and *The New England Journal of Medicine*.

The second edition, published in 2011, moved closer to the aims of providing more illustrations, figures, tables, and algorithms. In addition, the second edition included new chapters on myelodysplastic syndromes, Philadelphia chromosome-negative myeloproliferative neoplasms, T-cell lymphomas, small bowel cancer and appendiceal tumors, inflammatory breast cancer, and penile cancer.

In the third edition, we have continued the tradition of including evidence-based management algorithms in the form of flowcharts and diagrams, shaped by the clinical experience of our world-class faculty at MD Anderson. Readers are also provided with a practical guide to the diagnostic and therapeutic strategies used at MD Anderson.

The new edition of *The MD Anderson Manual of Medical Oncology* contains new chapters on cord blood transplant, haploidentical stem cell transplantation, cellular therapy in allogeneic hematopoietic cell transplantation, pediatric cancers, molecular biomarkers and cancer, immuno-oncology, targeted therapies in cancer, applied biostatistics, oncocardiology, pulmonary complications of cancer therapy, and cancer-associated thrombosis. In addition, there is expanded coverage of the rapidly growing areas of biological and immune therapies of cancer, with one chapter co-authored by our very own Nobel Laureate, Jim Allison.

The new edition of *The MD Anderson Manual of Medical Oncology* will also be a continually updated version of the book, online, with the latest science and clinical recommendations from the world-renowned clinical investigators at MD Anderson.

We hope that this edition serves to help oncologists everywhere provide high-quality, state-of-the-art cancer care to their patients.

KEY CONCEPTS

- Acute lymphoblastic leukemia (ALL) is classified into B-cell ALL, T-cell ALL, and natural killer cell ALL. Cytogenetics are key in the diagnosis of ALL because they hold a predictive and prognostic value. A Philadelphia chromosome–like signature that lacks the expression of BCR-ABL1 fusion protein but does have a gene expression profile similar to *BCR-ABL1*+ ALL has been recently defined.
- Measurement of measurable residual disease (MRD) using multiparameter flow cytometry, quantitative polymerase chain reaction, and next-generation sequencing is standard of care in the treatment of patients with ALL, and it holds prognostic as well as predictive significance. Treatment of patients with MRD-positive disease after achievement of response consists of the use of immunotherapy, such as blinatumomab or combinatorial agents.
- The frontline therapy of patients with ALL consists of four major components: induction of remission, consolidation, maintenance, and central nervous system prophylaxis. Intensive induction chemotherapy regimens are modeled after either the pediatric-inspired roadmap regimens or the hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) regimen. Consolidation depends on the risk category and consists of either consolidation chemotherapy (e.g., high-dose methotrexate and cytarabine) or allogeneic hematopoietic stem cell transplant. Maintenance consists of POMP (Purinethol, Oncovin, methotrexate, and prednisone) or DOMP (Dexamethasone, Purinethol, Oncovin, and methotrexate) chemotherapy for 2 to 3 years. Clinical trials are evaluating the use of novel agents, such as antibody–drug conjugates and bispecific antibodies, in the frontline setting.
- The combination of chemoimmunotherapy is the mainstay of treatment of patients with ALL and is a field of ongoing research to identify the best combinations as well as timing of their use.
- In adolescents and young adults, pediatric regimens and the hyper-CVAD regimen showed similar complete remission rates, remission duration, and survival outcomes.
- The role of allogeneic hematopoietic stem cell transplantation (AHSCT) in first remission remains currently valid in certain high-risk circumstances, such as (1) KMT2A-rearranged ALL, (2) early T-cell precursor ALL, and (3) ALL with complex cytogenetics and hypodiploidy.
- In the salvage setting, a number of novel agents have been approved, including monoclonal antibodies, bispecific antibodies, and chimeric antigen receptor T-cell therapies.

EPIDEMIOLOGY AND ETIOLOGY

Acute lymphoblastic leukemia (ALL) is characterized by the proliferation and accumulation of lymphoid progenitor cells in the blood, bone marrow, and other tissues. It has a bimodal distribution. The overall age-adjusted incidence is 1.7 per 100,000 persons, with a peak in early childhood and then a smaller peak in older adults. Approximately 60% of cases are diagnosed in patients who are 20 years old or younger. In 2020, the American Cancer Society estimated that 6150 individuals would be diagnosed with ALL in the United States that year, and 1520 patients would succumb to the disease.[1] ALL is projected to represent 20% of adult leukemias and 46% of leukemias in teenagers (15–19 years old) and will be the most common childhood acute leukemia in children 14 years old and younger, representing approximately 75% in this patient population.[1]

The cause of ALL is unknown in most cases.[2–6] Chromosomal translocations occurring in utero during fetal hematopoiesis have suggested genetic factors as the

primary cause of pediatric ALL and postnatal genetic events as secondary contributors. Monozygotic and dizygotic twins of patients with ALL and individuals with genetic disorders, such as Klinefelter (XXY and variants) and Down (trisomy 21) syndromes, or inherited diseases with excessive chromosomal fragility, such as Bloom syndrome, Fanconi anemia, and ataxia telangiectasia, have all been found to have higher incidence of ALL, implicating a possible genetic predisposition. Additional studies have postulated infectious causes.[3]

CLINICAL PRESENTATION AND LABORATORY ABNORMALITIES

The presenting symptoms can be nonspecific, particularly in children. They largely reflect bone marrow failure and include malaise, fatigue, bleeding or bruising, and secondary infections. The B symptoms, such as fever, night sweats, and weight loss, are frequent. White blood cell (WBC) count at presentation varies widely, and circulating blasts are generally noted. Symptoms related to hyperleukocytosis are rare in ALL, given the lymphoblast morphology, even when WBC counts are high.

Leukemic involvement of the central nervous system (CNS), ranging from cranial neuropathies to meningeal infiltration, occurs in fewer than 10% of patients at presentation. It is more common in mature B-cell acute lymphoblastic leukemia (B-ALL) or Burkitt leukemia.[7] A history or findings of abdominal masses, significant spontaneous tumor lysis syndrome, and chin numbness (mental nerve) indicating cranial nerve involvement are also more common in this subtype of ALL.[8] Lymphadenopathy and hepatosplenomegaly, although rarely symptomatic, are observed in approximately 20% of patients.[8]

DIAGNOSIS

The revised World Health Organization (WHO) classification recognizes three types of ALL: B-ALL, T-cell acute lymphoblastic leukemia (T-ALL), and natural killer cell acute lymphoblastic leukemia (NK-ALL)[9] (Table 1–1). ALL can involve predominantly bone marrow or predominantly extramedullary sites. In patients with extramedullary lymphoblastic lymphoma, an arbitrary cut-off of 25% blasts in bone marrow was applied to distinguish lymphoblastic leukemia from lymphoma in the past.[10] Currently, this distinction has been practically abandoned, and the current WHO classification uses a combined term "lymphoblastic leukemia/lymphoma." In contrast to acute myeloid leukemia, there is no agreed-upon minimal blast percentage required for a diagnosis of ALL. The current WHO classification states that the diagnosis of ALL "should be avoided when there are <20% blasts" but at the same time does recognize that cases of ALL with blasts of less than 20% do exist.[9]

Morphologically, ALL is characterized by the presence of a large number of lymphoblasts. Blasts may show significant variation in cell size, nuclear shape, visibility of nucleoli, amount of cytoplasm, and cytoplasmic basophilia or vacuolization. Auer rods are consistently absent. In the past, the French-American-British (FAB) Cooperative Group recommended the separation of ALL cases into three subtypes (L1, L2, and L3) based on cytologic characteristics;[11] this cytologic classification is no longer used. In fact, Burkitt lymphoma/leukemia, which was a part of B-ALL in the FAB classification scheme under the L3 subtype, has been moved to the mature B-cell lymphoma category.[9] Table 1–2 summarizes lineage assignment.

The initial diagnosis of ALL is largely based on flow cytometric immunophenotyping (FCI). FCI successfully assigns lineage in more than 95% of cases. True mixed-phenotype acute leukemia is rare.[12] Aberrant myeloid antigen expression of markers is reported in 15% to 50% of adult and 5% to 35% of pediatric ALL cases.[13–15] ALL blasts are negative for myeloperoxidase (MPO), although a low-level MPO positivity (<3%) may occur in rare cases that otherwise are typical for ALL.[16] The diagnosis of ALL requires the detection of

immature markers, such as CD34 or terminal deoxynucleotidyl transferase (TdT), as well as lineage-specific markers. For B-ALL, it requires a combination of strong CD19 and at least one additional B-cell marker, such as CD22 and cytoplasmic CD79a or CD10; if CD19 is weak, it requires at least two additional markers. Cytoplasmic CD3 is the lineage-defining marker for T-ALL. In addition, T-ALL is often bright positive for CD7, with variable expression of other markers. CD19 can be aberrantly expressed in 10% to 20% of T-ALL blasts.

The immunophenotypic classification of ALL is summarized in Table 1–2. The original classification proposed by the European Group for the Immunological Characterization of Leukemias in 1995 separated B-ALL cases into four categories according to the stages of maturation: pro-B-ALL, early pre-B-ALL, pre-B-ALL, and mature B-ALL.[17] The mature B-ALL group was subsequently removed from B-ALL categories. This immunophenotypic classification of B-ALL is still used in some practice, but with the advances in genetic and molecular characterization of B-ALL, its clinical importance became obsolete.

In contrast to B-ALL, the immunophenotypic classification of T-ALL has acquired a critical clinical importance since the concept of early T-cell precursor lymphoblastic leukemia (ETP-ALL) was introduced.[18] As with B-ALL, the European Group for the Immunological Characterization of Leukemias separated T-ALL cases according to the stages of maturation in four categories: pro-T, pre-T, cortical T, and medullary T.[17] In 2009, gene expression profiling studies in pediatric patients identified a unique subgroup within the pro-T category, which was associated with high risk of induction failure and relapse and thereafter designated as ETP-ALL.[18] The study conducted at our institution confirmed a poor clinical outcome of patients with ETP-ALL in adolescent and adult patient populations.[19] Immunophenotypically, ETP-ALL is defined by the lack of CD8 and CD1a, negative or dim expression of CD5 (as defined by CD5 expression in <75% lymphoblasts or 1 log scale dimmer than normal T-cells), and expression of at least one myeloid or stem cell marker (e.g., CD13, CD33, CD34, CD65, CD117, or HLA-DR).[18]

Although the original description of ETP-ALL phenotype stresses the absent or weak CD5 expression on lymphoblasts, an original study described three patients with an immunophenotype similar to ETP except for no decrease in CD5 but showing a gene expression profile of ETP-ALL.[19] These findings were confirmed in subsequent studies,[20] which led to the introduction of the term of "near ETP-ALL" (also known as "close to ETP-ALL") to describe T-ALL with a phenotype typical for ETP-ALL with an exception of normal or bright CD5.

NK-ALL has been recently added to the WHO classification as a provisional entity.[9] The entity remains ill-defined and extremely challenging to diagnose,[9] in part because of the limited knowledge about early stages of NK cell development. The information mostly comes from ex vivo analyses of normal CD34-positive progenitor populations;[21] the information regarding its malignant counterpart is sparse. The true frequency of NK-ALL remains unknown. The neoplastic cells are reported to express CD56, CD94, and CD161 and cytoplasmic CD3-epsilon. CD2, CD7, and even CD5 could be positive, but CD16 is usually absent.[9] T-cell receptor (TCR) gene rearrangement is germline.

Cytogenetic and Molecular Profiling

Frequent cytogenetic and molecular abnormalities associated with adult ALL offer insight into

leukemogenesis and leukemic progression (Table 1–3).[22] They are of both prognostic and predictive significance and have varying frequencies in children and adults, which explains some of the differences in outcomes in these two groups. This is particularly true in the case of B-ALL harboring Philadelphia chromosome [t(9;22)] (Ph) or other chromosomal changes with prognostic relevance, such as t(4;11)/mixed lineage leukemia (*KMT2A)-AF4*. Cytogenetic alterations provide an important basis for B-ALL subclassification. In T-ALL, an abnormal karyotype is found in about 50% to 70% of cases, commonly involving *TCR* loci, 14q11.2/*TCR* alpha/delta, 7p14-15/*TCR* gamma, or 7q35/*TCR* beta. The partner genes involve 10q24/*HOX11*,5q35/*HOX11L2*,1q32/*TAL1*,11p15/*LMO1*, or 8q24/*MYC*. del(9p) with the loss of *CDKN2A* is also common. Activating mutations in *NOTCH1* are detected in around 50% and *FBXW7* in about 30% of cases of T-ALL. The presence of *NOTCH1/FBXW7* mutations in the absence of *KRAS/NRAS* or *PTEN* abnormalities is associated with a good outcome.[23] On the other hand, the absence of *NOTCH1/FBXW7* mutations, the presence of *KRAS/NRAS* mutations, and the presence of *PTEN* mutations are associated with a poor prognosis in T-ALL.[24] Next-generation sequencing (NGS), expression proteomics, and oligonucleotide microarrays have transformed our understanding of the genomic landscape of ALL, yielding new molecular subgroups with actionable targets.[25–27]

Recently, a Ph-like signature has been defined using genome-wide gene expression arrays, which is found in 10% of children with standard-risk ALL and as many as 25% to 30% of young adults with ALL. This subgroup lacks the expression of BCR-ABL1 fusion protein but does have a gene expression profile similar to *BCR-ABL1*+ ALL.[28–30] The vast majority of these patients have deletions in genes encoding key transcription factors involved in B-cell signaling, such as *IKZF1*, *TCF3*, *EBF1*, *PAX5*, and *VPREB1*, as well as kinase-activating alterations involving *ABL1*, *ABL2*, *CRLF2*, *CSF1R*, *EPOR, JAK2, NTRK3, PDGFRB, PTK2B, TSLP*, or *TYK2* and sequence mutations involving *FLT3*, *IL7R*, or *SH2B3*. The most common alterations (~60% in adults) are rearrangements of *CRLF2*, which activate downstream signaling through Janus kinases (JAKs), and approximately half of *CRLF2*-rearranged cases

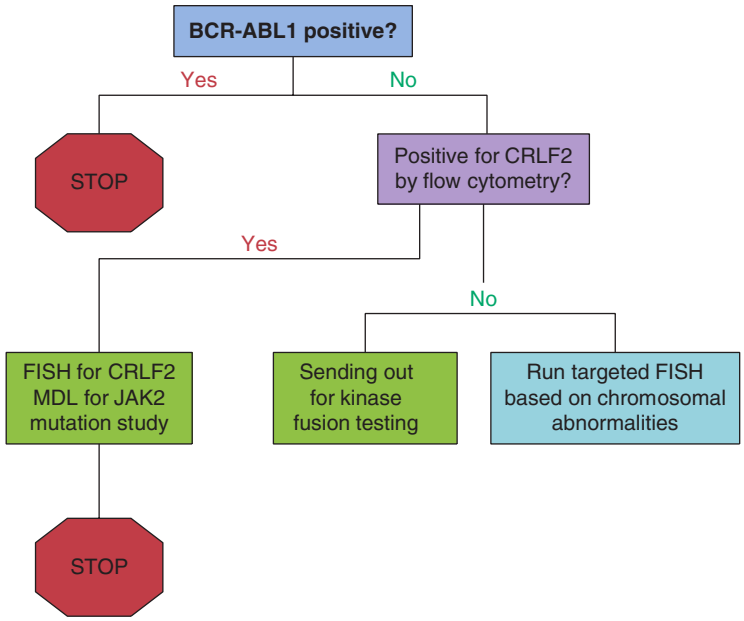

FIGURE 1-1 Philadelphia chromosome–like acute lymphoblastic leukemia molecular lesions and associated molecular fusions or mutations. FISH, fluorescence in situ hybridization.

have activating mutations in *JAK1* or *JAK2* (Fig. 1–1). *CRLF2* expression can be rapidly detected by flow cytometry, and a positive *CRLF2* expression correlates 100% with *CRLF2* rearrangement by fluorescence in situ hybridization (FISH).[31] Importantly, Ph-like ALL with *ABL1, ABL2, CSF1R*, and *PDGFRB* expression fusions (the ABL class) has been shown sensitive to tyrosine kinase inhibitors (TKIs; e.g., dasatinib) both by in vitro and in vivo human xenograft models. On the other hand, rearrangements in *EPOR, IL-7R*, and *JAK2* are sensitive to JAK inhibitors (e.g., ruxolitinib); and the *ETV6-NTRK3* fusion is sensitive to ALL kinase inhibitors (e.g., crizotinib).[29] The identification of kinase alterations expands therapeutic options in this subgroup of ALL with a poor outcome (Table 1–4).

At our institution, we use the following algorithm to stratify B-ALL cases (see Fig. 1–1). For every new patient with B-ALL, we perform FISH for *BCR/ABL1* and test for *CRLF2* expression by FCI. If FCI detects *CRLF2* expression, FISH studies are ordered to confirm *CRLF2* rearrangement, and molecular studies are ordered to check for *JAK2* (or *JAK1, JAK3*) mutations. In the absence of

Measurable Residual Disease

Measurable residual disease (MRD), or minimal residual disease, is defined as residual leukemic blasts detected after cytoreductive chemotherapy despite apparent morphologic remission (<5% blasts in the bone marrow). Assessment of MRD has become a standard-of-care practice in the management of patients with ALL because of its powerful prognostic value as a predictor of relapse and survival.[32] The significant prognostic value of MRD spans across all subtypes of ALL and supersedes that of historical parameters, such as age, WBC count, and cytogenetics.[24] A meta-analysis of 13,637 pediatric and adult ALL patients showed that across all subgroups and covariates, MRD negativity has a hazard ratio (HR) of 0.23 in pediatric patients and 0.28 in adults for event-free survival (EFS) and an HR of 0.28 in both children and adults for overall survival (OS).[33] In adult patients, this translated to 10-year OS rates of 60% and 15% for patients who were MRD negative and MRD positive, respectively.

There are different methods to assess MRD after treatment, including multiparameter flow cytometry (MFC), quantitative polymerase chain reaction (PCR), and NGS. Ideally, MRD should be tested on a bone marrow sample because it can be 1 to 3 logs higher in MRD levels than that in the peripheral blood.[34–36] MRD assessment is recommended to perform on bone marrow with morphologic remission after induction, at approximately 3 months, and every 3 to 6 months thereafter. MRD information is currently used to guide postinduction therapy. Bassan et al.[37] assigned patients who achieved complete remission (CR) after intensive chemotherapy to either maintenance or allogeneic hematopoietic stem cell transplantation (AHSCT) based on their MRD status and found a 75% OS rate for patients who achieved MRD negativity and did not undergo AHSCT, regardless of their cytogenetic or clinical risk stratification at diagnosis. Another example of the use of MRD to guide therapies is the use of blinatumomab in patients with poor MRD clearance. In a multicenter single-arm phase II study of blinatumomab in MRD-positive ($\geq 10^{-3}$) B-ALL in morphologic CR, MRD negativity was achieved in 88 of 113 (78%) patients. Complete MRD responders had longer relapse-free survival (RFS) (23.6 vs 5.7 months; $P = .002$) and OS (38.9 vs 12.5 months; $P = .002$) compared with patients whose MRD did not clear after blinatumomab. The 4-year OS rate was 52% among MRD responders.[38] These findings were further confirmed using propensity score matching by comparing them with historical data.[39]

The time to achieve MRD negativity is also a strong prognostic factor, particularly in Ph-negative ALL. A study from our institution analyzed 215 patients with newly diagnosed Ph-negative B-ALL who received intensive chemotherapy and had available MRD assessment by MFC at CR and around 12 weeks. Early responders defined as MRD negativity at CR had better outcome, with 3-year EFS rates of 65% vs 42% in late responders ($P < .001$) and 3-year OS rates of 76% vs 58% ($P = .001$). On multivariate analysis, the *KMT2A* rearrangement and MRD positivity at CR were the only factors that correlated with worse OS.[40]

FRONTLINE THERAPY

The treatment of patients with ALL consists of four major components: induction of remission, consolidation, maintenance, and CNS prophylaxis.[41] The goal of induction is to induce remission by eradicating leukemic cells from the bone marrow. Intensive induction chemotherapy regimens are modeled after either the pediatric-inspired roadmap regimens or the hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone) regimen developed at MD Anderson Cancer Center (MDACC). Pediatric-inspired regimens have previously been studied in patients of all ages, but their use in patients older than 40 years has largely fallen out of favor because of higher rates of toxicity and treatment-related mortality rates in this patient population, and they are generally reserved for use in the adolescent and young adult (AYA) population.[42] After achieving CR, the consolidation phase aims to eradicate any residual leukemia cells remaining after induction and, depending on the risk category, consists of either consolidation chemotherapy (e.g., high-dose methotrexate and cytarabine) or AHSCT. Consolidation is followed by maintenance therapy to prevent relapse and prolong remission. Maintenance consists of daily 6-mercaptopurine, weekly methotrexate, and monthly pulses of vincristine and prednisone or dexamethasone, given over 2 to 3 years (POMP [Purinethol, Oncovin, methotrexate, and prednisone] or DOMP (Dexamethasone, Purinethol, Oncovin, and methotrexate), depending on corticosteroid used).[43] Maintenance is omitted in mature B-ALL because of high cure rates, and BCR-ABL1 TKIs are included in all phases for patients with Ph-positive ALL.

One extensively studied regimen used in treatment of adult ALL is the hyper-CVAD regimen, in which patients receive hyper-CVAD alternating with high-dose methotrexate and cytarabine for a total of eight alternating cycles approximately every 3 to 4 weeks.[42] This is followed by 2.5 years of POMP maintenance therapy interspersed with intensification courses during months 6, 7, 18, and 19.

The advances made in the field of immunotherapy and the remarkable results achieved in the salvage

setting of ALL led to the investigation of chemoimmunotherapy in the frontline setting. To improve outcomes of younger patients with newly diagnosed B-ALL, an ongoing phase II trial is investigating the sequential use of hyper-CVAD and blinatumomab with promising safety and efficacy. The regimen consists of four cycles of hyper-CVAD followed by four cycles of blinatumomab. Blinatumomab is started after two cycles of chemotherapy for patients at high risk for relapse, including those with Ph-like ALL, complex karyotype, t(4;11), low-hypodiploidy, or near triploidy or who are MRD positive. Four cycles of blinatumomab are also incorporated in the POMP maintenance (three cycles of POMP followed by one cycle of blinatumomab) for a total of 16 cycles (i.e., 18 months) of maintenance therapy. Among 27 patients treated, the median age was 27 years (range, 18–57 years). The CR rate was 100%, and MRD negativity was achieved in 96%. There were no induction deaths. One-third of patients underwent AHSCT because of the presence of high-risk disease features. With a median follow-up period of 17 months, 93% of patients were still alive; one patient died after of AHSCT-related complication, and one died of sepsis during reinduction after relapse. The 1-year RFS and OS rates were 76% and 89%, respectively. This trial is currently ongoing at our institution (NCT02877303).[44]

Central Nervous System Prophylaxis and Treatment

Regularly scheduled lumbar punctures with intrathecal (IT) chemotherapy are a mainstay of ALL therapy to prevent or treat CNS disease and are implemented throughout the eight courses of the hyper-CVAD regimen in a risk-adapted manner. In Ph-negative B-ALL and T-ALL, a total of eight IT treatments (two per course for the first four courses) are given, which has decreased the rate of isolated CNS relapse to approximately 6%.[42,45] Because outcomes for patients with Ph-positive B-ALL improved with the addition of BCR-ABL TKIs to the hyper-CVAD regimen, leading to better survival, a higher percentage of CNS relapse is observed with only eight IT courses (~10%).[46] The addition of four more IT courses (12 IT in total) in Ph-positive B-ALL reduced the CNS relapse rate to 0% and hence is our current practice.[47] In patients with Burkitt leukemia or mature B-ALL, prophylaxis is further intensified to include 16 IT doses, a dosing strategy that has successfully reduced the risk of isolated CNS relapse in this patient population.[45]

During hyper-CVAD courses, IT chemotherapy alternating methotrexate and cytarabine is given on days 2 and 8, respectively. However, to avoid the simultaneous administration of IT methotrexate and systemic high-dose methotrexate during the even cycles, we have changed practice during the methotrexate and cytarabine (even) courses, reversing the sequence of IT therapy to avoid increased risk of neurotoxicity. Therefore, IT cytarabine is administered on day 2 and methotrexate on day 8.[48]

CNS disease is diagnosed by the presence of more than five lymphoblasts per microliter in the cerebrospinal fluid (CSF). Patients with CNS involvement are treated with triple IT therapy (hydrocortisone 50 mg, cytarabine 40 mg, and methotrexate 12 mg) twice per week until the CSF is negative for malignant cells on two occasions, then weekly IT for four to eight doses followed by every other week for four doses, and then the normal prophylaxis schedule is resumed with the remaining chemotherapy treatment. After this, consolidative craniospinal irradiation is considered in select patients with a curative intent, particularly before AHSCT.

Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia

The combination of cytotoxic chemotherapy with TKIs has been the mainstay of the frontline treatment of patients with Ph-positive ALL, with the early introduction and continuous administration of TKIs leading to best results.[49–52] Imatinib, a first-generation TKI, combined with intensive and nonintensive chemotherapy, results in CR rates greater than 90% and OS rates ranging from 33% to 50%.[53,54] The best results are achieved when imatinib is administered in a continuous fashion. Despite the improved outcomes with the addition of imatinib to chemotherapy, imatinib resistance is common and leads to a high incidence of relapse, which led to the evaluation of more potent TKIs for the frontline treatment of patients with Ph-positive ALL.

The second-generation TKI dasatinib has better potency and selectivity than the first-generation TKIs.[55] It was first developed for chronic myeloid leukemia in patients who could not tolerate or developed resistance to imatinib. Dasatinib is also reported to cross the blood–brain barrier.[56] A single-institution study conducted at MDACC of 72 patients with Ph-positive ALL treated with hyper-CVAD and dasatinib in the frontline setting led to 96% CR rate, 83% complete cytogenetic response (CCyR) rate after the first course, and 65% complete molecular response (CMR) rate. The 5-year OS rate was 46%.[55] These results were confirmed by a multicenter SWOG study of 94 patients with newly diagnosed Ph-positive ALL. At a median follow-up period of 26 months, the CR rate was 88%, and the 3-year OS rate was 71%.[57] Dasatinib in combination with low-intensity chemotherapy was also evaluated. The the European Working Group on Adult ALL (EWALL) study number 01 for Ph(+) ALL

(EWALL-PH-01) study investigated the combination of dasatinib with low-intensity chemotherapy in patients 55 years of age or older with newly diagnosed Ph-positive ALL, showing a 96% CR rate, 28% 5-year RFS, and 36% 5-year OS rate.[58] The majority (75%) of patients who relapsed had the T315I mutation, which confers resistance to all first- and second-generation TKIs.[58]

Nilotinib is another second-generation TKI with activity against most imatinib-resistant mutants of *ABL1*.[59] The EWALL international trial investigated the combination of low-intensity chemotherapy with nilotinib in older adult patients (median age, 65 years) with Ph-positive ALL. The regimen was well-tolerated. The CR rate was 94%, the 4-year EFS rate was 42%, and the OS rate was 47%. Thirty-two percent of patients underwent AHSCT, and the 4-year OS rate for transplanted patients was 61%.[60]

Because the emergence of T315I mutation is a driving force of relapse and the achievement of CMR is associated with better survival, an improvement of outcome relies on more potent TKIs that can suppress the emergence of T315I mutation. Ponatinib is a third-generation TKI that is active against the T315I mutation. In a phase II single-arm trial, patients with newly diagnosed Ph-positive ALL were treated with ponatinib and hyper-CVAD.[61] Ponatinib was given orally at 45 mg/day for the first 14 days of cycle 1 and then continuously at 45 mg/day for the subsequent cycles. After treating 37 patients, the protocol was amended after the occurrence of two fatal myocardial events to reduce the dose of ponatinib to 30 mg/day at cycle 2, with further reduction to 15 mg when a CMR (defined as absence of quantifiable BCR-ABL1 transcripts) was achieved. After the protocol amendment, no further vascular events occurred. A recent update was reported of 86 patients treated with hyper-CVAD and ponatinib with a median follow-up period of 43 months. The 3-month CMR rate was 74%, and the cumulative CMR rate was 84%. Only 18 patients (21%) underwent AHSCT in first CR (CR1). With a median follow-up period of 44 months, 71% of patients remain alive in remission, and only three relapses were observed in patients while still taking ponatinib. The 5-year CR duration and OS rates were 68% and 74%, respectively. A landmark analysis performed at 6 months showed a trend toward better OS in patients who did not undergo AHSCT in first remission (5-year OS rate of 66% for patients who underwent AHSCT compared with 83% for patients who did not [$P = .07$]).[62] The grade 3/4 toxicities included infections, liver function test abnormalities, thrombotic events, myocardial infarction, pancreatitis, and rash.[61–63]

The Gruppo Italiano Malattie Ematologiche Ddell'Adulto (GIMEMA) 1811 phase II trial included 42 patients with newly diagnosed Ph-positive ALL who were treated with ponatinib at 45 mg/day (for eight consecutive courses of 6 weeks) and steroids (prednisone days –14 to 29 during course 1). Complete hematologic response occurred in 95% of patients at 6 weeks and 91% at 24 weeks. The CMR rate at 24 weeks was 46%. The estimated 24-month OS rate was 60%.[64]

It is worth noting that although none of the TKIs has been compared head to head in Ph-positive ALL, one meta-analysis showed that ponatinib is more efficacious than earlier-generation TKIs in the frontline setting, with a higher percentage of patients achieving CMR with ponatinib-based therapy than with earlier-generation TKI-based therapies (79% vs 34%) and a higher OS with ponatinib (2-year, 83% vs 58%; 3-year, 79% vs 50%),[65] and one propensity-score analysis showed that ponatinib is superior to dasatinib: 3-month CMR rates were 82% versus 65% ($P = .03$); 3-year EFS and OS rates were 69% vs 46% ($P = .04$) and 83% versus 56% ($P = .03$), respectively.[66] The sequential combination of ponatinib combined with low-intensity chemotherapy followed by blinatumomab and ponatinib in patients with newly diagnosed Ph-positive ALL is currently being investigated in a clinical trial (NCT03147612).

The combination of blinatumomab with TKIs (mainly ponatinib) has been shown to be safe and effective in a small case series of 15 patients from MDACC with 50% CR rate and 75% CMR rate.[67] The GIMEMA group has recently presented early results from D-ALBA, the first trial investigating the sequential use of TKIs–steroid (in induction) and blinatumomab (in consolidation). Sixty-three patients were treated with this regimen of prednisone, dasatinib, and blinatumomab. The CR rate was 98%, and the 1-year disease-free survival (DFS) rate was 88%. Deep molecular response increased throughout therapy (29% after induction, 60% after two cycles of blinatumomab, and 80% after four cycles). Notably, T315I mutation was noted in 6 of 15 patients with rising MRD in the induction phase, all of which was cleared after blinatumomab.[68] However, T315I resistance mutation and patients harboring *IKZF1* and/or *PAX5* and/or *CDKN2A/B* deletions remain a therapeutic challenge. Several similar trials are evaluating the combination of blinatumomab with dasatinib (NCT02143414, NCT04329325) and ponatinib (NCT03263572) in both frontline and relapsed or refractory settings. At our institution, we are evaluating the combination of ponatinib with blinatumomab with promising early results.

Philadelphia Chromosome–Like Acute Lymphoblastic Leukemia

The treatment of patients with Ph-like ALL remains challenging because of the poor prognosis that this subtype confers. In a retrospective study from MDACC investigating the outcomes of patients with Ph-like ALL treated with standard intensive chemotherapy,

148 patients with untreated Ph-like ALL received hyper-CVAD or the pediatric-inspired augmented Berlin-Frankfurt-Münster (aBFM) regimen. Of the 148 patients, 56 patients (median age, 34 years) had Ph-like ALL, 37 of whom (61%) had *CRLF2* overexpression. The majority of patients with *CRLF2* rearrangements (84%) had concurrent *IKZF1* deletion. Patients with Ph-like ALL had lower rates of MRD negativity at CR and a worse 5-year survival rate (23% vs 59%; $P = .006$).[69]

Recently, the outcomes of 24 patients with B-ALL harboring *ABL*-class fusions and treated with a combination of TKIs and chemotherapy were reported in both frontline ($n = 19$) and relapse ($n = 5$) settings. The median age was 24 years (range, 5–72 years). Eleven patients (46%) harbored *IKZF1* deletions. After induction therapy, only 16 of 24 patients (67%) achieved CR, all with detectable MRD, including 7 with MRD of 10^{-2} or greater. In 14 of 18 patients (78%), an MRD level below 10^{-4} was achieved within a median time of 2.5 months (range, 1.4–14.8 months) after TKI initiation. The median remission duration and OS were not reached after a median follow-up period of 36 months. The 3-year EFS and OS rates were 55% and 77%, respectively.[70] Given that patients are more likely to remain MRD positive after induction therapy, the use of blinatumomab as frontline or for MRD in CR1 may improve outcomes.

Our current treatment strategies in patients with Ph-like ALL include the use of TKIs in patients with *ABL*-class fusions and blinatumomab and inotuzumab ozogamicin combinations mainly among patients with *CRLF2* and *JAK* activations.

Mature B-Cell and Burkitt Acute Lymphoblastic Leukemia

The addition of rituximab to short intensive chemotherapy has improved outcomes in adults with Burkitt and Burkitt-type lymphoma or ALL.[71–73] Its addition to hyper-CVAD resulted in a 3-year survival rate of 89% compared with 53% with chemotherapy alone. This was confirmed in a randomized, open-label, phase III trial, in which 260 patients with newly diagnosed Burkitt lymphoma/leukemia received intensive chemotherapy with or without rituximab. The addition of rituximab improved EFS (3-year rate, 75% vs 62%; $P = .024$) and OS (3-year rate, 83% vs 70%; $P = .011$).[74]

To further reduce early morbidity and mortality, a pilot study investigated dose-adjusted EPOCH (etoposide phosphate, prednisone, Oncovin, cyclophosphamide, and hydroxydaunorubicin) in combination with rituximab in 30 patients (median age, 33 years; age older than 40 years, 40%) diagnosed with Burkitt lymphoma. The treatment was safe and highly effective. The PFS and OS rates were 95% to 100% and 90% to 100%, respectively. Of note, the majority of patients (90%) had low- and intermediate-risk disease: only 13% had marrow involvement, and 3% had CNS involvement, both being known adverse factors.[75] One concern with the DA-EPOCH-R (dose-adjusted etoposide phosphate, prednisone, Oncovin, cyclophosphamide, hydroxydaunorubicin, and rituximab) regimen is the lack of highly CNS-penetrating chemotherapy agents, such as high-dose methotrexate and cytarabine, which are essential components of high-intensity chemotherapy for Burkitt leukemia. A recent report showed significantly higher 3-year rates of CNS relapse in patients with Burkitt leukemia treated with DA-EPOCH compared with regimens that incorporate agents with good CNS penetration, such as hyper-CVAD and CODO-M/IVAC (cyclophosphamide, Oncovin, doxorubicin, high-dose methotrexate/ifosfamide, etoposide, and high-dose cytarabine) (12% compared with 3%–4%), despite the use of IT CNS prophylaxis with DA-EPOCH.[76] A phase III clinical trial comparing R-CODOX-M/R-IVAC (cyclophosphamide, doxorubicin, vincristine, methotrexate/ifosfamide, etoposide, high-dose cytarabine) with DA-EPOCH-R in patients with newly diagnosed high risk mature B-ALL is underway (EudraCT Number: 2013-004394-27).

CD20-Positive Precursor B-Cell Acute Lymphoblastic Leukemia

Expression of cell surface marker CD20 in adult ALL ranges from 35% to ubiquitous, depending on the subtype, and has been associated with an inferior prognosis.[77] The addition of two doses of monoclonal CD20 antibody (rituximab) administered with the first four cycles of chemotherapy and during maintenance intensification at months 6 and 18 resulted in improved OS in younger patients compared with similar chemotherapy historical control participants (75% vs 47% at 3 years; $P = .003$).[45] Similar results were reported by the German Multicenter Study Group for ALL (GMALL).[78] The addition of rituximab to chemotherapy in the GRAAL-R 2005 randomized study improved the 2-year EFS and OS rates from 52% to 65% ($P = .038$) and 64% to 71% ($P = .095$; censoring for AHSCT, $P = .018$), respectively.[79]

Ofatumumab is a second-generation anti-CD20 monoclonal antibody that has a different binding site than rituximab, targeting a membrane proximal small-loop epitope on the CD20 molecule.[80] Ofatumumab in combination with hyper-CVAD was found to be highly effective in a phase II study of 69 patients with newly diagnosed Ph-negative CD20-positive B-ALL. All but one patient (98%) achieved CR, and the MRD negativity rate was 93% overall. At a median follow-up period of 44 months, the median RFS was 52 months, and the median OS was not reached. The 4-year RFS and OS

rates were 60% and 68%, respectively. For AYAs, the 4-year OS rate was 74%. Overall, the combination of hyper-CVAD plus ofatumumab was highly effective. Ofatumumab is our preferred anti-CD20 monoclonal antibody in ALL, particularly for patients with CD20 expression less than 20%.[81]

T-Cell Acute Lymphoblastic Leukemia

Treatment of adults with T-ALL and T-cell lymphoblastic lymphoma (T-LL) results in long-term survival rates of 40% to 60%; the outcome is strongly associated with the T-cell phenotype.[18,82] Nelarabine, a T-cell-specific purine nucleoside analog, is approved for the treatment of patients with relapsed and refractory T-ALL, leading to CR rates of 31% to 36% in phase II trials,[83,84] allowing some patients to undergo AHSCT with long-term survival. In the pediatric experience, the addition of nelarabine to frontline aBFM chemotherapy in patients with T-ALL up to 31 years of age improved the 4-year DFS rate from 83% with aBFM alone to 89% ($P = .0332$).[85] However, these results have not yet been replicated in adult patients. A single-arm phase II study from MDACC of nelarabine combined with frontline hyper-CVAD regimen in 67 patients failed to improve CR duration or OS rates compared with historical control participants treated with hyper-CVAD alone.[86] This study has now been amended to include the incorporation of nelarabine, peg-asparaginase, and venetoclax into the hyper-CVAD regimen.

Recent insights into the biology of ETP-ALL have revealed BCL-2 dependence, which perhaps explains the sensitivity to BCL-2 antagonism.[87] The addition of venetoclax to lower-intensity chemotherapy in older adults with newly diagnosed ALL has yielded encouraging early results in interim reports of 10 patients treated (three with T-ALL, including two with ETP-ALL), with 90% CR/CR with incomplete hematologic recovery (CRi) rate and 90% MRD negativity.[88] The combination of venetoclax and navitoclax may also be particularly promising in this subgroup. Clinical trials evaluating the efficacy and safety of venetoclax with navitoclax (NCT03181126) and in combination with chemotherapy (NCT03808610; NCT03504644; NCT03576547; NCT03319901) in patients with relapsed and refractory ALL are currently ongoing. Studies evaluating the biology of near ETP-ALL are ongoing at our institution to better tailor the treatment and thus improve the outcome of this poor-risk subgroup.

Adolescent and Young Adult Acute Lymphoblastic Leukemia

The AYA population consists of patients 15 to 39 years of age. The biology of ALL differs between children, AYAs, and older adults, which is the rationale behind tailoring ALL therapy to the different treated populations. Such differences include (1) a higher T-cell phenotype in patients aged 10 to 40 years old; (2) a near absence of the two favorable subgroups of ALL (hyperdiploidy and t(12;21)/*ETV6-RUNX1*) during the second decade of life compared with a 60% prevalence in children; and (3) an increasing prevalence of high-risk Ph-positive ALL with age, from 3% in children to almost 50% in older adults.[89] In the US intergroup trial C10403 of 295 AYA patients (17–39 years of age) treated with a pediatric regimen, the 3-year OS rate was 73%.[90] At MDACC, a nonrandomized study including AYA patients showed no difference between the pediatric asparaginase-containing aBFM regimen and the non-asparaginase-containing hyper-CVAD regimen. The 5-year CR duration rate was 53% with hyper-CVAD, compared with 55% with aBFM. The 5-year OS rates were 60% in both groups. The aBFM regimen had a higher incidence of asparaginase adverse effects, such as hepatotoxicity (41%), pancreatitis (11%), and thrombosis (19%), and myelosuppression-related complications were more common with hyper-CVAD.[91] More recently, the hyper-CVAD and ofatumumab combination reported a 4-year OS rate of 74% in the AYA population.[81]

In summary, pediatric regimens and the hyper-CVAD regimen showed similar CR, remission duration, and survival outcomes. In the absence of a randomized study comparing both regimens in the AYA population, our practice is to use the hyper-CVAD regimen as a backbone for clinical trial development because this regimen has less organ-specific toxicity than asparaginase-based regimens and is thus more conducive to combination with investigational agents.

Acute Lymphoblastic Leukemia in Older Patients

In older patients with ALL (generally defined as those older than 55–60 years), intensive chemotherapy results in CR rates of 80% but with unacceptable toxicities.[92] One-third of patients achieving CR may die of myelosuppression-associated complications. The historical long-term cure rate is 15% to 20%.[93] Among 727 older adult patients (older than 65 years; 2007–2012) treated under Medicare, the majority of patients did not receive chemotherapy; in those who received chemotherapy, the median OS period was only 10 months.[94] In the National Cancer Institute Surveillance, Epidemiology, and End Results database, among 1675 adults (age 60 years or older) with ALL (1980–2011), the median survival time was 4 months, and the 3-year survival rate was 12.8%.[95]

Strategies to de-intensify treatment regimens have been thus investigated in this population. Inotuzumab ozogamicin with mini hyper-CVD (i.e., a lower

intensity version of the hyper-CVAD regimen without anthracycline), with or without blinatumomab, is one such strategy and appears to be promising in the older adult population. Among 64 patients treated with this regimen, the median age was 68 years (range, 60–81 years), and 42% of patients were 70 years of age or older. The CR rate was 98%, and 95% achieved MRD negativity. The 3-year CR duration and OS rates were 76% and 54%, respectively. A propensity-matched analysis showed that this regimen significantly improved survival compared with a historical 3-year OS rate of 32% with hyper-CVAD in this older population (P = .007). No early deaths occurred during induction. However, the rates of death in remission were 33% overall and were significantly higher in those 70 years of age or older compared with those ages 60 to 69 years (50% vs 22%, respectively; P = .02). For the population of patients 70 years of age or older, the protocol has now been amended to decrease the number of mini hyper-CVD and inotuzumab ozogamicin cycles from four to two and to replace POMP maintenance with blinatumomab monotherapy to mitigate toxicity in this population.[96]

Role of Allogeneic Hematopoietic Stem Cell Transplantation

AHSCT has traditionally been reserved for patients with high-risk features, including B lineage with WBC 30 × 109/L or greater; T-lineage with WBC 100 × 109/L of greater; hypodiploid; Ph-positive; or *KMT2A* translocation ALL [e.g., t(4;11)]. However, there has been some debate regarding who should be referred for AHSCT in CR1 because of the emergence of newer promising therapies that have improved outcomes in this disease. As an alternative, many centers have incorporated MRD via Flow cytometry (FCM) or reverse transcription PCR after induction or consolidation to stratify patients based on their response to chemotherapy.[97] In one study, MRD status at various time points after CR was used to guide treatment in adult patients with ALL.[37] Patients who remained MRD positive at the end of consolidation were deemed to be higher risk and underwent AHSCT instead of receiving prolonged maintenance therapy. Patients who achieved MRD-negative status had a significantly improved 5-year OS (75% vs 33%; P = .001). Ph-like ALL and ETP-ALL confer a poor prognosis, and AHSCT should be considered regardless of MRD status.[19,98] The GRAALL (Group for Research in Adult Acute Lymphoblastic Leukemia)-2003/2005 trials showed that postinduction MRD positivity, the presence of *IKZF1* mutations in B-ALL, and the absence of *NOTCH1* or *FBXW7* mutations in T-ALL are the main factors predicting benefits of AHSCT in CR1.[23,69] It is noteworthy that newer agents, such as blinatumomab, are potent in eradicating MRD, as was proved by the BLAST trial, which showed no difference in OS or RFS between patients who received AHSCT during CR1 and those who did not.[99] Hence, the role of AHSCT in the era of new therapeutics is becoming increasingly questionable.

Similarly, in the era of potent TKIs, the role of AHSCT in patients with Ph-positive ALL is also becoming controversial, even though it has been historically shown that AHSCT does improve outcomes in these patients. Although a study showed that AHSCT improved RFS and OS in patients with Ph-positive ALL treated with hyper-CVAD and dasatinib, a subgroup analysis according to molecular responses was not performed.[57] On the other hand, achievement of a 3-month CMR predicted a very good prognosis in patients who received chemotherapy plus TKIs, suggesting that these patients might not need AHSCT.[100,101] An analysis performed on patients treated with hyper-CVAD and ponatinib with censoring at time of transplant showed that the long-term probability of survival is the same, suggesting that most of these patients may be cured without AHSCT.[61,63]

The role of AHSCT in CR1 remains currently valid in certain high-risk circumstances, such as (1) *KMT2A*-rearranged ALL, (2) ETP-ALL, and (3) ALL with complex cytogenetics and hypodiploidy. Patients with Ph-like ALL with negative MRD and those in CR1 who achieve MRD negativity after blinatumomab may not need AHSCT. Patients with Ph-positive ALL with 3-month CMR should not be referred to AHSCT; in contrast, patients with positive MRD should be considered for blinatumomab or other MRD-targeted therapy and eventually AHSCT, particularly in patients who remain positive for MRD. Patients with ALL in CR2 should be referred for AHSCT (Fig. 1–2).

SALVAGE THERAPY

The prognosis of adult patients with relapsed ALL was historically associated with a dismal prognosis, with a cure rate of less than 10%[102,103] and CR rates of 30% to 40% in first relapse and 20% to 25% in second relapse with standard chemotherapy regimens, with an AHSCT rate of only 10% to 30% in adult patients.[102,103] The recent advent of monoclonal antibodies, bispecific antibodies, and chimeric antigen receptor T-cell (CAR T) therapies has revolutionized the treatment of ALL and resulted in a number of Food and Drug Administration approvals for the treatment of ALL in the salvage setting, such as blinatumomab in 2014 and inotuzumab ozogamicin and tisagenlecleucel in 2017.[104–106] These agents are currently the subject of investigation in different schemas and combinations (Table 1–5).

Table 1–5 Seminal Trials for Treatment of Relapsed or Refractory B-Cell Acute Lymphoblastic Leukemia

Clinical Trial	Disease Setting	Patients (*n*)	Response	Median Overall Survival Time (months)	MRD Negativity (%)[a]
Blinatumomab					
TOWER[103]	R/R Ph- ALL	271	ORR: 44% CR: 34%	7.7	76
ALCANTARA[109]	R/R Ph+ ALL	45	ORR: 36% CR: 31%	7.1	88[b]
Inotuzumab Ozogamicin					
INO-VATE[105]	R/R ALL	109	ORR: 81% CR: 35.8%	7.7	78
mini-hyper-CVD + inotuzumab ozogamicin ± blinatumomab[115]	R/R ALL	84	ORR: 80% CR: 58%	S1: 25 S2: 6 S3: 7	82
CAR T-Cell Therapy					
ELIANA[105,123]	R/R ALL (age younger than 26 years)	79	ORR: 82% CR/CRi: 62%	NR	98
Anti-CD19 CAR T cells[124]	R/R ALL (adults)	53	CR: 83%	12.9	67

[a]Measured by flow cytometry.
[b]Within two cycles.
ALL, acute lymphoblastic leukemia; CAR, chimeric antigen receptor; CR, complete remission; CRi, complete response with incomplete hematologic recovery; CVD, cyclophosphamide, vincristine, and dexamethasone; MRD, measurable residual disease; NR, not reported; ORR, objective response rate; Ph, Philadelphia; R/R, relapse or refractory; S1, salvage 1; S2, salvage 2; S3, salvage 3.

Blinatumomab

Blinatumomab is an anti-CD19-directed CD3 bispecific T-cell engager constructed using BiTE antibody technology.[107] It consists of a recombinant monoclonal antibody composed of an anti-CD19 fragment antigen-binding (Fab) region joined by a short linker to

an anti-CD3 Fab region.[107] In the confirmatory phase II study of 189 patients with Ph-negative ALL, blinatumomab was associated with an objective response rate (ORR) of 43%. The median response duration was 9 months, and the median OS period was 6 months.[108]

Following these results, a phase III trial (TOWER study) was conducted in more than 400 patients with relapsed or refractory Ph-negative ALL randomized (2:1) to blinatumomab (n = 271) or standard of care (n = 134). The rate of CR with full, partial, or incomplete hematologic recovery was significantly higher in the blinatumomab group than in the chemotherapy group (44% and 25%, respectively; P <.001). Molecular remission rates among responders, defined as MRD less than 10^{-4} in the first 12 weeks, were 76% and 48%, respectively. Blinatumomab prolonged survival, the primary study endpoint; the median OS was 7.7 months versus 4.0 months (P = .01). A total of 24% of the patients in each group underwent AHSCT.[104]

A recent report from a phase III study with 1:1 randomization of 208 children and AYAs in first salvage to blinatumomab or standard of care showed that blinatumomab induced a higher rate of MRD negativity (79% with blinatumomab compared to 21% with standard of care; P <.001) and a better 2-year OS rate (79% with blinatumomab compared with 59% with standard of care; P = .005).[109]

In patients with relapsed or refractory Ph-positive ALL, blinatumomab also demonstrated a positive effect. In the phase II ALCANTARA trial, 45 patients with relapsed or refractory Ph-positive ALL were treated. Thirty-six percent achieved a response. The median RFS and OS periods were 6.7 months and 7.1 months, respectively; 44% of patients received AHSCT.[110]

Inotuzumab Ozogamicin

Inotuzumab ozogamicin is a novel anti-CD22 monoclonal antibody conjugated to the toxin calicheamicin.[111] In a single-institution phase II study in patients with relapsed or refractory ALL, inotuzumab ozogamicin was administered at a starting dose of 1.3 to 1.8 mg/m^2 intravenously (IV) every 3 to 4 weeks. Forty-nine patients were treated. The ORR was 57%, and the median survival period was 5.1 months. Nearly half of the patients treated with inotuzumab ozogamicin proceeded to AHSCT.[112] To minimize toxicities and based on pharmacokinetic and pharmacodynamic data, inotuzumab ozogamicin was administered on a weekly basis at 0.8 mg/m^2 IV on day 1 followed by 0.5 mg/m^2 IV on days 8 and 15 every 3 to 4 weeks in 40 patients. The study yielded a similar response rate as inotuzumab ozogamicin given every 3 to 4 weeks (59% vs 57%), with a median survival period of 9.5 months. Weekly administration of inotuzumab ozogamicin resulted in fewer adverse events, including lower rates of veno-occlusive disease (VOD).[113] In a separate, multicenter phase II trial in heavily pretreated patients with relapsed or refractory ALL, inotuzumab ozogamicin therapy resulted in a remission rate of 66%, with 78% of patients who achieved CR becoming MRD negative. The median survival period was 7.4 months.[114]

These results led to a randomized trial comparing inotuzumab ozogamicin with physician's choice of chemotherapy in patients with relapsed ALL. The CR rates were 81% with inotuzumab ozogamicin and 29% with standard of care (P <.0001). Among responders, the MRD negativity rates were 78% and 28% (P <.0001), respectively. The median survival period was 7.7 versus 6.7 months (P = 0.02; HR, 0.77). The 2-year survival rates were 23% and 10%, respectively. Serious toxicities included VOD after AHSCT, mainly in patients who received double alkylators in pretransplant conditioning. Age was also a risk factor for VOD.[105]

Recently, inotuzumab ozogamicin was assessed in 48 children and AYAs (median age, 9 years).[1–21] The ORR and MRD negativity rates were 62% and 65%, respectively. The 12-month OS rate was 40%.[115]

Combination Immunotherapies

Given the encouraging results achieved with these novel antibody constructs in ALL, they were further evaluated in combination with lower-intensity chemotherapy backbone with the goal of further improving outcomes.

Inotuzumab ozogamicin was evaluated with mini hyper-CVD in relapsed or refractory B-cell Ph-negative ALL (details described earlier). Among the initial 59 patients with relapsed or refractory ALL treated, the response rate was 78%, with 82% of responders achieving MRD negativity. The 1-year RFS and OS rates were 46% and 41%, respectively. The median OS and RFS were 11 months and 8 months, respectively. Almost half of the patients were able to receive subsequent AHSCT, with an estimated 1-year survival rate of 63% among these patients. The rate of VOD was 15%, mainly in patients with prior or subsequent AHSCT (23%). When compared with a historical cohort of patients treated with inotuzumab ozogamicin monotherapy in the salvage setting, the results of the combination were significantly better (median survival 9.3 months vs 5.6 months, P = .02). To further improve these outcomes, the study was amended to investigate the addition of four cycles of blinatumomab following four cycles of the combination of weekly lower doses of inotuzumab ozogamicin and mini hyper-CVD. The hypothesis is that the

addition of blinatumomab may allow for the use of less chemotherapy and lower doses of weekly inotuzumab ozogamicin, the eradication of MRD, and the distancing of AHSCT from the last dose of inotuzumab ozogamicin, thereby leading to less treatment-related morbidity, less VOD, and less mortality. In fact, the incidence of VOD was significantly reduced (from 15% to 5%) by using lower and fractionated doses of inotuzumab ozogamicin (first dose of 0.6 mg/m^2; then 0.3 mg/m^2 for each subsequent dose) and by spacing out the last dose of inotuzumab ozogamicin from AHSCT by 3 to 6 months. In the overall cohort of patients treated with mini hyper-CVD with inotuzumab ozogamicin (n = 59) alone and those treated with sequential combination with blinatumomab (n = 30), the 2-year survival rate was 39%, and the median survival period was 14 months. In 62 patients treated in first salvage with mini hyper-CVD and inotuzumab ozogamicin with or without blinatumomab, the CR/CRi rate was 92%, the MRD negativity rate was 86%, the median survival time was 25 months, and the 3-year OS rate was 42%. The 60-day mortality rate was 3%.[116] These results compare favorably with the results obtained with single-agent inotuzumab ozogamicin and blinatumomab and historical salvage chemotherapy with median survival period of only 6 to 12 months. Longer follow-up is needed to assess the relative contribution of blinatumomab to the regimen.

The SWOG 1312 study is a phase I trial of inotuzumab ozogamicin and CVP (cyclophosphamide, vincristine, and prednisone) for relapsed or refractory ALL. Fifty patients (median age, 43 years) were enrolled, among whom five patients were identified as having a Ph-like signature. The CR/CRi rate was 61% in the 23 evaluable patients treated at the maximal tolerated dose (MTD), and 60% (three of five) in patients with the Ph-like signature. The median OS periods were 7.7 months for all patients and 10.9 months for patients treated at the MTD.[117]

BH3 Mimetics

The BH3 mimetics venetoclax and navitoclax have demonstrated promising preclinical activity in cell lines of B-TALL and T-ALL.[118–120] Navitoclax is a BH3 mimetic that inhibits BCL-2, BCL-xL, and BCL-W with encouraging antileukemic activity in ALL cells.[120] A particularly strong activity was seen in *KMT2A*-rearranged B-ALL, and both single-agent activity as well as synergistic killing in combination with chemotherapy were observed because of the upregulation of *BCL-2* in these cell lines.[118,119] In a phase I trial, 36 patients with relapsed or refractory ALL (median age, 27 years; range, 6–72 years) were treated with venetoclax and navitoclax in combination with chemotherapy. The ORR was 56%, and the 6-month duration of response rate was 43%.[121]

Chimeric Antigen Receptor T-Cell Therapies

CAR T cells are autologous T cells that are genetically engineered to express a chimeric antigen receptor that is composed of different structural parts, including a binding site of a specific antibody and a signal transduction part with or without additional costimulatory domains.[122] CAR T cells are powerful therapeutic innovations that combine the antigen specificity of antibodies and the cytotoxic activity of T-cells and hence harness the power of targeted therapy and immunotherapy. Although first-generation CAR T cells expressing anti-CD20 or -CD19 CAR T cells failed to expand in vivo and produce significant antitumor effects,[122] second- and third-generation CAR T cells, incorporating one or more co-stimulatory domains, respectively, demonstrated strong expansion and persistence in vivo and powerful antitumor activity. In fourth-generation CAR T cells, cytokines are added to further increase the expansion and survival of CAR T cells.

A multicenter phase I/II study was conducted in 25 centers around the world and treated 79 children and young adults (median age, 11 years) with relapsed or refractory CD19-positive B-ALL with a single infusion of tisagenlecleucel, anti-CD19 CAR T cells produced by Novartis. Among the 65 patients with CR/CRi, 64 (98%) were MRD negative within 3 months. The median duration of response was not reached. The estimated 18-month RFS rate was 66%. Median OS was not reached, and the estimated 18-month OS rate was 70%.[106,123] Tisagenlecleucel is now approved for patients up to age 25 years with B-ALL that is refractory to frontline therapy or with two or more relapses.

Anti-CD19 CAR-T cells were also studied in 53 adult patients at Memorial Sloan Kettering Cancer Center and showed a CR rate of 83%. The median EFS and OS were 6.1 months and 12.9 months, respectively. The median EFS in patients with low (<5% bone marrow blasts) and high disease burden (≥5% bone marrow blasts or extramedullary disease) were 10.6 months and 5.3 months, respectively. The median OS periods were 20.1 and 12.4 months, respectively. Patients with a higher burden of disease had a greater incidence of cytokine release syndrome (CRS) and neurotoxic events as well.[124] ZUMA-3 is a phase I trial that investigated the autologous anti-CD19 KTE-X19 in adults with relapsed or refractory ALL and successfully refined the dosing and the safety of the product,[125] leading to a pivotal phase II trial that is currently ongoing (NCT02614066).

There are two main safety concerns with CAR T-cell therapy: CRS and neurotoxicity, occurring in 77% to

Table 1–6 Ongoing Trials at MD Anderson Cancer Center Available for Patients with Acute Lymphoblastic Leukemia (Frontline and Salvage Settings)

	Trial Characteristics	
ALL Subgroup	**Frontline Setting**	**Salvage Setting**
Pre-B-cell ALL	1. Hyper-CVAD + inotuzumab ozogamicin + blinatumomab 2. Hyper-CVD + inotuzumab ozogamicin + blinatumomab	1. Hyper-CVD + inotuzumab ozogamicin + blinatumomab 2. Hyper-CVD + venetoclax 3. ADCT-602 4. CAR T cells (UCART19, UCART22, KTE-C19) 5. CAR-NK cells
Pre-B-cell ALL, MRD+	1. Blinatumomab 2. Inotuzumab ozogamicin	
T-cell ALL	1. Hyper-CVAD + nelarabine + peg asparaginase + venetoclax 2. Hyper-CVD + venetoclax	1. Hyper-CVD + venetoclax
Ph-positive ALL	1. Hyper-CVD + ponatinib + blinatumomab 2. Blinatumomab + ponatinib	1. Blinatumomab + ponatinib 2. Venetoclax + ponatinib

ALL, acute lymphoblastic leukemia; CAR, chimeric antigen receptor; CVAD, cyclophosphamide, vincristine, doxorubicin, and dexamethasone; CVD, cyclophosphamide, vincristine, and dexamethasone; MRD, measurable residual disease; NK, natural killer; Ph, Philadelphia chromosome.

83% and 40% to 43% of patients, respectively, and being more common in patients with a higher disease burden at baseline.[126] Grade 3 or greater CRS, including one death, was observed in 26% of patients and grade 3 or greater neurotoxicity in 42% of patients, and most of them required treatment with the anti–interleukin-6 monoclonal antibody tocilizumab.[124]

Strategies to improve the safety of CAR T cells while preserving their efficacy are an active area of basic and translational research. A novel anti-CD19 CAR T cell product with a lower affinity to CD19 and fast-off rate has been evaluated and showed improved in vitro proliferation and cytotoxic activity and enhanced proliferation and in vivo antitumor effect.[127] To circumvent CD19 antigen escape as a mechanism of resistance, CD22-targeted CAR T cells and dual CD19 and CD22 CAR T cells have also been developed.

Tremendous efforts have also been made to develop new platforms of "off-the-shelf" CAR-based therapies to decrease the high cost and manufacturing complexity and delay associated with currently approved CAR T cells. Allogeneic CAR T cells manufactured from healthy donors have been investigated. For example, UCART19 is an allogeneic, genetically modified second-generation CAR T cell product manufactured from healthy donor T-cells, in which *TRAC* and *CD52* genes have been knocked out to allow its administration to non–human leukocyte antigen–matched patients without increasing the risk of graft-versus-host disease. "Off-the-shelf" NK cells derived from umbilical cord blood and modified to express CAR (CAR-NK cells) are being developed at our institution with promising results in B-lymphoid malignancies.[128]

EMERGING THERAPIES: MD ANDERSON APPROACH

A number of innovative therapies for various stages of disease, tailored to risk-adapted strategies, are transforming the treatment of adult ALL and resulting in significant improvements in long-term outcomes. Several ongoing trials are available for patients with ALL at our institution and elsewhere in the frontline and salvage settings (Table 1–6).

Our preferred approach to newly diagnosed Ph-negative B-ALL is the addition of blinatumomab to hyper-CVAD in the frontline setting. In this ongoing protocol, only four cycles of chemotherapy are given instead of the standard eight cycles followed by four cycles of blinatumomab incorporated into an 18-month maintenance regimen (half the duration of standard POMP maintenance). With the addition of blinatumomab, the goal is to both decrease the amount of intensive chemotherapy received and deepen responses. This protocol was recently amended to add the CD22 antibody–drug conjugate inotuzumab ozogamicin, thereby incorporating all of the most active agents in B-ALL into our frontline regimen.

Because older adult patients often cannot tolerate intensive chemotherapy, our preferred regimen consists of low-intensity chemotherapy (hyper-CVD) combined with both inotuzumab ozogamicin (given at a lower fractionated dose to decrease the rate of VOD) and blinatumomab to deepen the level of response. We also use this regimen in the relapsed or refractory setting at any age. We also have protocols for low-intensity chemotherapy with venetoclax in older patients

with Ph-negative ALL and for patients with relapsed or refractory ALL (mainly T-ALL).

In patients with Ph-positive ALL, there is a rationale to combine ponatinib with a less intensive chemotherapy backbone (mini hyper-CVD). Given its activity in patients with Ph-positive ALL, blinatumomab is also added to this regimen. The goal is that by reducing toxicity from intensive chemotherapy and incorporating the most active agents in Ph-positive ALL (blinatumomab and ponatinib), we will reduce treatment-related morbidity and mortality and further increase the cure rate. This regimen is open to patients of all ages with newly diagnosed Ph-positive ALL. In older patients (60 years and older) with newly diagnosed Ph-positive ALL or younger patients who are unfit for intensive chemotherapy, we are also evaluating a chemotherapy-free combination of ponatinib and blinatumomab, which is also available for patients with relapsed or refractory Ph-positive ALL at any age.

In the salvage setting, we designed a phase I/II study of the combination of hyper-CVD plus venetoclax for patients with relapsed or refractory ALL. This regimen is particularly promising for patients with T-ALL. Another phase I/II trial available at our institution is investigating ADCT-602, which is an antibody drug conjugate composed of a humanized monoclonal antibody directed against CD22, conjugated to the cross-linking cytotoxic agent tesirine (SG3249). The hope is that this agent will be a potent anti-CD22 therapy, without the hepatic toxicity associated with inotuzumab ozogamicin. Moreover, we have a number of CAR-based therapies being investigated in clinical trials, including those targeting both CD19 and CD22 as well as both autologous (KTE-C19) and allogeneic approaches (UCART19, UCART22, and CAR NK-cell therapies).

Finally, for relapsed or refractory Ph-positive ALL, besides the chemotherapy-free combination of ponatinib and blinatumomab being investigated, we have an ongoing phase I/II trial of the oral, chemotherapy-free regimen, consisting of the combination of venetoclax and ponatinib, for patients of all ages with relapsed or refractory Ph-positive ALL. There is a significant preclinical rationale for the combination of venetoclax and ponatinib, showing synergistic activity. Ponatinib may also help to prevent venetoclax resistance by preventing upregulation of Mcl-1, an established resistance mechanism of venetoclax-based regimens.

CONCLUSION

Therapeutic capabilities in adult ALL have rapidly reached new heights over the past decade with the introduction of highly promising monoclonal antibodies, immune conjugates, CAR T cells, and new-generation TKIs. Genomic profiling has identified new prognostic markers (e.g., *IKZF1*) as well as new therapeutic targets (e.g., *ABL*, *JAK1/2*, *ETV6-NTRK3*) to improve the adverse prognosis of some ALL subsets, such as Ph-like ALL. As many of the newer agents advance through the final stages of development, we will seek to determine the optimal combination and order of delivery and the role of cytotoxic chemotherapy in the safest achievement of durable cure rates. Moreover, the frontline introduction of these effective therapies can be expected to increase the rate of MRD negativity, optimize responses, and close the outcome gap separating pediatric from adult ALL. Harnessing the full potential of the immune system with the durable presence of autologous or allogeneic T-cell constructs may ultimately lead to obviation of AHSCT in search of better cure rates in adult ALL.

MD ANDERSON PRACTICE TIPS

- There are several ongoing clinical trials at MDACC for patients with ALL. The treatment follows a risk-tailored strategy. Our preferred approach to patients with newly diagnosed Ph-negative B-ALL is the addition of blinatumomab to hyper-CVAD in the frontline setting.
- Our preferred regimen in older adult patients consists of low-intensity chemotherapy (hyper-CVD) combined with both inotuzumab ozogamicin (given at a lower fractionated dose to decrease the rate of VOD) and blinatumomab to deepen the level of response. We also use this regimen in the relapsed or refractory setting at any age. We also have protocols for low-intensity chemotherapy with venetoclax in older patients with Ph-negative ALL and for patients with relapsed or refractory ALL (mainly T-ALL).
- In patients with Ph-positive ALL, we combine ponatinib with a less intensive chemotherapy backbone (mini hyper-CVD). Given its activity in Ph-positive ALL, blinatumomab is also added to this regimen. In older patients (60 years or older) with newly diagnosed Ph-positive ALL or younger patients who are unfit for intensive chemotherapy, we are also evaluating a chemotherapy-free combination of ponatinib and blinatumomab, which is also available for patients with relapsed or refractory Ph-positive ALL at any age.
- In the salvage setting, we have a number of trials including the combination of hyper-CVD with venetoclax and antibody drug conjugates as well as CAR-based therapies with T-cells as well as NK cells.

2 Adult Acute Myeloid Leukemia

Tapan M. Kadia
Joseph D. Khoury
Farhad Ravandi

KEY CONCEPTS

- Newer techniques and wider applicability of genomic sequencing have identified numerous recurrent somatic mutations and patterns of mutation that reveal the extensive heterogeneity of acute myeloid leukemia (AML). Better understanding of the biology behind the genomic aberrations has led to more accurate disease prognostication as well as development of specific therapies for genomically defined subgroups. The most recent European LeukemiaNet (ELN) 2017 classification system incorporates several of these mutations for risk classification. Therefore, pretreatment assessment of these mutations (*FLT3, NPM1, CEBPA, TP53, RUNX1, ASXL1*) along with conventional karyotyping is becoming a part of standard practice.
- Since 2017 and as of 2020, several new therapies have been approved or reintroduced for the treatment of patients with AML. These include the FLT3 (fms-like tyrosine kinase 3) inhibitors midostaurin and gilteritinib, the IDH1 inhibitor ivosidenib, the IDH2 inhibitor enasidenib, the BCL2 inhibitor venetoclax, the hedgehog inhibitor glasdegib, the CD33 antibody–drug conjugate gemtuzumab ozogamicin (GO), the liposomal formulation CPX-351, and oral azacytidine.
- The CD33 antibody–drug conjugate GO has been shown to provide significant survival benefit in patients with favorable or intermediate-risk disease and should be incorporated into the frontline treatment of core-binding factor AML when appropriate. GO also has an important role in the treatment of patients with acute promyelocytic leukemia.
- Chemotherapy combined with an FLT3 inhibitor such as midostaurin or others on clinical trial are now part of the standard of care for patients with newly diagnosed *FLT3*-mutated AML.
- The BCL2 inhibitor venetoclax has significantly improved outcomes for older and unfit patients with newly diagnosed AML, having demonstrated a significant survival benefit in combination with hypomethylating agents (HMAs) compared with HMAs alone.
- Monitoring of minimal residual disease (MRD) by multiparameter flow cytometry or molecular methods at the time of remission after induction and after consolidation is a powerful tool to help predict the risk of relapse and guide risk stratification, including postremission strategies such as stem cell transplant (SCT). Complete remission with or without MRD positivity is being incorporated into response criteria.
- Maintenance therapy with oral azacytidine (CC486) has become the standard of care for patients not eligible for postremission SCT after demonstrating improvement in survival compared with placebo. Maintenance strategies with targeted therapies after achieving remission and even after SCT are being investigated.
- Repeat molecular testing for mutations at the time of relapse should be strongly considered to allow incorporation of specific targeted therapies that are indicated in genomically defined subgroups (eg, enasidenib, ivosidenib, gilteritinib).

Acute myeloid leukemia (AML) consists of a heterogeneous group of hematologic neoplasms characterized by clonal proliferation of myeloid blasts involving peripheral blood and bone marrow, with occasional tumor formation in extramedullary tissues. Despite advances in our understanding of the molecular biology of AML, its treatment remains challenging, and outcomes vary greatly depending on a constellation of cytogenetic and molecular features as well as age and comorbidities.

AML is thought to be the culmination of genetic mutations and chromosomal aberrations within myeloid precursors resulting in disrupted differentiation, excessive proliferation, and suppressed apoptosis of neoplastic cells referred to as *blasts*.

Over the past several decades, improvements in chemotherapeutic regimens, supportive care, and improved understanding of underlying biology have resulted in significant progress in treating patients with AML. Knowledge of the biological underpinnings and heterogeneity of AML has resulted in the identification of new therapeutic targets and rationally designed inhibitors for a number of these targets. Despite these advances, the majority of patients with AML have an incurable disease and succumb from relapses or complications of their disease. With better definition of molecular abnormalities and elucidation of the pathogenic events in various AML subtypes and with the development of novel targeted agents, a better outcome for patients with AML may be achievable in the near future.

EPIDEMIOLOGY, ETIOLOGY, AND RISK FACTORS

Approximately 19,000 individuals are diagnosed with leukemia annually in the United States. The incidence of AML is 4.3 per 100,000. The median age at presentation is 68 years. The incidence of AML, as well as myelodysplastic syndrome (MDS), rises with age, with the majority of AML patients being older than 60 years old.[1] The incidence of AML is slightly higher in males and in populations of European descent. Acute promyelocytic leukemia (APL), a distinct subtype of AML, has been reported to be more common among populations of Hispanic background.[2]

An increased incidence of AML is seen in patients with disorders associated with increased chromatin fragility such as Bloom syndrome, Fanconi anemia, Kostmann syndrome, Wiskott-Aldrich syndrome, and ataxia-telangiectasia. Other syndromes, such as Down (trisomy of chromosome 21), Klinefelter (XXY and variants), and Patau (trisomy of chromosome 13) syndromes, have also been associated with a higher incidence of AML.[3]

Exposure to cytotoxic therapies increases AML risk. Two categories of therapy-related AML have been described. Patients exposed to alkylating agents (eg, cyclophosphamide, melphalan, nitrogen mustard) or radiation therapy can develop AML after a latency period of 4 to 8 years, which is often associated with abnormalities of chromosomes 5 and/or 7 and/or complex karyotype but may also present without characteristic chromosome abnormalities.[4,5] Recent analysis of next-generation sequencing (NGS) data also suggests an enrichment of *TP53* mutations among patients with therapy-related AML.[6,7] Exposure to agents that inhibit the DNA repair enzyme topoisomerase II (eg, etoposide) is also associated with secondary AML with a typically shorter latency period, usually 1 to 3 years.[8] Benzene, smoking, dyes, herbicides, and pesticides have been implicated as potential risk factors for development of AML.[9]

AML may also be secondary to transformation of an antecedent myeloid disorder, such as MDS, myeloproliferative neoplasm (MPN), or MDS/MPN, or other bone marrow disorders, such as aplastic anemia.

CLINICAL PRESENTATION

Fatigue, bruising or bleeding, fever, and infection, reflecting a state of bone marrow failure, are common in patients with AML. Only 10% of patients present with white blood cell (WBC) count greater than $100 \times 10^9/L$[1]; these patients are at higher risk of tumor lysis syndrome, central nervous system involvement, and leukostasis. Leukostasis may manifest as dyspnea, chest pain, headaches, altered mental status, cranial nerve palsies, or priapism. Leukostasis and tumor lysis syndrome are oncologic emergencies and require prompt recognition and management.

Physical findings other than bleeding and infection may include organomegaly, lymphadenopathy, sternal tenderness, retinal hemorrhages, and infiltration of gingivae, skin, soft tissues, lungs, or meninges (more common in AML with monocytic differentiation). Disseminated intravascular coagulopathy (DIC) with bleeding diathesis is a common presentation in APL.

DIAGNOSIS AND CLASSIFICATION

The diagnosis of AML is typically defined as the presence of 20% or more myeloid blasts in the bone marrow or peripheral blood in accordance with World Health Organization (WHO) classification criteria (Table 2–1).[10] AML subtypes in the WHO classification are defined on the basis of morphology, immunophenotype, and molecular or genetic features. In some patients, AML presents as a mass in extramedullary tissues (myeloid sarcoma). Patients who have the "AML-defining" cytogenetic abnormalities t(8;21)(q22;q22), inv(16)(p13q22) or t(16;16)(p13;q22), and t(15;17)(q22;q12) are diagnosed with AML regardless of the blast percentage.

Bone marrow sampling is essential for the initial workup of a patient with suspected acute leukemia. Sampling should include a core (trephine) biopsy as well as aspiration material. The core biopsy is used to perform touch preparations, which are invaluable in

Table 2–1 Acute Myeloid Leukemia and Related Precursor Neoplasms and Acute Leukemias of Ambiguous Lineage

Myeloproliferative neoplasms (MPN)
- Chronic myeloid leukemia (CML), BCR-ABL11
- Chronic neutrophilic leukemia (CNL)
- Polycythemia vera (PV)
- Primary myelofibrosis (PMF)
- PMF, prefibrotic/early stage
- PMF, overt fibrotic stage
- Essential thrombocythemia (ET)
- Chronic eosinophilic leukemia, not otherwise specified (NOS)
- MPN, unclassifiable

Mastocytosis

Myeloid/lymphoid neoplasms with eosinophilia and rearrangement of
- PDGFRA, PDGFRB, or FGFR1, or with PCM1-JAK2
- Myeloid/lymphoid neoplasms with PDGFRA rearrangement
- Myeloid/lymphoid neoplasms with PDGFRB rearrangement
- Myeloid/lymphoid neoplasms with FGFR1 rearrangement
- Provisional entity: Myeloid/lymphoid neoplasms with PCM1-JAK2

Myelodysplastic/myeloproliferative neoplasms (MDS/MPN)
- Chronic myelomonocytic leukemia (CMML)
- Atypical chronic myeloid leukemia (aCML), BCR-ABL12
- Juvenile myelomonocytic leukemia (JMML)
- MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T)
- MDS/MPN, unclassifiable

Myelodysplastic syndromes (MDS)
- MDS with single lineage dysplasia
- MDS with ring sideroblasts (MDS-RS)
- MDS-RS and single lineage dysplasia
- MDS-RS and multilineage dysplasia
- MDS with multilineage dysplasia
- MDS with excess blasts
- MDS with isolated del(5q)
- MDS, unclassifiable
- Provisional entity: Refractory cytopenia of childhood

Myeloid neoplasms with germ line predisposition

Acute myeloid leukemia (AML) and related neoplasms

AML with recurrent genetic abnormalities
- AML with t(8;21)(q22;q22.1);RUNX1-RUNX1T1
- AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22);CBFB-MYH11
- APL with PML-RARA
- AML with t(9;11)(p21.3;q23.3);MLLT3-KMT2A
- AML with t(6;9)(p23;q34.1);DEK-NUP214
- AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); GATA2, MECOM
- AML (megakaryoblastic) with t(1;22)(p13.3;q13.3);RBM15-MKL1
- Provisional entity: AML with BCR-ABL1
- AML with mutated NPM1
- AML with biallelic mutations of CEBPA
- Provisional entity: AML with mutated RUNX1

AML with myelodysplasia-related changes

Therapy-related myeloid neoplasms

AML, NOS
- AML with minimal differentiation
- AML without maturation
- AML with maturation
- Acute myelomonocytic leukemia
- Acute monoblastic/monocytic leukemia
- Pure erythroid leukemia
- Acute megakaryoblastic leukemia
- Acute basophilic leukemia
- Acute panmyelosis with myelofibrosis

Myeloid sarcoma

Myeloid proliferations related to Down syndrome
- Transient abnormal myelopoiesis (TAM)
- Myeloid leukemia associated with Down syndrome

Blastic plasmacytoid dendritic cell neoplasm

Acute leukemias of ambiguous lineage
- Acute undifferentiated leukemia
- Mixed phenotype acute leukemia (MPAL) with t(9;22)(q34.1;q11.2); BCR-ABL1
- MPAL with t(v;11q23.3); KMT2A rearranged
- MPAL, B/myeloid, NOS
- MPAL, T/myeloid, NOS

B-lymphoblastic leukemia/lymphoma
- B-lymphoblastic leukemia/lymphoma, NOS
- B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities
- B-lymphoblastic leukemia/lymphoma with t(9;22)(q34.1;q11.2);BCR-ABL1
- B-lymphoblastic leukemia/lymphoma with t(v;11q23.3);KMT2A rearranged
- B-lymphoblastic leukemia/lymphoma with t(12;21)(p13.2;q22.1); ETV6-RUNX1
- B-lymphoblastic leukemia/lymphoma with hyperdiploidy
- B-lymphoblastic leukemia/lymphoma with hypodiploidy
- B-lymphoblastic leukemia/lymphoma with t(5;14)(q31.1;q32.3) IL3-IGH
- B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3);TCF3-PBX1
- Provisional entity: B-lymphoblastic leukemia/lymphoma, BCR-ABL1–like
- Provisional entity: B-lymphoblastic leukemia/lymphoma with iAMP21

T-lymphoblastic leukemia/lymphoma
- Provisional entity: Early T cell precursor lymphoblastic leukemia
- Provisional entity: NK cell lymphoblastic leukemia/lymphoma

NK, natural killer.

case of a dry tap. The aspiration material is typically used to prepare a clot and aspirate smears, in addition to having portions submitted for flow cytometry, cytogenetics, and molecular diagnostics. Wright-Giemsa–stained aspirate smears or touch preparations are evaluated, and the percentage of blasts is determined through a 500-cell manual differential count.

Confirmation of myeloid lineage is commonly accomplished using flow cytometry immunophenotyping. In most AML cases, blasts express one or more markers of immature hematopoietic precursors such as CD34, CD117, and HLA-DR, in addition to dim CD45 (common leukocyte antigen). Myeloid lineage is predicated on the expression of antigens associated with granulocytic, monocytic, erythroid, and/or megakaryocytic differentiation by blasts (Table 2–2). Expression of myeloperoxidase (MPO) is considered specific for myeloid differentiation, although AML blasts may lack MPO expression. Although aberrant expression of lymphoid antigens is commonly seen in some cases with a bona fide AML phenotype, such expression is generally limited to one or a few lymphoid antigens. Acute leukemia with ambiguous lineage is beyond the scope of this discussion; briefly, it refers to acute leukemia with overlapping expression of myeloid and lymphoid antigens or lack of both.

Molecular diagnostics play a critical role in the laboratory workup of AML. Whereas the scope of known molecular alterations in AML was limited until a few years ago, the advent of NGS has dramatically increased our understanding of the molecular landscape of AML. As a result, the limited number of polymerase chain reaction (PCR)–based assays that used to be performed during AML workup have now been largely replaced by NGS-based panels that simultaneously assess the mutation status of tens to hundreds of genes. The current NGS mutation panel for new and relapsed myeloid malignancies used at our institution assesses the coding sequences of the 81 genes listed in Table 2–3.

RISK STRATIFICATION OF ACUTE MYELOID LEUKEMIA

After a diagnosis of AML has been made, risk stratification is the critical next step to determine therapy, prognosis, and longer-term management. Several variables are predictive of outcome, including patient-related variables, such age and performance status, as well as disease-related predictors, such as cytogenetic and molecular characteristics.

TABLE 2–4 Risk Stratification of Acute Myeloid Leukemia European LeukemiaNet Criteria, 2017

ELN	Genetic Abnormality
Favorable	t(8;21)(q22;q22), inv(16)/t(16;16)(p13;q22), *NPM1*-mutated and *FLT3*-ITD-wild type (normal karyotype) or *FLT3*-ITD mutated (low allelic ratio), mutated *CEBPα* (normal karyotype)
Intermediate	*NPM1*-mutated and *FLT3*-ITD mutated (high allelic ratio[a]) *NPM1*-wild type and *FLT3*-ITD mutated (low allelic ratio) *NPM1*-wild type and *FLT3*-ITD wild type Cytogenetics that are neither favorable nor adverse t(9;11)(p21.3;q23.3); *MLLT3-KMT2A*
Adverse	inv(3)/t(3;3)(q21;q26); t(6;9)(p23,q34); t(v;11q23.3), *KMT2A* rearranged; t(9;22) BCR-ABL; -5 or del(5q); -7; abnl(17p); complex karyotype; monosomal karyotype; NPM1-wildtype and FLT3-ITD (high allelic ratio); RUNX1, ASXL1, TP53 mutations

[a]Low allelic ratio is <0.5; high allelic ratio is ≥0.5.
Abn, abnormal; ELN, European LeukemiaNet; inv, inversion

The karyotype remains one of the best predictors of outcome in patients with AML. The European LeukemiaNet (ELN) guidelines have proposed a risk-stratification system based on cytogenetics and molecular analysis.[1] As listed in Table 2–4, patients are classified as having favorable-, intermediate-, or unfavorable-risk disease. A limitation of the current ELN classification system is that it takes into account only a few of the commonly mutated genes for prognostication. As more validated data on other mutations and co-mutations become available, a more expansive prognostication system may help refine risk stratification. For example, it is known that the favorable prognosis attributed to mutant *CEBPA* is true in cases of biallelic *CEBPA* mutation rather than the monoallelic mutation.[11] In patients with *FLT3*-wild-type/*NPM1*-mutated AML, *DNMT3A* assessment is of importance. Loghavi et al[12] showed that in patients with karyotypically normal AML with *NPM1* mutations, the presence of concurrent *DNMT3A* mutation has an adverse effect on outcomes, with the effect being more detrimental than either *FLT3-ITD* or *FLT3-TKD* mutations. This analysis demonstrated that in patients with de novo karyotypically normal AML, particularly those younger than 60 years old, patients with AML$^{DNMT3A/FLT3/NPM1}$ (sometimes referred to as triple-positive) seem to have the worst clinical outcomes followed by those with AML$^{FLT3/DNMT3A}$ and then those with AML$^{NPM1/DNMT3A}$.[12] Currently, normal karyotype AML patients with *NPM1*-mutated/*FLT3*-wild-type disease are considered favorable risk according to the ELN guidelines.

The presence of *TP53* mutations is associated with a poor outcome.[13] A recent report by German and Austrian investigators indicated that the outcome of patients with *TP53* mutations is worse than that of patients with the monosomal karyotype known to be an adverse prognostic indicator.[14] In this study, the analysis showed that the *TP53* mutation was commonly associated with older patients and a monosomal karyotype and correlated with a low complete remission (CR) rate and shorter relapse-free survival (RFS), event-free survival (EFS), and overall survival (OS). On multivariate analysis, *TP53* mutations were associated with the worst prognosis.[14] We recently reported the importance of *TP53* variant allelic frequency in determining outcome to various intensities of therapy.[15]

Several novel molecular aberrations, including mutations of the *DNMT3A*, *TET2*, *MLL*, and *PHF6* genes, have been described, particularly in patients with a normal karyotype.[16] However, their utility in current clinical practice remains limited, and they have limited value in determining best treatment strategies for patients. However, the presence of other mutations such as *RUNX1* and *ASXL1* has been recognized to have an adverse prognostic impact as reported in the revised version of ELN classification.

TREATMENT OF ACUTE MYELOID LEUKEMIA

In the 1960s, Freireich et al[17] demonstrated the significance of achieving a CR to improve survival. Since then, the objective of therapy has been to produce and maintain CR, the only currently accepted approach to AML cure. Criteria for CR have been defined by the International Working Group and are followed in the clinic and in clinical trials for response assessment.[1,18] After 3 years in CR, the probability of AML recurrence declines sharply to less than 10%,[19] and patients in continuous CR for 3 or more years can be considered "potentially cured." However, the definition of CR is an arbitrary one, signaling control of the disease burden and recovery of spontaneous hematopoiesis; with improved technology,

the precision for detection of residual disease after the initial therapy has increased prompting the addition of minimal residual disease (MRD) status to the definition of CR (ie, CR with or without detectable MRD). The persistence of MRD after remission induction and consolidation has important implications on risk of relapse as well as indications for and success of allogeneic stem cell transplant (allo-SCT).[20] Whether the improved detection and application of novel strategies to eradicate the residual leukemia will translate to improved cure rates is the subject of ongoing and future trials.

After AML is diagnosed, the need for emergency therapy must be assessed. Emergency treatment is required (1) in cases of APL, (2) in cases of circulating blast count greater than 50 to 100 × 10^9/L or rapid rate of proliferation, and (3) in the presence of DIC or organ dysfunction (especially pulmonary) attributed to leukemic infiltration (mostly seen in patients with >10 × 10^9/L circulating blasts and/or M4 or M5 French-American-British [FAB] morphology). In the latter situation, it is important to initiate immediate chemotherapy. Leukapheresis for severe leukocytosis and/or leukostasis should also be considered,[21] although a number of studies have suggested that this has limited value on long-term outcome. In patients presenting with low WBC counts, several studies have demonstrated that initiation of therapy can be delayed for several days until all the necessary diagnostic information is available,[22] however, this delay should be as short as possible.

At the University of Texas MD Anderson Cancer Center (MDACC), most patients are enrolled in clinical trials, if eligible. Urgent cytoreductive therapy is given when needed, with clinical trials designed to accommodate and expressly allow emergent chemotherapy before enrollment. The therapy is tailored to the individual patients' characteristics, including their pretreatment cytogenetic and molecular profiles. We discuss here the therapies for the various patient groups with AML.

INDUCTION THERAPY IN ACUTE MYELOID LEUKEMIA

Conventional treatment for AML with intensive chemotherapy, divided into remission induction and postremission therapy, has been with combinations of anthracyclines and cytarabine (ara-C).

Anthracyclines and Cytarabine

At MDACC, young patients (younger than 60 years old) with AML are treated with a core backbone of idarubicin (IDA) plus cytarabine-based regimens. The dosage of IDA is 10 to 12 mg/m^2 for 3 days, and ara-C is given at a dosage ranging from 1 to 2 g/m^2 for 4 to 5 days (IA). An alternative used by many cooperative groups and in the community is the "3 + 7 regimen," in which the anthracycline (ie, IDA or daunorubicin [DNR]) is usually given daily for 3 days and ara-C is given at a lower dosage of 100 to 200 mg/m^2 daily for 7 days by continuous infusion. Based on evidence of synergy, a second nucleoside analogue such as fludarabine, clofarabine, or cladribine has been added to the IA backbone (discussed in detail later).

In clinical practice, a bone marrow aspirate is usually obtained 2 to 3 weeks after beginning therapy. A biopsy is needed only if the quality of the aspirate does not permit determination of cellularity. If the day 21 marrow is hypoplastic, therapy is usually delayed until count recovery (in the case of remission) or until it is clear that there is persistence of leukemia, at which time the second course begins. A second repeated course of induction therapy can produce remissions in a subset of patients, but these are usually of shorter duration than remissions produced after one course of therapy. The timing of a second course with persistent AML is controversial. Several cooperative groups advocate starting a second course if there is persistent AML on days 10 to 15 of chemotherapy. With high-dose ara-C (HDAC), a delay of a second course with persistent disease on days 21 to 28 may be indicated if the blasts are decreasing because most (90%) CRs are obtained after the first course and response to a second course is poor. It is important to recognize that the initial marrow obtained after a period of hypoplasia may occasionally demonstrate a higher percentage of blasts, sometimes as high as 30% to 40%, as a reflection of the regeneration of normal, not "leukemic," marrow elements while peripheral blood counts are recovering. In this circumstance, follow-up (eg, at 1- to 2-week intervals) marrows may show sequential reduction in blast percentages concomitant with a rise in neutrophils and platelets.[23] Detection of persistent cytogenetic or pretreatment clonal abnormalities in the blasts can help distinguish disease-related versus healthy regenerating blasts. Such a distinction can also be achieved using flow cytometry immunophenotyping in specialized centers.

Typically, when in remission after treatment with the induction course, patients receive postremission consolidation therapy, with the same drugs administered at approximately monthly intervals for 4 to 6 months. After sufficient consolidation therapy, patients may be referred for allo-SCT or be offered long-term maintenance therapy.

Choice of Anthracyclines

Randomized trials have attempted to identify the superior anthracycline (eg, IDA, DNR, mitoxantrone [MTZ], aclarubicin).[24] In a three-arm randomized

study comparing DNR, IDA, and MTZ as part of the induction regimen for older patients, there was no advantage for any one arm.[25] In contrast, in a three-arm randomized trial conducted by the European Organization for Research and Treatment of Cancer (EORTC) and Italian Group for Hematological Diseases in Adults (GIMEMA) comparing the same three agents, the 5-year disease-free survival (DFS) and OS were significantly better for patients receiving IDA and MTZ (P = .03 and .02, respectively). The recovery time was longer with IDA and MTZ (P <.0001).[26] A study by Pautas and colleagues[27] randomized 468 patients to either DNR 80 mg/m^2 daily for 3 days versus IDA 12 mg/m^2 daily for 3 or 4 days combined with standard-dose cytarabine. Three days of IDA resulted in a higher CR rate (83% vs 70%; P = .007) and a trend for better 4-year EFS (21% vs 12%) and survival (32% vs 23%) rates, with no additional benefit seen with 4 days of IDA. Gardin et al[28] analyzed pooled data from trials conducted in patients with AML who were age 50 years of age or older. These trials compared the efficacy of IDA versus DNR in induction and consolidation. They assessed the outcomes of these patients and showed that IDA resulted in a higher CR rate of 69% (vs 61% with DNR; P = .02) but did not lead to superior OS (median OS, 14.2 months; P = .13).[28]

Different doses of DNR have been evaluated in several trials, combined with standard-dose ara-C (SDAC; 100 or 200 mg/m^2 daily for 7 days). Two studies showed that using DNR 90 mg/m^2 had better outcomes than DNR 45 mg/m^2 regardless of age. Both studies showed higher CR rates and OS in patients receiving a higher dose of DNR, without any additional toxicity. The beneficial effect was mostly seen in patients younger than 50 years old and with more favorable cytogenetics.[29,30] More recently, a French group also showed that DNR 60 mg/m^2 had similar relapse rate, RFS, and OS compared with DNR 90 mg/m^2.[31]

Although there is not a clear survival advantage with IDA over DNR, CR rates and RFS favor the use of IDA, with a trend for OS advantage. Based on these data, at MDACC, IDA is the preferred anthracycline of for intensive induction therapy.

CPX-351

CPX-351 is a liposomal formulation for delivery of ara-C and DNR preferentially to leukemic cells. In this formulation, ara-C and DNR are encapsulated in a 5:1 fixed molar ratio that was found to be consistently synergistic in vitro. A multicenter, open-label, phase II study was conducted across 18 centers in the United States in the first-line setting. Patients older than 60 years old with de novo AML were randomized to receive the CPX-351 versus the 7 + 3 regimen. Higher response rates were noted with CPX-351, with an overall response rate (ORR) of 66.7% (vs 57.6%; P = .06). Improvements in the median OS (14.7 months vs 12.9 months) and EFS (6.5 months vs 2 months) were noted in the CPX-351 cohort.[32] Based on these data and a significant signal of efficacy in secondary AML, a randomized phase 3 trial was conducted in patients with newly diagnosed secondary AML. Among 309 patients randomized to CPX-351 versus the 3 + 7 regimen, CPX-351 was associated with a significantly improved OS compared with the 7 + 3 regimen(9.56 vs 5.95 months; hazard ratio [HR], 0.69;P = .005). The CR rate was 38% with CPX-351 versus 26% with the 3 + 7 regimen(P = .035), and the CR + complete response with incomplete hematologic recovery (CRi) rate was 48% versus 33% (P = .016).[33] CPX-351 was well tolerated and associated with lower induction morality but was associated with more prolonged myelosuppression compared with the 7 + 3 regimen. More of the patients achieving CR after CPX-351 were able to undergo later allo-SCT (20% vs 12%); their survival was also longer after SCT. This pivotal study was the basis for Food and Drug Administration (FDA) approval of CPX-351 as frontline therapy for patients with secondary AML. Combinations using CPX-351 as a new backbone for AML therapy, including gemtuzumab, venetoclax, IDH inhibitors, and FLT3 (fms-like tyrosine kinase 3) inhibitors are being investigated.

High-Dose Cytarabine

Several randomized trials have assessed the efficacy of HDAC (1–3 g/m^2) versus SDAC (100–200 mg/m^2) for induction therapy. The Cancer and Leukemia Group B (CALGB) and the Eastern Cooperative Oncology Group (ECOG) restricted their analysis to patients in CR, whereas the SWOG compared HDAC with SDAC during induction and randomized SDAC patients to SDAC or HDAC when the patients were in CR.[34] Finally, the Australian Leukemia Study Group (ALSG) randomized patients to HDAC or SDAC during induction only (Table 2–5).[35] These trials concluded that (1) the toxicity of HDAC (eg, cerebellar) outweighs the anti-AML effect in patients older than 65 years; (2) patients older than 60 years benefit from HDAC given during induction (SWOG, ALSG), in CR (CALGB, ECOG), and perhaps both (SWOG); and (3) HDAC potentially increases the cure rates to 70% to 80% in patients with inversion 16 or t(8;21) and to 30% to 40% in patients with normal karyotype, but little, if at all, in patients with adverse karyotypes. In a meta-analysis of three trials in 1691 patients, induction with HDAC was compared with SDAC. Although there was no difference in CR rates, the 4-year RFS (P = .03), 4-year OS (P <= .0005), and 5-year EFS (P <.0001) were better with HDAC.[36]

TABLE 2–5 Standard versus High-Dose Cytarabine (HDAC) in Patients with Newly Diagnosed Acute Myeloid Leukemia

Study	HDAC During:	Patients (*n*)	Beneficial Effect of HDAC
ALSG	Induction	279	CR duration
SWOG	Induction, consolidation, or both	723	EFS
ECOG	Consolidation	170	If age younger than 60 years
CALGB	Consolidation	596	If age younger than 60 years

ALSG, Australian Leukemia Study Group; CALGB, Cancer and Leukemia Group B; CR, complete response; EFS, event-free survival; ECOG, Eastern Cooperative Oncology Group.

A group of more recent randomized studies, in the era of modern supportive care, looked to reexamine the utility of higher dose cytarabine during AML induction and reported some nuanced results. Lowenberg et al[37] randomized 858 patients with a median age of 49 years to induction therapy with IDA combined with either high-dose cytarabine 1g/m^2 every 12 hours for 10 versus standard-dose cytarabine given at 200 mg/m^2 daily for 7 days. The study found no difference in rate CR, EFS, or OS between the two arms. Further examination of the treatment plan design reveals that all patients in both arms received high-dose cytarabine during cycle 2 of therapy, confounding the results and failing to have a clear comparison between higher or standard-dose cytarabine. The EORTC-GIMEMA cooperative group compared HDAC with standard-dose cytarabine in a backbone combining DNR and etoposide.[38] Among 1942 patients aged 60 years or younger, they found significantly higher rates of CR (82% vs 76%), rates of 6-year EFS (44% vs 35%), and OS (52% vs 43%) in patients receiving HDAC-based induction. These benefits were seen primarily and significantly in patients younger than 46 years of age, but there was only a trend for OS improvement in those aged 46 to 60 years.[38] Finally, Bassan et al[39] randomized 574 patients with a median age of 52 years to IDA + etoposide + standard-dose cytarabine or IDA plus sequential high-dose cytarabine. The sequential high-dose cytarabine arm was associated a higher CR rate after one course (81% vs 69%; $P = .0007$) and a significantly improved the 5-year survival rate (49vs versus 39%; $P = .045$). Our current approach at MDACC, therefore, is the incorporation of higher dose cytarabine during induction and consolidation for intensive regimens.

Gemtuzumab Ozogamicin

Gemtuzumab ozogamicin (GO) is a CD33-targeted immunoconjugate linking an anti-CD33 antibody to calicheamicin. It received an accelerated approval by the FDA for use in older adults with relapsed or refractory AML but was withdrawn voluntarily by the manufacturer from the market in 2010 because of toxicity concerns. However, in a trial by the French Leukemia Association, patients aged 50 to 70 years with previously untreated de novo AML were randomized to receive standard chemotherapy with the 7 + 3 regimen (DNR, ara-C) with or without GO. Gemtuzumab was administered in fractionated doses. The ORR was 81%. The OS (34 months vs 19 months; $P = .036$), EFS (15.6 months vs 9.7 months; $P = .0003$), and RFS (28 months vs 11 months; $P = .0003$) were significantly better in the GO group.[40] Another study by the Medical Research Council (MRC) in the United Kingdom showed a benefit for the addition of GO to ara-C and anthracycline-based induction regimen.[41] A recent meta-analysis examined five randomized trials in untreated patients with AML demonstrated that the addition of GO to frontline therapy of AML led to a significantly reduced risk of relapse and improved 5-year OS.[42] This was most evident in patients with favorable- and intermediate-risk cytogenetics but not in those with adverse karyotype. These data suggest utility of GO in patients with AML, supporting the recent re-approval of GO by the FDA.

TREATMENT OF YOUNGER PATIENTS WITH ACUTE MYELOID LEUKEMIA

Purine Analogues

The addition of the purine analogues clofarabine, cladribine, and fludarabine to cytarabine and anthracyclines has been associated with improved outcomes in a number of studies. Based on work by Plunkett and Gandhi,[43–48] the addition of a second nucleoside analogue such as fludarabine, cladribine, or clofarabine functioned as a potent inhibitor of ribonucleotide reductase, increased intracellular cytarabine concentration, and led to synergistic activity against leukemic blasts. Our frontline intensive induction therapy has evolved to incorporate a second nucleoside analogue (fludarabine, clofarabine, or cladribine) along with a lower dose of cytarabine (1–2 g/m^2) to optimize the balance of synergy and reduced extramedullary toxicity.[49]

Fludarabine, Idarubicin, and Cytarabine

The first translation of this preclinical work into the clinic was the combination of fludarabine, high-dose cytarabine, and IDA (FLAG-IDA or FIA), developed at MDACC for patients with AML.[43,50] The regimen has since been used internationally and forms a standard backbone for patients with newly diagnosed as well as relapsed AML. The MRC of the United Kingdom has published several analyses of the AML 15 randomized trial studying FLAG-IDA in younger patients with AML compared with 3 + 7 regimens without or with etoposide.[41,51,52] The FLAG-IDA regimen (cytarabine 2 g/m^2 on days 1–5, fludarabine 30 mg/m^2 on days 1–5, and IDA 8–10 mg/m^2 on days 1–5), among patients who were able to receive four courses, was associated with an improved 8-year survival rate of 66% compared with 47% in the standard arm.

Clofarabine, Idarubicin, and Cytarabine

Clofarabine is a second-generation nucleoside analogue that has activity in adult patients with AML. A phase I trial of clofarabine conducted at MDACC, in combination with IDA alone versus IDA and ara-C (CIA) in patients with relapsed, refractory AML showed a CR rate of 13% versus 48%, respectively. The median duration of remission was also longer with the CIA combination (15 months) compared with clofarabine and IDA (4.5 months).[53] This was followed by a phase II trial that investigated the CIA regimen in patients 60 years old or younger with newly diagnosed AML. Patients who achieved a response (CR or CRp) went on to receive up to six cycles of consolidation therapy. The cycles were administered every 4 to 6 weeks. All patients received prophylactic antibiotics, antifungals, and antivirals. The median age of the patients was 48 years (range, 19–60 years), 66% had intermediate-risk cytogenetics, and 36% had diploid and 34% adverse karyotype. The ORR was 79%, with 74% CR and 3% CRp. Eighteen percent of patients received two induction cycles to achieve a CR or CRp, and 42% went on to receive an allo-SCT in first CR. The median OS and RFS were not reached, whereas the median EFS was 13.5 months. A subset analysis showed better OS (P = .04) and EFS (P = .04) in patients 40 years old or younger compared with those older than 40 years.[54]

Cladribine

Holowiecki et al[55] conducted a randomized phase III trial evaluating the addition of cladribine or fludarabine to DNR/ara-C in younger patients with untreated AML. A total of 652 patients, with a median age of 47 years (range, 17–60 years), were randomized to receive DNR plus ara-C (DA), DA plus cladribine (DAC), and DA plus fludarabine (DAF). The consolidation regimen was the same for all arms and included two consecutive courses of ara-C (1.5 g/m^2 intravenously [IV] days 1–3) plus MTZ (10 mg/m^2 IV days 3–5) and HDAC (2 g/m^2 IV twice a day on days 1, 3, and5). The overall CR rate was 61%, with 56% achieving a CR after one cycle of induction and 5% after two cycles. The CR rate was higher in the DAC arm compared with the DA arm (62% vs 51%; P = .02). The CR rates were similar in the DA and DAF arms. The median OS was significantly higher in the DAC arm (24 months) compared with the DA arm (14 months; P = .02). There was no significant difference in the median OS between the DAF and DA arms.[55]

Based on these data, we designed a higher-dose cytarabine-based combination of cladribine (5 mg/m^2 IV on days 1–5), IDA (10 mg/m^2 IV on days 1–3), and cytarabine (1 g/m^2 IV on days 1–5) (CLIA) for patients with AML. In a recent update of our data with CLIA in 73 fit patients with newly diagnosed AML, we observed a CR/CRi rate of 76% with 58% of patients having undetectable MRD at the time of response.[56] The median OS and DFS were 21.9 months and none reached, respectively. Based on these promising results and tolerability, CLIA currently forms our frontline backbone for younger and fit patients with AML.

TREATMENT OF PATIENTS 60 YEARS OF AGE OR OLDER

AML in older adults (60 years or older) is considered a biologically and clinically distinct entity. The outcomes of older AML patients are poor with the standard anti-AML therapies. The analysis of the Swedish Acute Leukemia Registry (1976–2005) showed that the early death rates in all patients with AML, regardless of age, were lower with intensive therapy compared with palliative therapy.[57] However, most older patients may not be ideal candidates for intensive chemotherapy because of disease- and patient-related factors. Newer, lower intensity therapies with less toxicity and preserved efficacy are being developed to help address this challenging subset.

AML in older adults has adverse biologic features such as higher frequency of stem cell–like phenotype of leukemic blasts, higher frequency of multilineage involvement with dysplastic features, higher frequency of antecedent hematologic disorders, and higher frequency of *MDR-1* gene expression, which leads to higher potential for cytotoxic drug extrusion by the leukemic blasts, causing resistance to chemotherapeutic agents.[58] AML in older patients is more frequently associated with poor-risk cytogenetics (≤50% vs 10%–15% in younger patients).[59] Given the poor outcomes associated with standard therapy in these high-risk

subgroups, most older patients with newly diagnosed AML should be considered for investigational clinical trials. Other factors contributing to worse outcomes in older patients include poor performance status, organ dysfunction, and a higher incidence of an antecedent hematologic disorders. In general, patients with three or more of these factors have expected CR rates of less than 20%, 8-week mortality rates greater than 50%, and 1-year survival rates of less than 10% using conventional regimens. These patients constitute 25% to 30% of older adult patients with AML. Approximately 20% of older adult patients have none or one of these adverse factors and have a reasonable outcome with expected CR rates above 60%, 8-week mortality rates of 10%, and 1-year survival rates of 50% or greater.[60] Several groups have proposed predictive models for geriatrics assessment before determining what therapy to assign older patients.[61,62] These models look at several prognostic factors, including functional status, cytogenetics, age, and molecular status, to predict mortality and survival with therapy. This suggests that a careful assessment of the patient and disease characteristics is needed before assigning therapy to older patients.

Low-Dose Cytarabine

Low-dose ara-C (LDAC) was superior to hydroxyurea in a randomized trial enrolling 204 older adult patients with AML considered unfit for chemotherapy.[63] The CR rates were 15% with LDAC and 1% with hydroxyurea (P = .0003); the 1-year survival rates were 27% versus 3% (P = .0004). Although the responses were modest and not widely used in clinical practice as a single-agent, this trial confirmed the benefit of *treating* older patients with newly diagnosed AML rather than considering only supportive care.

Clofarabine

A randomized phase II study compared clofarabine (30 mg/m^2 IV × 5 days) versus clofarabine and ara-C (20 mg/m^2 subcutaneously daily × 14 days) in 70 older adult patients with AML.[64] Combination therapy achieved a better CR (63% vs 31%; P = .025) and better EFS (7.1 months vs 1.7 months; P = .04) but did not improve OS (11.4 months vs 5.8 months; P = .1).

Hypomethylating Agents

Building on their activity in myelodysplastic syndrome, hypomethylating agents (HMAs) such as decitabine (DAC) and 5-azacitidine (5-AZA) have been studied in and become the de facto lower intensity therapy for older and unfit patients with newly diagnosed AML. Kantarjian et al[65] conducted a randomized phase III trial comparing DAC 20 mg/m^2 for 10 days with physician's choice in 485 patients. This study showed that DAC improved CR/CRp rates compared with physician's choice (18% vs 8%; P = .001). DAC was well tolerated with a good safety profile. The primary analysis showed a nonsignificant improvement in the OS, but an unplanned analysis 2 years later demonstrated an improvement in the OS AML who are older than 65 years old have an ORR of 47% (CR rate, 42%) with intensive chemotherapy and an ORR of 29% (CR rate, 28%) with epigenetic therapy (azacitidine, DAC) (P ≤.001).[40] The median OS was similar in both the groups (0.5 months; P = .413).[66] These studies show that hypomethylating agents have similar survival outcomes in older patients with AML compared with intensive chemotherapy.

In the AML-AZA 001 trial, patients 65 years of age or older with newly diagnosed de novo or secondary AML who were deemed ineligible for transplant and with intermediate- or poor-risk cytogenetics were enrolled. Patients were randomized to receive either azacitidine or a conventional care regimen. Azacitidine was administered at 75 mg/m^2/day for 7 days subcutaneously. A prolongation in the median OS was observed in the azacitidine arm (6.4 months vs 3.2 months; P = .0185). The conventional care regimen included best supportive care in 18%, LDAC in 64%, and intensive chemotherapy in 18%.[67] Several groups have consistently shown a CR rate of 31% to 47% with DAC 20 mg/m^2 administered daily for 10 days, with a median OS of 9 to 12 months. However, the associated increased myelosuppression leads to increased rates of hospitalization for infections.[68]

Venetoclax

One of the most important advances in the treatment of AML in older and unfit patients has been the development of the BCL-2 inhibitor venetoclax in this disease. Based on the observation of modest single-agent activity in AML,[69] venetoclax was studied in combination with lower intensity (HMA or LDAC) in older and unfit patients with newly diagnosed AML. Single-arm phase Ib/II studies of venetoclax in combination with either HMA or LDAC demonstrated ORRs of 54% to 68% and median OS ranging from 10.1 to 17.5 months, leading to the accelerated FDA approval of these combinations in November 2018. The recently reported phase III randomized VIALE-A study confirmed the OS benefit of the combination of AZA + venetoclax in older or unfit patients with newly diagnosed AML, establishing it as standard frontline therapy in this population. Among 431 patients with a median age of 76 years, AZA + venetoclax demonstrated a significant improvement in OS of 14.7 months versus 9.6 months (HR, 0.66; P <.001) compared with AZA alone.[70]

Ongoing studies in this population of patients continues to build on the backbone of HMA + venetoclax to optimize efficacy among subsets.

Cladribine + Low-Dose Cytarabine

Although HMAs have been safe and well tolerated in older patients with newly diagnosed AML, newer backbones and combinations may be developed to maintain safety and tolerability while augmenting efficacy. Based on the synergy of cladribine and cytarabine, we developed a lower intensity regimen combining cladribine (5 mg/m^2 IV on days 1–5) with LDAC (20 mg subcutaneously twice a day on days 1–10) alternating with two cycles of DAC (20 mg/m^2 IV on days 1–5). Among 118 patients with a median age of 69 years, we observed a CR/CRi rate of 68%, including a CR rate of 58%. The 4- and 8-week mortality rates were 1% and 7% , respectively.[71] With a median follow-up period of 37 months, the median OS was 13.8 months with a median DFS of 10.8 months. Although these data compare favorably with single-agent HMAs in this population, it is very similar to outcomes seen with HMA + venetoclax. Ongoing studies are evaluating the safety and efficacy of venetoclax and other targeted therapies added to the cladribine–LDAC backbone.

Targeted Therapy in Acute Myeloid Leukemia

The wider application of newer techniques in DNA NGS and a better understanding AML biology have demonstrated deep heterogeneity in AML and led to a surge in targeted therapy development for genomically defined subsets. Early detection of recurrent genetic abnormalities in newly diagnosed AML now not only help delineate prognosis but also provide opportunities for targeted therapy. Specific inhibitors have been developed and FDA approved for patients with AML.

FLT3-Mutated Acute Myeloid Leukemia

FLT3 is a member of the class III receptor tyrosine kinase family that plays an important role in the survival, proliferation, and differentiation of hematopoietic progenitor cells. *FLT3* is overexpressed in most patients with AML, and activating mutations of *FLT3* are among the most prevalent molecular abnormalities in AML, with internal tandem duplication (ITD) occurring in 25% to 35% of patients with normal karyotypes.[72] In addition, 5% to 7% of patients may have point mutations within the activation loop of the kinase domain or in the juxtamembrane domain. Patients with *FLT3* activating mutations have an inferior outcome with a shorter RFS and OS. In addition, after exposure to *FLT3* inhibitors, nearly one quarter of patients with *FLT3-ITD* develop mutations in the kinase domain as a mechanism of resistance.

Incorporation of FLT3 inhibitors into the treatment of AML is now the standard of care. Stone and colleagues conducted a randomized phase III RATIFY trial (CALGB 10603) in 717 patients younger than 60 years of age with newly diagnosed *FLT3*-mutated AML (*FLT3-ITD* and/or *FLT3-TKD*; median age, 48 years; range, 18–60 years) with the 7 + 3 regimen with or without the FLT3 inhibitor midostaurin.[73] The addition of midostaurin improved the CR rate (59% vs 54%, P = .045) and survival (median survival, 74.7 vs 25.6 months; P = .009). At MDACC, we have incorporated FLT3 inhibitors as our standard on clinical trials. In a matched-cohort analysis we similarly showed the benefit of adding the multikinase FLT3 inhibitor sorafenib to an IDA cytarabine backbone in *FLT3*-mutated AML.[74] More recently, our analysis with CLIA + FLT3 inhibitor (sorafenib–midostaurin) demonstrated a CR rate of 86% and a 1-year OS of 70%.[56] The second-generation FLT3 inhibitor gilteritinib has also been FDA approved for use in patients with relapsed or refractory FLT3-mutated AML. In the ADMIRAL study, patients with relapsed or refractory AML were randomized to either gilteritinib or one of four salvage chemotherapy regimens chosen by their doctor. Gilteritinib was associated with a higher CR rate (21.1% vs 10.5%) and a significant improvement in OS (9.3 vs 5.6 months; P = .007).[75] Studies in the frontline setting with gilteritinib and other FLT3 inhibitors in combination with intensive and lower intensity therapy are ongoing. Several new *FLT3* inhibitors currently under development.

IDH-Mutated Acute Myeloid Leukemia

Isocitrate dehydrogenase enzymes (IDH1, IDH2) play a critical role in cellular metabolism and are ubiquitously expressed. Recurrent point mutations in the *IDH1* and *IDH2* genes each occur in about 10% to 12% of AML cases, resulting in neomorphic enzyme activity and the aberrant production of the onco-metabolite 2-hydroxyglutarate (2-HG). The 2-HG competitively inhibits α-ketoglutarate and leads to dysregulated epigenetic function, a hypermethylated phenotype, and a block in maturation, contributing to AML leukemogenesis. Enasidenib is an orally bioavailable small molecule inhibitor of mutant *IDH2* that is FDA approved for the treatment of relapsed or refractory IDH2-mutated AML. A phase I/II trial of patients with relapsed or refractory IDH2-mutated AML treated with enasidenib demonstrated an ORR of 39%, a CR/CRh rate of 23%, a median response duration of 8.2 months, and a median survival period of 8.8 months.[76] Ivosidenib is a selective small molecule inhibitor of *IDH1* that is FDA approved for the treatment of relapsed or

refractory IDH2-mutated AML and recently was also approved in the frontline for patients ineligible for intensive therapy. A phase I/II clinical trial evaluating 179 patients with relapsed or refractory *IDH1* mutated reported an ORR of 42%, a CR/CRh of 30%, a CR of 22%, and a median survival period of 12 months.[77] In a phase 1 dose escalation or expansion study among older patients with newly diagnosed *IDH1*-mutated AML with a median age of 76.5 years, treatment with ivosidenib produced a CR rate of 30% and an ORR of 55%, allowing expansion of the indication to older, unfit patients with untreated disease.[78] Combinations of IDH inhibitors in the frontline and relapsed or refractory settings with chemotherapy and other targeted therapies are ongoing.

TP53-Mutated Acute Myeloid Leukemia

Mutations in *TP53* are present in 15% to 20% of patients with AML, particularly enriched among patients with therapy-related AML and complex karyotypes, and have been associated with an exceptionally adverse prognosis and poor response to intensive chemotherapy.[13] Lower intensity approaches with HMAs and other backbones have produced similar outcomes to intensive chemotherapy, with less toxicity and lower rates of early mortality.[79,80] Recent data suggest that the quantified variant allelic frequency (VAF) of mutated *TP53*, reflecting its clonal dominance within a bulk AML sample, may help predict whether intensive chemotherapy may benefit a subset of *TP53*-mutated patients. A TP53 VAF of less than 40%, for example, was associated with better outcomes when using intensive chemotherapy compared with those with a higher VAF.[15] This latter subgroup represents a challenging subset, in which there is a strong need for newer, more effective therapy. Our approach and recommendation for this subset of patients has been enrollment in clinical trials.

TREATMENT OF CORE-BINDING FACTOR ACUTE MYELOID LEUKEMIA

Core-binding factor (CBF) AML is a distinct entity. It is considered a favorable karyotype. It includes patients with a pericentric inversion of chromosome 16 (inversion 16; associated with FAB subtype M4EO) and translocation (16;16) or a translocation between chromosomes 8 and 21 (t[8;21]; associated with FAB subtype M2). Each of these abnormalities disrupts the function of a transcription factor, regulating the expression of genes important in hematopoietic differentiation: inv(16) and t(16;16) lead to the formation of the *CBF-MYH11* fusion gene, and $t^{8;21}$ leads to the formation of the *RUNX1-RUNXT1* fusion gene. The *CBF-MYH11*– and *RUNX1-RUNXT1*–related leukemias represent CBF-AML. These leukemias are chemo-sensitive to intensive induction and consolidation and are characterized by high rates of CR. About 10% of unselected newly diagnosed patients (typically younger patients) have CBF-AML. At MDACC, all newly diagnosed patients with CBF-AML are treated with fludarabine (30 mg/m^2/day on days 1–5) and HDAC (2 g/m^2/day on days 1–5) regimens with or without the addition of granulocyte colony-stimulating factor (G-CSF). This is followed by up to six courses of an HDAC-containing consolidation regimen. A CR rate of 93% and an EFS of 20 months in 114 newly diagnosed patients with CBF-AML were previously reported[52]. A frontline regimen of fludarabine, ara-C, and G-CSF (FLAG)-GO was evaluated at MDACC and showed a remission rate of 95% and a 3-year OS and RFS of 78% and 85%, respectively.[81] In the UK MRC-AML15 trial, 1113 patients with AML were randomized to receive or not receive a small dose of GO (3 mg/m^2) with their induction therapy. A benefit of adding GO to the induction regimen was seen in patients with CBF-AML.[28] In a meta-analysis of five clinical trials in which addition of GO to induction chemotherapy was evaluated, a significant improvement in OS was noted in patients with favorable- and intermediate-risk cytogenetics ($P = .01$). The improvement in survival was attributed to reduced relapse ($P = .00006$).[42] All of these studies strongly support the use of FLAG-based regimens for CBF-AML and advocate the addition of GO to the induction to improve survival and RFS in these patients.

Approximately 25% of patients with CBF-AML carry a gain-of-function mutation in the *KIT* gene, which results in a constitutively activated tyrosine kinase and an inferior outcome when using standard 7 + 3–based chemotherapy. Hence, the CALGB 10801 alliance and a group in Germany are evaluating the addition of a *KIT* inhibitor, dasatinib, to the standard induction therapy. The initial results showed a 92% CR rate and 1-year DFS and OS rates of 90% and 87%, respectively.[82] Further analysis of this data and confirmatory studies will help to better define the role of inhibiting KIT in CBF-AML.

MAINTENANCE THERAPY IN ACUTE MYELOID LEUKEMIA

Although dose intensification, novel drug combinations, and improvements in support care for have led to high response rates in newly diagnosed AML, disease relapse remains a major cause of treatment failure and mortality. Post remission consolidation with allo-SCT has been shown to improve remission duration and survival in patients with higher risk disease, but this is

not available to many patients, particularly for the older and unfit patients that make a up a large proportion of patients. Postconsolidation maintenance strategies in patients with AML have been investigated for decades, with no consistent evidence of survival benefit. Most of those strategies involved using the same or similar agents in maintenance that were used during induction and consolidation. With the discovery of new therapies with newer schedules of delivery, there has been a renewed focus to develop maintenance therapies in AML. The availability of low-dose and well-tolerated HMAs such as DAC or AZA has prompted investigation of these agents for maintenance in AML. The HOVON group conducted a randomized phase III study comparing maintenance with 5-AZA at a dosage of 50 mg/m^2 IV or subcutaneous on days 1 to 5 every 4 weeks with placebo among patients 60 years of age or older with AML in remission after two cycles of intensive chemotherapy. Among 116 patients, maintenance therapy with parenteral 5-AZA demonstrated a significant improvement in 12-month DFS compared with placebo (64% vs 42%; $P = .04$), but there was no OS benefit.[83] In the ECOG-ACRIN E2906 randomized study evaluating consolidation with clofarabine or high-dose cytarabine, a second randomization studied the utility of postconsolidation maintenance with IV DAC given at a dosage of 20 mg/m^2 IV on days 1 to 3 of a 4-week cycle. A total of 120 AML patients with a median age of 69 years who had received induction and two cycles of consolidation were randomized 1:1 to DAC or placebo. DAC maintenance was associated with an improved median OS of 25.8 versus 19.5 months (HR, 0.69 [0.43–1.09]; $P = .06$). Recently, an oral formulation of AZA, CC-486, demonstrated an OS benefit, leading to its FDA approval as maintenance therapy in AML. The international, multicenter QUAZAR AML-001 trial randomized 472 patients55 years of age or older in first CR after intensive chemotherapy, with or without consolidation to receive either CC-486 or placebo on days 1 to 14 of a 28-day cycle. CC-486 was associated with a significant improvement on median OS compared with placebo (24.7 months vs 14.8 months; $P < .001$), with 1- and 2-year OS rates of 73% and 51%, respectively.[84] Similarly, CC-486 was associated with an improvement in median RFS compared with placebo (10.2 vs 4.8 months; $P < .001$). Recent advances in the development of targeted drugs in AML has created the possibility of long-term remission maintenance with chronic dosing of small molecule targeted drugs in specific genetically determined subgroups. Demonstration of their long-term safety and tolerability has made these drugs ideal candidates for long-term ambulatory maintenance strategies. For example, the multikinase inhibitor sorafenib has been used successfully as an FLT3 inhibitor in patients with FLT3-mutated AML. The SORMAIN trial was a randomized double-blind placebo-controlled trial investigating the use of post-transplant sorafenib in patients with FLT3-mutated AML.[85] Among 83 patients randomized, with a median age of 54 years, sorafenib was associated with a significant improvement in 2-year PFS and OS in favor of sorafenib, effectively establishing this as a standard of care in the post-SCT setting in this subgroup. Similarly, the phase III ADMIRAL trial of the type I FLT3 inhibitor gilteritinib evaluated post-SCT maintenance in a nonrandomized observational manner. Among 35 patients who received post-SCT gilteritinib, there was an observed improvement in median OS of 16.2 versus 8.4 compared with patients who did not receive gilteritinib (HR, 0.39 [0.16–0.92]; $P = .024$).[75] Studies are ongoing evaluating FLT3 inhibitors, including gilteritinib, in the postconsolidation maintenance setting for FLT3-mutated AML. IDH inhibitors, including enasidenib (IDH2) and ivosidenib (IDH1), are currently approved as single agents in patients with relapsed AML with IDH2 or IDH1 mutated AML, respectively. As part of the approved treatment label, these patients are treated indefinitely with single-agent IDH inhibitor as part of the initial "induction" as well as ongoing, indefinite therapy to maintain response. They have thus demonstrated feasibility and excellent long-term tolerability in this setting. At MDACC, our approach is to design appropriate risk-adapted and genomically individualized postremission maintenance strategies for patients, including post-SCT–based maintenance in patients at high risk for relapse.

The treatment for newly diagnosed AML is summarized in Figures 2–1 and 2–2.

RELAPSED OR REFRACTORY ACUTE MYELOID LEUKEMIA

Although the outcome of patients with AML has improved, relapse remains frequent and constitutes the leading cause of death. Relapsed AML remains a major challenge with few therapies providing meaningful durable responses or cures. Breems et al[86] defined a prognostic score for patients with AML in first relapse based on the following variables: (1) relapse-free interval from first CR, (2) cytogenetics at diagnosis, (3) age at first relapse, and (4) SCT before first relapse. In an analysis of 818 patients who underwent one or more lines of salvage therapy at MDACC between 2002 and 2016, rates of CR decreased from 14% after first salvage to 9% and 3% after second and third salvage, respectively.[87] The median OS periods were 6.3, 4.07, and 2.98 months after first, second, and third salvage therapies, respectively.[87] In an updated analysis, we specifically patients treated at MDACC in the second salvage setting from 2000 to 2018 to determine factors predicting factors associated with OS and nonresponse to salvage

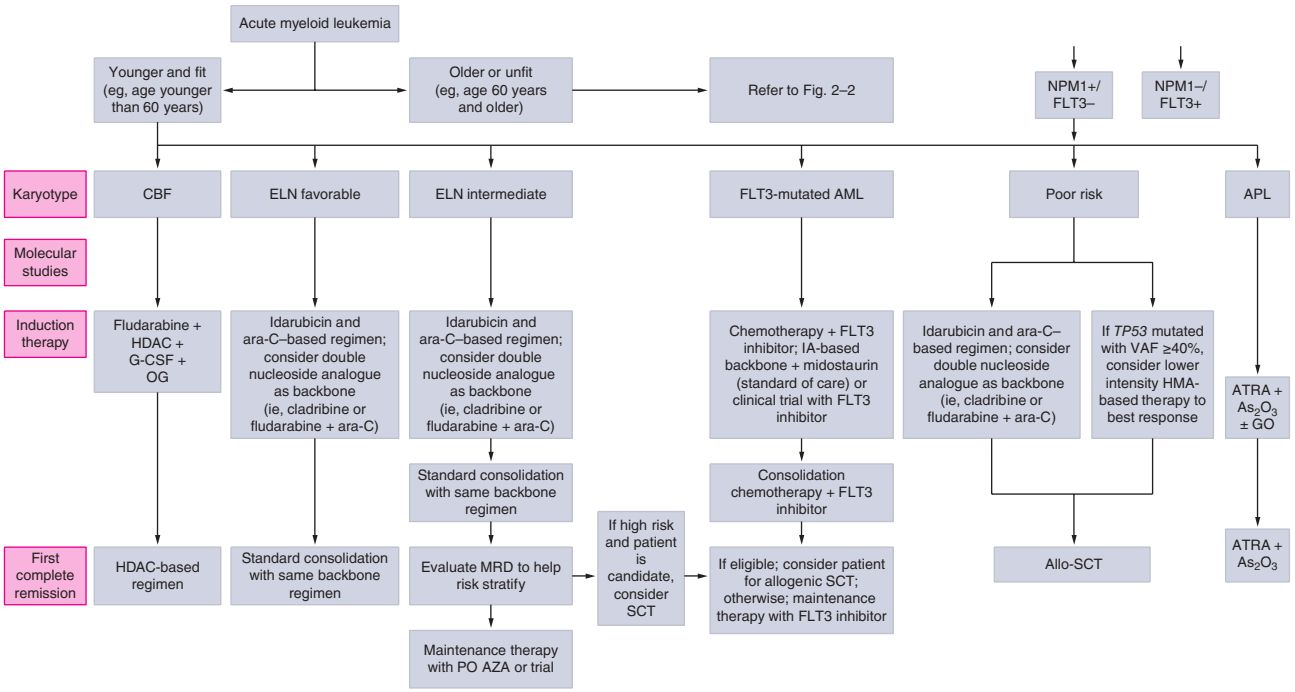

FIGURE 2–1 A proposed approach to the management of patients with newly diagnosed adult acute myeloid leukemia. allo-SCT, allogeneic stem cell transplantation; APL, acute promyelocytic leukemia; As_2O_3, arsenic trioxide; ATRA, all-*trans*-retinoic acid; CBF, core-binding factor leukemias (including inv[16], t[8;21]); FLT3, fms-like tyrosine kinase 3; G-CSF, granulocyte colony-stimulating factor; GO, gemtuzumab ozogamicin; HDAC, high-dose cytarabine; IA, idarubicin and cytarabine; MRD, minimal residual disease; NPM1, nucleophosmin; PO, oral.

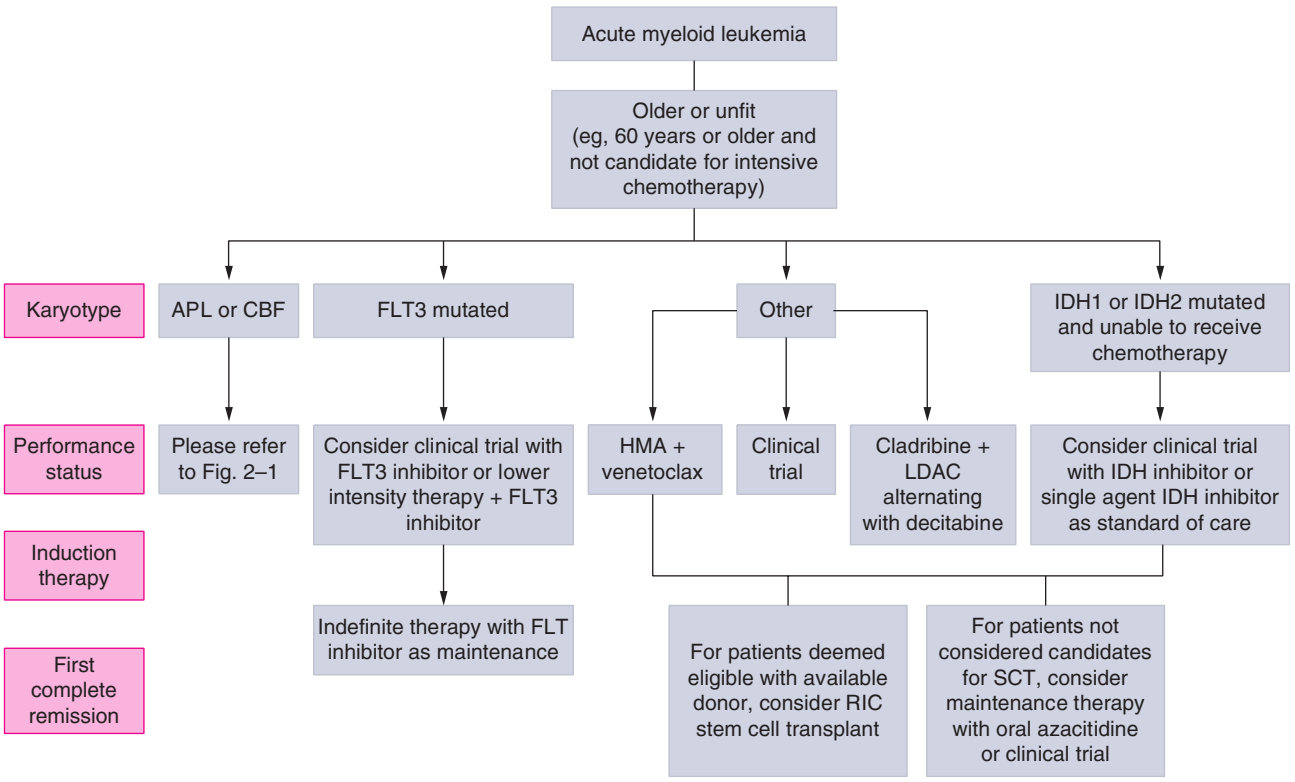

FIGURE 2–2 A proposed approach to the management of newly diagnosed adult acute myeloid leukemia in patients 60 years of age or older. therapy. By multivariate analysis, independent factors associated with worse survival were age 60 years or older, platelets less than 50, peripheral blasts 20% or greater, albumin 3 g/dL or less, and complex karyotype (three or more abnormalities). Independent factors associated with nonresponse (CR-CRp) in the second salvage setting were platelets less than 50, complex karyotype, treatment with regimens that did not include cytarabine or HMAs, and no prior CR for 12 months or longer (Fig. 2–3).[88] Recent identification and approval of targeted therapies such as FLT3 inhibitors and IDH inhibitors for specific populations in the relapsed setting have started to provide the framework for a path of how we may divide and overcome the enormous challenge of treating patients with relapsed disease.

STEM CELL TRANSPLANTATION

High-dose chemotherapy with or without radiation followed by SCT is increasingly used as therapy for AML patients in first CR. In prospective, nonrandomized trials in Europe and the United States, patients younger than age 55 years in first CR with a human leukocyte antigen (HLA)–matched sibling were assigned to allogeneic transplantation or, if no donor, to autologous transplantation or one further course of HDAC (with DNR in the European study) (Table 2–6).[89–92]

In a meta-analysis of 24 prospective clinical trials involving more than 6000 patients with AML in first CR, Koreth et al[93] showed that allo-SCT has significant

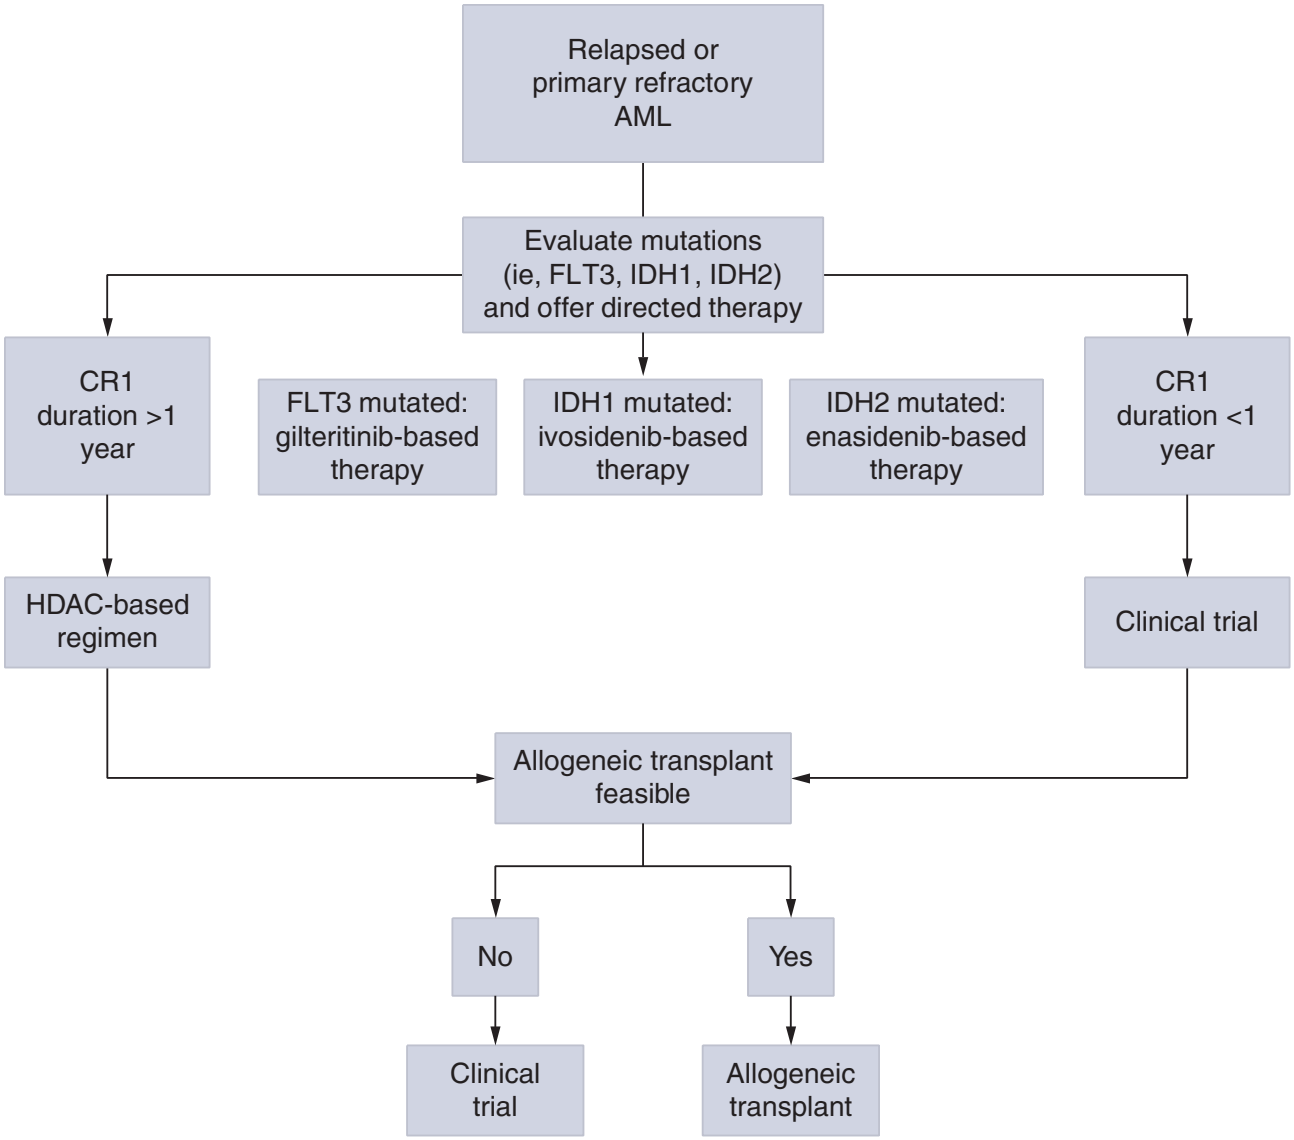

FIGURE 2–3 A proposed algorithm for management of relapsed or refractory acute myeloid leukemia (AML). CR1, first complete remission; HDAC, high-dose cytarabine.

survival benefit in patients with intermediate- and poor-risk AML but not with good-risk AML. This finding contrasts with the retrospective review of 999 patients by Ferrant et al[94] that observed similar benefit with allogeneic and autologous transplantation for patients with poor-risk karyotype and a benefit with allo-SCT only in patients with good- and intermediate-risk cytogenetics. However, further stratification of risk groups based on molecular markers within individual karyotypes suggests that only specific subsets of patients may benefit from allo-SCT . Schlenk et al[95] demonstrated superior OS with allo-SCT compared with intensive chemotherapy in only the following groups of patients with normal-karyotype de novo AML: (1) *FLT3-ITD* positive and (2) *NPM1*/*CEBPA*/*FLT3-ITD* negative. Patients with inversion 16 or t(8;21) do better with chemotherapy.[96] Patients with AML who are younger than 20 years old have a relatively low transplant-related mortality rate and may do better with allo-SCT.

New concepts in both transplantation and chemotherapy have emerged. These include the use of peripheral blood rather than marrow as the source of SCT,[97] the use of nonmyeloablative regimens to allow engraftment and take advantage of the graft-versus-leukemia effect, and the use of IV busulfan to overcome the erratic pharmacology of the oral form.[98] In particular, nonmyeloablative regimens (reduced-intensity conditioning or "mini-transplant") have gained particular traction in older adult patients, who have traditionally experienced high treatment-related mortality rates with conventional myeloablative regimens. The principles of this approach include reduction of regimen-related toxicities and shifting the burden of tumor cell kill from high-dose cytotoxic therapy to graft-versus-leukemia effects. A number of recent studies have reported 2- to 5-year survival rates of 25% to 64% after nonmyeloablative allo-SCT for older patients with high-risk MDS and AML. Survival was similar for recipients of related and unrelated HLA-matched grafts. The nonrelapse mortality rate was 16% to 39%, resulting mainly from complications of graft-versus-host disease and comorbidities preceding SCT. Relapse rates ranged from 16% to 53% and were influenced both by disease burden and cytogenetics at the time of SCT.[99] Further details on this subject are beyond the scope of this chapter.

SUPPORTIVE CARE

Adequate and close supportive care is extremely important in the care of patients with acute leukemia. Both G-CSF and granulocyte-macrophage colony-stimulating factor have reduced the median time to neutrophil recovery by an average of 5 to 7 days.[100] Antileukemic therapeutic efficacy is not compromised by these agents. Therapy of acute leukemia often results in rapid reduction of elevated WBC counts. This is often associated with the development of tumor lysis, characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, acidosis, and renal failure. Prevention of tumor lysis syndrome requires administration of IV fluids and allopurinol (or rasburicase) if the blast count is above 10×10^9/L. Saline or steroid eye drops daily should be given to patients undergoing HDAC therapy until 24 hours after completion of chemotherapy. In these patients, neurologic assessments for cerebellar neurotoxicity should be performed before each dose of HDAC.

Acute pulmonary failure during induction therapy for AML is a serious complication. Predictive factors identified at diagnosis include male sex, diagnosis of APL, poor ECOG performance status, lung infiltrates at diagnosis, and an increased serum creatinine. Fluid restriction, high-dose steroids, and continuous veno-venous hemofiltration have been shown to be effective strategies in treating acute pulmonary failure.

Infectious complications are a major cause of morbidity and death. Prophylactic administration of antibiotics in the absence of fever is usually offered. The development of fever (>101°F), unrelated to administration of chemotherapy, calls for administration of broad-spectrum antibiotics, such as carbapenem or a third- (eg, ceftazidime) or fourth-generation cephalosporin (eg, cefepime). Antibiotic selection should be prompt, individualized, and in accordance with the updated antibiotic susceptibility profile of each institution. If infection

TABLE 2–6 Allogeneic Stem Cell Transplantation (Allo-SCT) versus Chemotherapy in Patients with Acute Myeloid Leukemia in First Complete Remission (CR)

LFS, leukemia-free survival.

persists, G-CSF should be started, and if indicated, granulocyte transfusions, using G-CSF to increase the donors' granulocyte counts, should be given. Close fluid balance is critical because fluid retention is common, can radiologically mimic pneumonia, and may increase the risk of diffuse alveolar hemorrhage during induction.

Another controversial area is whether adherence to a neutropenic diet (avoidance of fresh fruits and vegetables) during induction chemotherapy decreases the risk of infection. A total of 153 patients with AML diagnosed at MDACC were admitted to a high-efficiency particulate air-filtered room for induction chemotherapy.[101] They were randomized to receive a diet containing no raw fruits or vegetables (cooked diet) or to a diet containing fresh fruits and vegetables (raw diet). Twenty-nine percent of patients in the cooked group and 35% of patients in the raw group developed a major infection ($P = .60$). Time to major infection and survival time were similar in the two groups, suggesting that a neutropenic diet did not prevent major infection or death.

ACUTE PROMYELOCYTIC LEUKEMIA

APL is a distinct subtype of AML, accounting for 5% to 15% of cases, with unique clinical, morphologic, and cytogenetic features. It results from a translocation between the retinoic acid receptor α (RARα) locus on chromosome 17 and the promyelocytic leukemia protein (PML) locus located on chromosome 15.[102] This *PML-RARα* fusion is demonstrable in 95% to 100% of cases. Independent risk factors for a diagnosis of APL in a patient with AML are younger age, Hispanic ethnicity, and obesity.[2] The main clinical presentation is bleeding diathesis resulting both from plasmin-dependent primary fibrinolysis and DIC.[103] Cytogenetic analysis detects the distinctive t(15;17). In the rare case in which such analysis does not show the t(15;17) but the clinical or morphologic picture is suggestive, molecular test for *PML-RARα* can be confirmatory. The POD test, an immunohistochemical test that can be performed in few hours, can detect the characteristic disruption of PML in virtually all cases and is a rapid and reliable quick test for APL. Recognition of APL is crucial because appropriate treatment with all-*trans*-retinoic acid (ATRA) and arsenic trioxide (ATO) is different than for other types of AML and is curative in most patients.[104] A stratification system has been developed that distinguishes newly diagnosed patients with APL as low, intermediate, or high risk. Low-risk patients present with WBC count less than 10×10^9/L and platelet count above 40×10^9/L; a WBC count above 10×10^9/L identifies high-risk patients. Others are at intermediate risk. At MDACC, we only use the WBC cut-off of 10×10^9/L to distinguish low- or high-risk patients. Anticipated cure rates are close to 100%, 90%, and 70% in low-, intermediate-, and high-risk patients, respectively (Table 2–9).[105]

Several findings have contributed recently to the increased cure rates in APL. Anthracyclines were historically the first effective treatment, inducing a cure rate of 30% to 40% in patients with APL. The role of ara-C is questionable and probably beneficial only in the setting of suboptimal anthracycline therapy. Addition of ATRA 45 mg/m^2 twice daily to chemotherapy (eg, IDA 12 mg/m^2 on days 2, 4, 6, and 8) increases the CR rate and, more dramatically, increases the cure rate from 40% to 70%. The major toxicity of ATRA is a potentially fatal APL differentiation syndrome characterized by fever and leakage of fluid into the extravascular space producing fluid retention, effusions, dyspnea, and hypotension; it is effectively treated with dexamethasone (10 mg IV twice a day for 35 days, with a rapid taper).[106] A molecular test (*PML-RARA*α fusion transcript by PCR) that detects molecular evidence of the t(15;17) provides a relatively sensitive and highly specific means to document MRD negativity and detect impending relapse.[107]

When a diagnosis of APL is suspected, it is imperative that the patient be given ATRA, even before the diagnosis is confirmed. ATRA is given at a dosage of 45 mg/m^2/day in divided doses. It serves to prevent coagulopathy and start induction therapy.[108]

ATO plus ATRA was shown to be at least noninferior, and possibly superior, to ATRA and chemotherapy in low- and intermediate-risk APL. In the Italian-German APL 0406 trial, Lo-Coco et al[109] showed that the CR rate was 100% in the ATRA + ATO arm versus 95% in the ATRA plus chemotherapy (IDA) arm, with a superior

TABLE 2–7 Risk Stratification of Acute Promyelocytic Leukemia

Risk Group	WBC Count (10^9/L)	Platelet Count (10^9/L)	RFS (%)
Low	≤10	>40	98
Intermediate	≤10	≤40	89
High	>10		70

RFS, relapse-free survival; WBC, white blood cell.

OS of 98.7% versus 91.1% (P = .02). This regimen is now considered the best option for patients with standard-risk APL. Patients with high-risk disease require the addition of either GO or chemotherapy such as IDA.

The regimens generally used for treatment of patients with APL, according to risk category, are summarized in Tables 2–8 to 2–10.

Ravandi et al[110] evaluated outcomes of newly diagnosed APL patients treated with ATRA and ATO with or without GO without traditional cytotoxic chemotherapy. The regimen is summarized in Table 2–13. They reported CR rates of 95% and 81%, respectively, for low- and high-risk patients. The estimated 3-year survival rate was 85%.

Hence, in the modern era of APL treatment, it is possible to have long-term cure for APL without the use of conventional chemotherapy, which is a tremendous achievement for modern-day oncology.

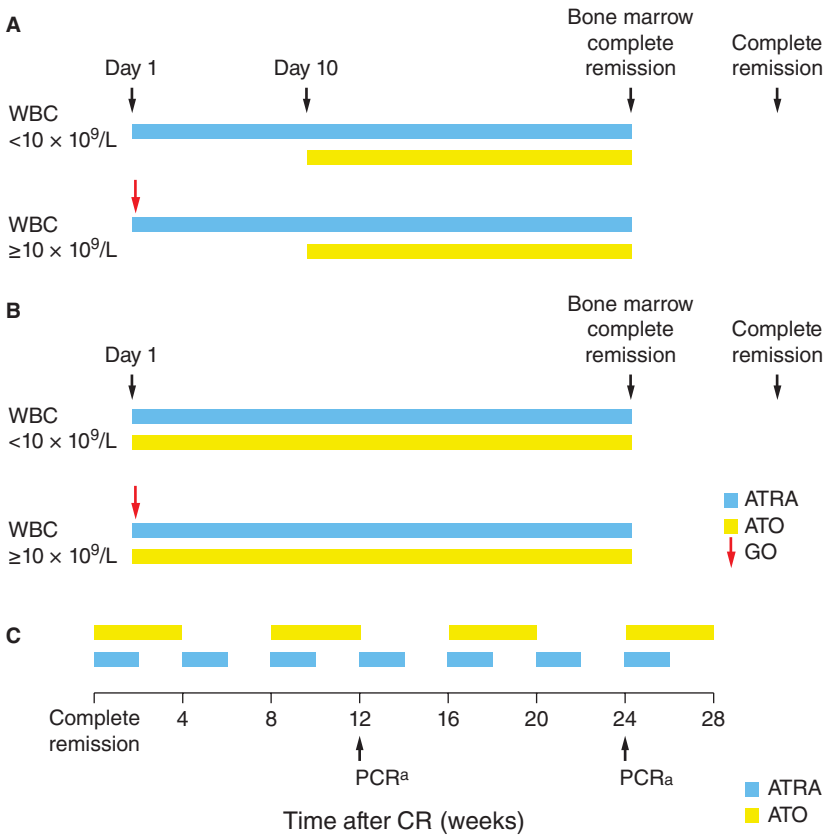
MINIMAL OR MEASURABLE RESIDUAL DISEASE

Minimal or measurable residual disease (MRD) is defined as any measurable disease detectable above a certain level of detection, depending on the methodology applied. In AML, this usually refers to the detection of disease that cannot be discerned by morphologic examination alone. MRD evaluation may be done using flow cytometry immunophenotyping assays aimed at identifying leukemic cells with at a sensitivity level of 0.01%. MRD assessment using molecular techniques can often attain deeper sensitivity levels.

MRD predicts a failure to maintain CR, and its detection is critical to assess the quality of response after induction therapy and to outline postremission therapy based on the individual risk of relapse. As mentioned in the section on APL, the detection of

TABLE 2–8 Treatment of Patients with High-Risk Acute Promyelocytic Leukemia (APL)

APL INDUCTION THERAPY	APL CONSOLIDATION THERAPY
Preferred Regimens	
ATRA 45 mg/m^2 (days 1–36, divided) + age-adjusted idarubicin 6–12 mg/m^2 on days 2, 4, 6, and 8 + ATO 0.15 mg/kg (days 9–36 as 2-hour IV infusion)	ATRA 45 mg/m^2 for 28 days + ATO 0.15 mg/kg/day for 28 days for one cycle; then ATRA 45 mg/m^2 for 7 days every 2 weeks × 3 + ATO 0.15 mg/kg/day for 5 days for 5 weeks for one cycle
ATRA 45 mg/m^2 in divided doses + ATO 0.15 mg/kg/day IV + a single dose of GO 9 mg/m^2 may be given on day 1, day 2, day 3, or day 4	ATO 0.15 mg/kg daily 5 days/wk for 4 weeks every 8 weeks for a total of four cycles + ATRA 45 mg/m^2 for 2 weeks every 4 weeks for a total of seven cycles; if ATRA or ATO is discontinued because of toxicity, a single dose of GO 9 mg/m^2 may be given once every 4–5 weeks until 28 weeks from CR
ATRA 45 mg/m^2 in divided doses + ATO 0.3 mg/kg IV on days 1–5 of week 1 and 0.25 mg/kg twice weekly on weeks 2–8 (category 1) + a single dose of GO 6 mg/m^2 may be given on day 1, day 2, day 3, or day 4	ATRA 45 mg/m^2 for 2 weeks every 4 weeks (or for 2 weeks on and 2 weeks off) in consolidation courses 1–4 + ATO 0.3 mg/kg on days 1–5 of week 1 in consolidation courses 1–4 and 0.25 mg/kg twice weekly in weeks 2–4 in consolidation courses 1–4 (category 1); if ATRA or ATO is discontinued because of toxicity, a single dose of GO 9 mg/m^2 may given once every 4–5 weeks until 28 weeks from CR
Other Recommended Regimens	
ATRA 45 mg/m^2 in divided doses + daunorubicin 50 mg/m^2 for 4 days (IV days 3–6) + cytarabine 200 mg/m^2 for 7 days (IV days 3–9)	ATO 0.15 mg/kg/day for 5 days for 5 weeks every 7 weeks for a total of two cycles; then ATRA 45 mg/m^2 × 7 days + daunorubicin 50 mg/m^2 for 3 days for two cycles
ATRA 45 mg/m^2 in divided doses + daunorubicin 60 mg/m^2 for 3 days + cytarabine 200 mg/m^2 for 7 days	Daunorubicin 60 mg/m^2 for 3 days + cytarabine 200 mg/m^2 for 7 days for one cycle; then cytarabine 2 g/m^2 (age younger than 50 years) or 1.5 g/m^2 (age 50–60 years) every 12 hours for 5 days + daunorubicin 45 mg/m^2 for 3 days for one cycle + five doses of IT chemotherapy
ATRA 45 mg/m^2 in divided doses + idarubicin 12 mg/m^2 on days 2, 4, 6, and 8	ATRA 45 mg/m^2 for 15 days + idarubicin 5 mg/m^2 and cytarabine 1 g/m^2 for 4 days for 1 cycle; then ATRA × 15 days + mitoxantrone 10 mg/m^2/day × 5 days for one cycle; then ATRA for 15 days + idarubicin 12 mg/m^2 for 1 day + cytarabine 150 mg/m^2/8 hours for 4 days for one cycle



ATO, arsenic trioxide; ATRA, all-*trans*-retinoic acid; CR, complete remission; GO, gemtuzumab ozogamicin; IT, intrathecal; IV, intravenous.

TABLE 2–11 Monitoring of Acute Promyelocytic Leukemia Therapy

- Document MR at end of consolidation
- Monitor PCR (BM or PB) every 3 months for 2 years
  - High risk
  - Age older than 60 years
  - Long treatment delays during consolidation
- If PCR becomes positive from negative, confirm!
- If confirmed, intervene.
- Try to use the same laboratory for PCR.

BM, bone marrow; MR, molecular response; PB, peripheral blood; PCR, polymerase chain reaction.

*PML-RARA*α fusion transcript after achieving CR and its subsequent monitoring to detect early relapse has become the standard of care for patients with APL. Detection of MRD in non-APL AML is an upcoming field in which guidelines and standard of care need to be defined. Several methods are being assessed to determine the best method for detection of MRD in patients with AML. There are several issues with the detection of MRD, including lack of a standardized methodology to measure MRD, inconsistency in MRD thresholds, and uncertainty of the ideal time for evaluation of MRD.

Konopleva et al[111] reported that in patients with newly diagnosed AML who have abnormal cytogenetics at presentation, determination of cytogenetics in the marrow at day 21 of induction chemotherapy predicts RFS independent of the number of blasts. Chen et al[112] from MDACC demonstrated that persistence of cytogenetic abnormalities at the time of morphologic CR portends a worse outcome. They looked at patients with abnormal cytogenetics at the time of diagnosis who achieved a morphologic CR after induction. Twenty-eight percent of patients in CR had abnormal karyotype (ACCR), and the remaining 72% had normal cytogenetic CR (NCCR). Patients with ACCR had a shorted RFS and OS compared with patients with NCCR (6 months vs 21 months; $P < .001$; and 11 months vs 46 months; $P < .001$, respectively). The RFS and OS for patients with unfavorable cytogenetics at diagnosis who were NCCR were similar to those in patients with favorable or intermediate risk at diagnosis who were ACCR. The ACCR patients who underwent an allo-SCT had a significantly longer 3-year RFS (33% vs 9%; $P = .04$) and a 3-year OS (33% vs 8%; $P = .06$) than the patients who did not undergo an SCT. Interestingly, the RFS and OS achieved by patients with ACCR, who underwent an allo-SCT, were similar to the NCCR patients who did not undergo an SCT. This suggests a role for individualizing AML therapy based on cytogenetic MRD status.

Another method of quantitative detection of MRD in AML is real-time PCR (RT-PCR) (Table 2–14). RT-PCR rapidly quantifies PCR products by reverse transcriptase fluorescent signals during exponential amplification. The sensitivity of molecular detection of fusion transcripts ranges from 1 leukemic cell in 1000 to 100,000 normal cells, that is, 0.1% to 0.001% The fusion transcripts most extensively used to monitor MRD in AML (in addition to *PML-RAR*α for APL) are *AML1-ETO*, *CBF*β*-MYH11*, and *MLL-AF9*, which are present in approximately one third of non-APL AML cases.[113] Various mutations, such as *FLT3, NPM1*, and c-*KIT*, can also be assessed by RT-PCR to determine the residual disease status. PCR analysis of *NPM1* mutations after therapy is prognostic and can be used to predict relapse. *NPM1* mutations are present in 30% of all patients with AML and in 50% of patients with normal-karyotype AML. Chou et al[114] looked at the role of MRD analysis of *NPM1* mutations by PCR and the impact on outcomes. A total of 194 samples from 38 patients with de novo AML and *NPM1* mutations were analyzed over 10 years. The samples were taken 1 month after induction and 3 months after consolidation. Any rise in the

TABLE 2–12 Advantages and Disadvantages of Real-Time Reverse Transcriptase Polymerase Chain Reaction

Advantages	Disadvantages
Very sensitive reactions	Applicable to a limited number of molecular targets • *PML-RARα* • CBF leukemias • *NPM1*
Mutations and translocations are commonly found in AML	CBF-AML may have persistence of qualitative assay positivity for years
	Can miss therapy-related AML
	Expensive
	Longer turnaround time

AML, acute myeloid leukemia; CBF, core-binding factor.

mutant signals during follow-up was associated with a 3.2 times increased risk of relapse. Of the relapsed patients, the rise in the mutation levels predicted a relapse at a median of 4.9 months (range, 1–12.3 months) before a clinical relapse being seen. This analysis also showed that the degree of reduction in mutation levels affects outcomes and that there is a co-relation between MRD after consolidation and OS and RFS (but not after induction). The Wilms tumor 1 gene (*WT1*) is highly expressed in most acute leukemias, and its detection in bone marrow has been associated with the presence, persistence, or relapse of leukemia. Recently, investigators from Turin, Italy, systematically applied their best-performing *WT1* RT-PCR assay on 620 patient samples and demonstrated that application of a standardized *WT1* assay can indeed provide independent prognostic information in patients with AML.[115] Studies are ongoing to further elucidate the role of the *WT1* gene assay to risk stratify patients who might benefit from intensification of therapy to improve outcomes.

Leukemic cells express abnormal patterns of cellular markers, and these aberrant immunophenotypes can be identified by multiparameter flow cytometry. To yield a sensitivity of 0.01% (10^{-4}), at least 200,000 cells are needed per tube (at least 200,000 events are required to detect 20 aberrant blasts), and three to four tubes are run per patient; 0.1% is the commonly used threshold in most studies in the literature. An advantage of flow cytometry–based studies of MRD is that they can accurately quantify residual leukemic cells and can also distinguish aberrant blasts from normal myeloid precursors. An immunophenotypic fingerprint of the AML can be established for MRD analysis for follow-up. However, there are several advantages and disadvantages with this technique (Table 2–15).

Rubnitz et al[116] reported outcomes with MRD-directed therapy in childhood AML. In this study, patients were randomized to receive HDAC-based induction versus LDAC-based induction. MRD levels, on day 22 after induction, were used to allocate GO to determine the timing of the second induction. MRD was determined, and GO was given to patients with poor early response; high-risk patients were allocated to allo-SCT. This study showed that MRD was no different with high-dose chemotherapy versus low-dose chemotherapy at day 22 of induction 1. MRD greater than 1% on day 22 was a significant prognostic factor influencing OS and EFS in the high-risk patients but not in the standard- or favorable-risk patients. Patients with low-level MRD (0.1% to <1%) did as well as the MRD-negative cohort. An Italian group analyzed the outcomes of adult AML patients based on MRD levels after induction and consolidation and reported that the MRD status at the end of consolidation was the most important predictor of prognosis. In the MRD-positive group, patients who underwent an allo-SCT had improved outcomes.[117]

In general, a lack of standardization among different laboratories, identification of thresholds, and time points during follow-up represent the major subjects of controversy for the routine implementation of MRD detection in non-APL AML at this time.

CONCLUSION

After a period of paucity in discoveries and approvals, new strategies are finally evolving, and since 2017,

TABLE 2–13 Advantages and Disadvantages of Flow Cytometry for Minimal Residual Disease Assessment

Advantages	Disadvantages
Widely applicable (90%–95% of cases)	Interpretation often challenging; requires experience
	Can be expensive
	Lack of standardization
Relatively rapid turnaround time	LAIPs may not cover all leukemic blasts; partial overlap with normal
	Antigen shift resulting from selection or emergence of subclones: a complete change in LAIPs in ~20% of AML cases, with 80% having at least one LAIP similar to the original
	Posttherapy sample is hypocellular; not enough cells or events
	Use of a comprehensive panel of antibodies to establish baseline

AML, acute myeloid leukemia; LAIP, leukemia-associated immunophenotype.

new drugs have been approved to improve outcomes in patients with AML. The biology of the disease is now better understood, and development of targeted therapy is now catching up with the science. Individualized therapy for patients with FLT3, IDH1, and IDH2 mutated AML is now available and part of the standard of care. Safe *and* highly effective therapy is now available for newly diagnosed older and unfit patients with AML with the discovery of venetoclax. Careful genomic annotation of patients at diagnosis followed by subgroup analyses in large cohorts have identified subgroups that may benefit more or less from selected targeted therapies, as is the case of gemtuzumab and CBF-AML. Patients with APL have benefited from newer treatment with ATRA and arsenical derivatives while avoiding classic chemotherapy. Combinations of these newer drugs are being investigated to optimize future treatment. Better definition of the complex process initiating and sustaining the leukemic process will lead to a better definition of targets for therapeutic intervention that may translate into improved cure rates. Specific attention must be given to prognostic factors that identify subsets of AML in which specific tailored therapies will be helpful.

MD ANDERSON PRACTICE TIPS

- In patients with newly diagnosed CBF-AML, at MDACC, we use the combination of FLAG + GO, achieving high rates of CR and long-term survival rates of 70% to 80%. Dose modifications to the FLAG backbone are implemented to offer these patients the potential for cure. Close monitoring of RT-PCR for the CBF transcript is critical for risk stratification, with the goal to achieve at least 3-log reduction from baseline at the end of consolidation.
- Our frontline approach to newly diagnosed, young, fit patients with newly diagnosed AML is to offer double-nucleoside intensive chemotherapy with either cladribine or fludarabine combined with a higher dose of cytarabine (1–2 g/m^2) combined with IDA as the preferred anthracycline. All patients have baseline genomic sequencing and karyotyping. Patients with targetable mutations receive FLT3 inhibitors, IDH inhibitors, or venetoclax in combination with these backbones on clinical trials. Patients with TP53 mutations with high allelic frequency and complex karyotype may be offered less intensive clinical trials in the frontline setting.
- We recommend close, often inpatient monitoring for patients with newly diagnosed AML during the induction cycle of chemotherapy. We routinely use antibacterial, antifungal, and antiviral prophylaxis in all of our patients with AML when appropriate.
- Our frontline approach to newly diagnosed, older, and unfit patients with AML includes lower intensity therapy on clinical trials in combination with targeted therapy (ie, FLT3 inhibitor, IDH inhibitor) when appropriate. Lower intensity regimens include a newer backbone on clinical trial, involving cladribine + low-dose cytarabine + venetoclax or HMA + venetoclax. When in remission, dose and schedule modifications are implemented to minimize toxicity and prolonged myelosuppression that can be observed after repeated cycles.
- Postremission therapy is recommend based on age, fitness, and risk assessment at baseline and during therapy (ie, MRD monitoring). Maintenance therapy with oral azacytidine or targeted therapy combinations on clinical trials are recommended for most higher risk patients who are not candidates for SCT. Studies of post-transplant maintenance therapy are also being conducted.

3 Chronic Lymphocytic Leukemia and Associated Disorders

Nitin Jain
Philip Thompson
Carlos Bueso-Ramos
Susan M. O'Brien
William G. Wierda

KEY CONCEPTS

- Chronic lymphocytic leukemia (CLL) is the most common leukemia in the United States and has a median age of diagnosis of 70 years.
- The diagnosis of CLL can be established by peripheral blood flow cytometry in the majority of the patients.
- Treatment of patients with CLL has evolved from chemoimmunotherapy (CIT) to targeted therapies. Most patients are currently treated with oral targeted therapies. Oral targeted therapies include Bruton tyrosine kinase inhibitors, B-cell lymphoma 2 (BCL2) inhibitors, and phosphoinositide 3-kinase (PI3K) inhibitors. Randomized studies have shown improved progression-free survival (PFS) and overall survival (OS) with oral targeted therapies compared with CIT in CLL.
- Targeted therapies approved for first-line CLL include ibrutinib, acalabrutinib +/- obinutuzumab, and venetoclax + obinutuzumab. Ibrutinib and acalabrutinib are intended to be given daily continuously. Venetoclax and obinutuzumab is a time-limited treatment approach of 1-year duration.
- In relapsed CLL, the combination of venetoclax + rituximab has shown improved PFS and OS compared with bendamustine and rituximab. Additional approved therapies for relapsed CLL include ibrutinib and acalabrutinib. The PI3K inhibitors idelalisib and duvelisib are also approved for patients with relapsed CLL.
- Richter transformation remains an unmet medical need. Outcomes with CIT remains dismal with median survival of less than 1 year. There are emerging data with checkpoint inhibition, use of venetoclax-based combination therapies, and chimeric antigen receptor T-cell therapy

Chronic lymphocytic leukemia (CLL) is a clonal hematopoietic disorder involving expansion of CD5-positive B cells. Chemoimmunotherapy (CIT) has been the standard first-line treatment for patients with CLL.[1] In the past several years, novel oral small-molecule therapies have become available, and these have significantly improved the outcomes of patients with CLL.

EPIDEMIOLOGY

CLL is the most common leukemia in the Western Hemisphere, accounting for about 25% of all leukemias in the United States. The estimated number of new CLL cases for 2020 was 21,040, with 4060 deaths. CLL is uncommon in the Asian population and accounts for only 2.5% of all leukemias in Japan. The incidence is age related, with an increase from 5.2 per 100,000 persons older than 50 years to 30.4 per 100,000 persons older than 80 years. Population studies have not identified specific occupational or environmental risk factors for developing CLL.[2] The risk of CLL is not increased in Asians settled in Western countries, indicating that genetic factors play a part in CLL risk.[3] Up to 15% to 20% of patients with CLL have a family member with CLL or a related lymphoproliferative disorder.[4] Genome-wide association studies identified several single nucleotide polymorphisms associated with an increased risk of CLL.[5,6]

BIOLOGY

Surface Antigen Phenotype

CLL is a clonal B-cell lymphoid leukemia. CLL cells morphologically resemble small mature lymphocytes arrested in an intermediate stage of the B-cell

differentiation pathway. The hallmark of CLL cells is that they are monoclonal and express CD5, an antigen commonly found on T cells. CD5-positive B cells can be found in the mantle zone of lymphoid follicles, but they constitute a minor fraction of the B-cell population. CD19, CD20, and CD23 are B-cell markers expressed on CLL cells. Surface immunoglobulin (Ig), FMC7, CD22, CD11c, and CD79b are either weakly expressed or negative in CLL. Based on the antigen expression profile, CLL appears to arise from an "activated" B cell.

Somatic Hypermutation of Immunoglobulin Heavy-Chain Variable Gene

Normal B-cell development involves an antigen-independent phase and an antigen-dependent phase. During the antigen-independent phase, B cells undergo rearrangement of the variable (V), diversity (D), and joining (J) genes in the bone marrow. Somatic mutation of the heavy- and light-chain variable gene occurs after encounter with antigen in the germinal center. Assessment for somatic hypermutation of immunoglobulin heavy-chain variable gene (*IGHV*) defines two subsets of CLL. Approximately 50% of patients with CLL have somatic hypermutation (>2% deviation from germline sequence) of the *IGHV* gene and thus appear to arise from postgerminal B cells, whereas the subset of CLL lacking *IGHV* gene hypermutation (≤2% deviation from germline sequence) appears to arise from naïve B cells.[7,8] The mutation status of CLL cells is fixed, and mutational status is not gained or lost throughout the course of disease. With the use of CIT, patients with unmutated *IGHV* have worse clinical outcomes than those with mutated IGHV.[9–11]

Because historically, sequencing of the *IGHV* gene to identify the mutational status was labor intensive and not universally available, Damle et al[7] studied the correlation of *IGHV* mutation status with CD38 expression as a surrogate prognostic marker for *IGHV* mutation status. A significant association between CD38 expression and unmutated *IGHV* status was noted. Gene expression profiling of mutated versus unmutated *IGHV* CLL cases showed zeta-associated protein 70 (*ZAP-70*) to be the most differentially expressed gene with higher expression in unmutated *IGHV* cases, providing another surrogate for *IGHV* mutation status.[12,13]

Genomic Alterations

Using conventional chromosome banding techniques, cytogenetic abnormalities can be detected in up to 50% of CLL cases. These techniques are hampered by the low mitotic activity of CLL cells; B-cell mitogens may be used to enhance this activity. In addition, metaphases obtained for karyotyping may also arise from normal T cells in the sample, as indicated by sequential immunotyping followed by karyotypic analysis. Fluorescent in situ hybridization (FISH) performed on interphase cells using genomic DNA probes greatly enhanced the ability to detect molecular abnormalities in malignant cells. FISH demonstrated that molecular abnormalities occur in over 80% of CLL cases. Del(13q) is the most common genetic aberration found in CLL by FISH (55%) followed by del(11q) (18%), trisomy 12 (16%), and del(17p) (7%).[14] When divided into five prognostic categories—del(17p), del(11q), trisomy 12, no observed abnormalities, and del(13q) (as the sole abnormality)—the survival times were 32, 79, 114, 111, and 133 months, respectively. Patients with del(11q) tend to have more prominent lymphadenopathy. Patients with del(17p) and del(11q) tend to have more advanced disease and respond poorly to chemotherapy-based regimens.[9] Clonal evolution can occur over time and with treatment; therefore, FISH assessment should be repeated whenever a therapeutic intervention is being considered.

Whole-exome sequencing of CLL cases has identified genes that are recurrently mutated and may contribute to the pathogenesis of the disease.[15,16] Recurrently mutated genes include *TP53*, *NOTCH1*, *SF3B1*, *MYD88*, *XPO1*, and *ATM*. *TP53* mutations are typically associated with del(17p). *ATM* and *SF3B1* mutations are typically associated with del(11q).

CLINICAL FEATURES

At diagnosis, most patients are older than 60 years, with more than 90% being older than 50 years. The diagnosis of CLL is often incidental; a routine blood count may reveal an elevated absolute lymphocyte count (ALC). In symptomatic patients, fatigue and infections may be presenting features. B symptoms (fever, weight loss, night sweat) can also occur but are uncommon at initial diagnosis. Exaggerated skin reactions to insect bites (Wells syndrome) are frequent in those with CLL. Leptomeningeal involvement is rare. Some patients may present with autoimmune hemolytic anemia or immune thrombocytopenia. Physical examination may reveal cervical, axillary, or inguinal lymphadenopathy. Splenomegaly and hepatomegaly are not uncommon.

LABORATORY FEATURES

Laboratory findings invariably show lymphocytosis. CLL cells resemble mature lymphocytes; they have dense chromatin as well as scant cytoplasm and lack nucleoli (Fig. 3–1). Preparation of the blood smear may damage these fragile lymphocytes and produce "smudge" cells. The bone marrow is typically hypercellular for age, and infiltration varies in terms of the percentage of marrow involved as well as in the pattern of involvement, which may be nodular, interstitial, or diffuse (Fig. 3–2). Erythroid, myeloid,

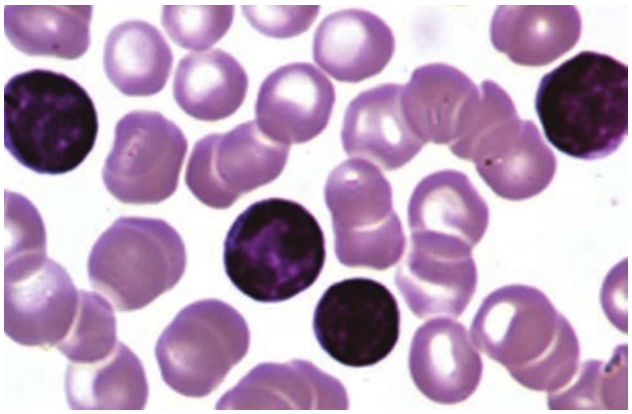

FIGURE 3–1 Chronic lymphocytic leukemia. Peripheral blood smear showing mature-appearing lymphocytes. Note dense chromatin, scant cytoplasm, absence of nucleoli, and smudge cells.

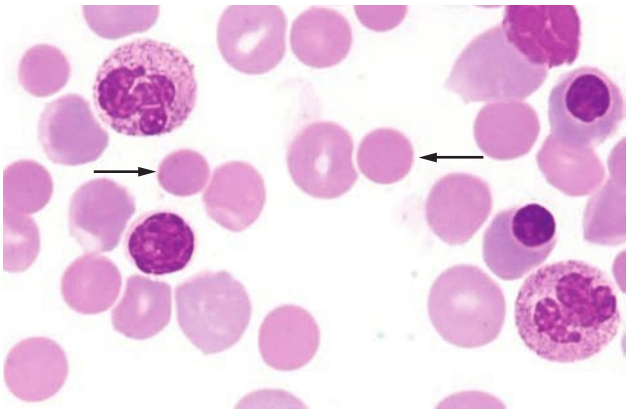

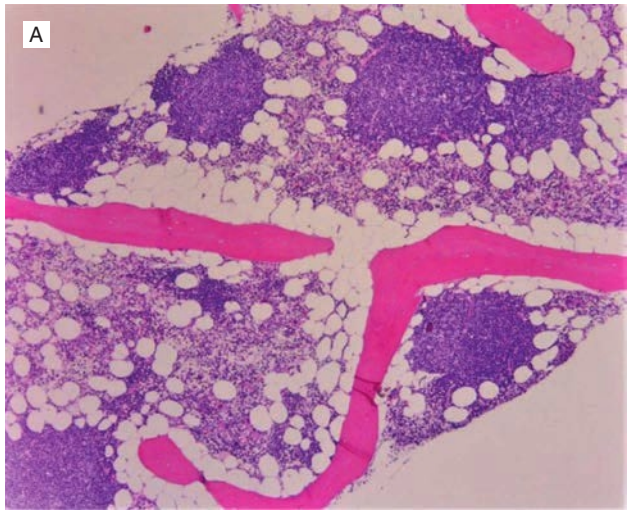

FIGURE 3–3 Immune hemolytic anemia. Presence of microspherocytes (***arrows***) and nucleated red cells indicates immune destruction of red cells. Diagnosis is confirmed by demonstrating the presence of immunoglobulin G (IgG) or complement on red cells.

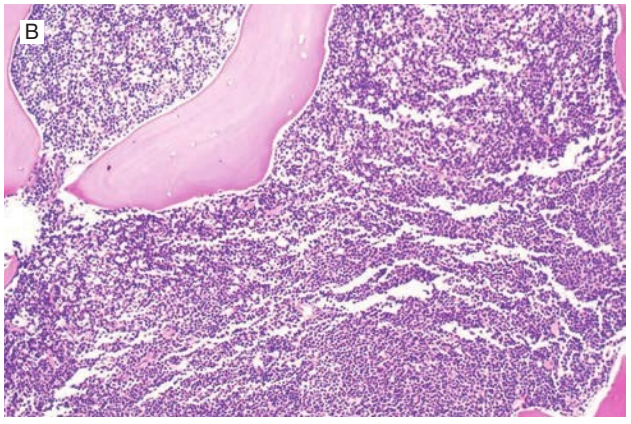

FIGURE 3–2 A and B. Chronic lymphocytic leukemia. Bone marrow biopsies showing nodular, diffuse, and interstitial patterns of involvement.

and megakaryocytic precursors may be normal or decreased. Anemia or thrombocytopenia may result from marrow infiltration or from immune destruction. Findings of microspherocytes in the peripheral blood smear (Fig. 3–3), reticulocytosis, and demonstration of Ig G or complement on red cells support the diagnosis of immune hemolytic anemia. Pure red cell aplasia has been described in 1% to 6% of cases. Patients often develop hypogammaglobulinemia, which can progress in severity with advancing disease. Monoclonal gammopathy may also develop. Other laboratory abnormalities include elevated serum beta-2-microglobulin (B2M); lactate dehydrogenase (LDH) is rarely elevated.

Up to 5% of otherwise normal individuals older than the age 40 years may harbor a population of monoclonal CD5+/CD19+/CD23+ B cells. These individuals are asymptomatic (absence of cytopenia and lymphadenopathy or organomegaly); when the absolute monoclonal lymphocyte count is less than 5000/μL and there is no palpable enlarged lymph node, they are characterized as having monoclonal B lymphocytosis (MBL).[17] It is estimated that the rate of progression from MBL to CLL is 1% to 2% per year.

DIAGNOSIS

In 2018, the International Workshop on Chronic Lymphocytic Leukemia (IWCLL) updated the recommendations on diagnosis and treatment of patients with CLL.[18] The diagnosis of CLL requires 5×10^9 or greater clonal B lymphocytes/L in the peripheral blood, with less than 55% of the cells being prolymphocytes. A monoclonal B-cell count 5×10^9/L or greater was

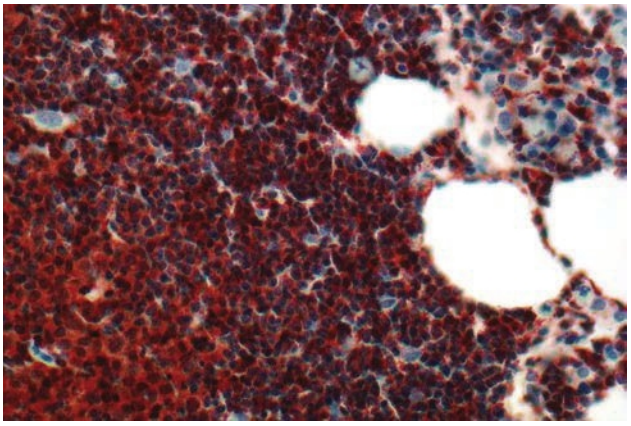

FIGURE 3–4 Zeta-associated protein 70 (ZAP-70) expression in chronic lymphocytic leukemia cells indicates poor prognosis. Immunohistochemistry (*above*) or flow cytometry can be used to detect ZAP-70 expression.

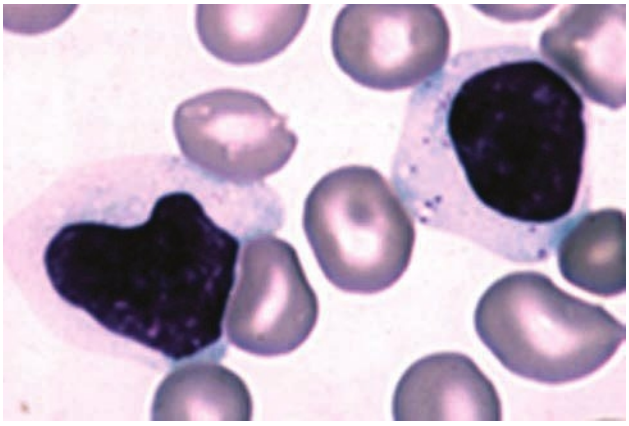

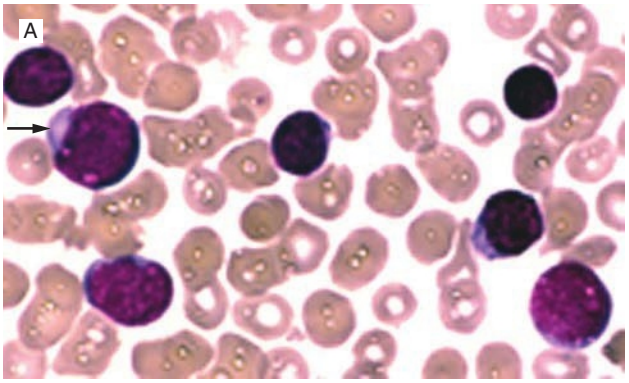

FIGURE 3–6 Large granular lymphocytes with cytoplasmic azurophilic granules.

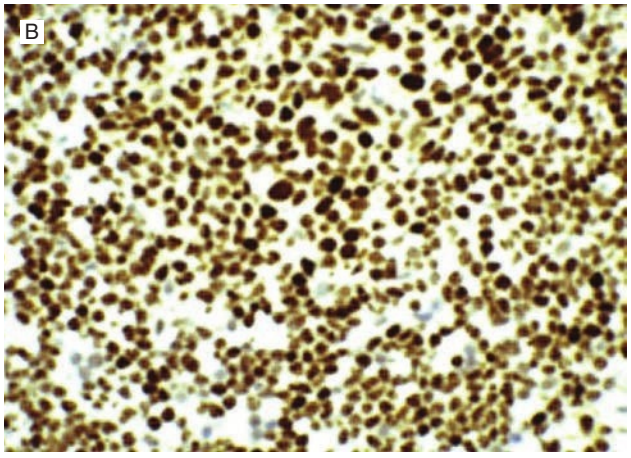

FIGURE 3–5 **A.** Mantle cell lymphoma (MCL) in leukemic phase. MCL cells (*arrow*) are larger than mature lymphocytes (*center*) with speckled chromatin; some show nuclear cleft. **B.** Nuclear cyclin D1 staining in mantle cells.

specified to distinguish CLL from small lymphocytic lymphoma in patients with palpable lymph nodes or splenomegaly. B-lymphocyte clonality should be demonstrated by using flow cytometry, which should also confirm expression of B-cell surface antigens (CD19, CD20, CD23), low-density surface Ig (M or D), CD200, and CD5. ZAP-70 (Fig. 3–4) expression in CLL cells has prognostic implication. Distinguishing CLL from mantle cell lymphoma (MCL); Figs. 3–5A and B) (see "Differential Diagnosis") and large granular leukemia (Fig. 3–6) is of utmost importance.

The presence of more than 55% of prolymphocytes favors a diagnosis of prolymphocytic leukemia (PLL). Prolymphocytes (<55%) can be seen in peripheral blood or bone marrow of patients with CLL (Fig. 3–7).

DIFFERENTIAL DIAGNOSIS

Clinical, morphologic, immunophenotypic, and cytogenetic help to distinguish between CLL and other diseases such as MCL, follicular lymphoma, T-cell PLL (T-PLL), hairy cell leukemia (HCL), marginal zone lymphoma, and Waldenström macroglobulinemia. Table 3–1 summarizes the immunophenotypic features of these disorders. Distinguishing CLL from MCL is important because both can express CD5 (see Fig. 3–5A). Unlike CLL, MCL cells are typically CD23 negative, CD200 negative, and FMC-7 positive and have strong surface Ig staining. Confirmation of MCL can be made by detection of the t(11;14) translocation or positive nuclear cyclin D1 staining (see Fig. 3–5B).

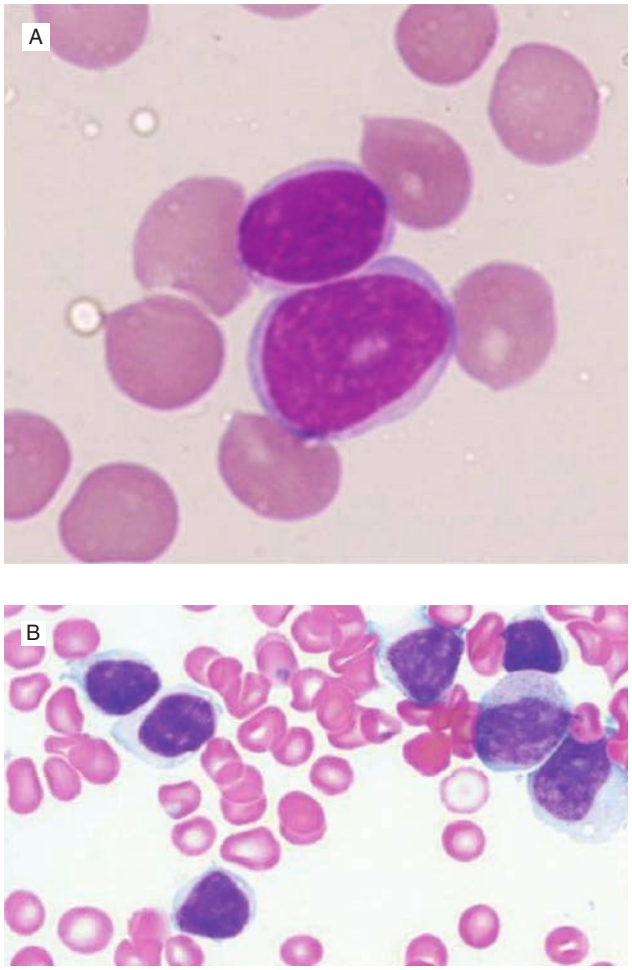

FIGURE 3–7 **A.** High-power view of a prolymphocyte juxtaposed with a mature-appearing lymphocyte. Note larger size, less condensed chromatin, and prominent nucleolus in prolymphocyte. **B.** Bone marrow smear from a 58-year-old man with a 3-year history of untreated chronic lymphocytic leukemia (CLL). There are small lymphocytes and larger prolymphocytoid lymphocytes with abundant lightly basophilic cytoplasm, fine chromatin, and variably prominent nucleoli. **C.** Interphase fluorescent in situ hybridization. Almost all the lymphocytes show deletion of one locus of D13S319 (***white arrow***) (except two lymphocytes on slide 1, left low), and a large subset of CLL cells also showed trisomy 12 (+12). Interestingly, +12 is almost only seen in prolymphocytoid lymphocytes. The small lymphocytes with clumped chromatin and scant cytoplasm usually do not show +12.

TABLE 3–1 Immunophenotypic Analysis in Chronic B-Cell Disorders

Disease	sIg	CD5	CD10	CD20	CD22	CD23	CD79B	CD103	FMC7
CLL	Weak	++	–	+	–/+	++	–/+	–	–/+

MCL	Strong	++	–	++	++	–	++	–	++

B-PLL, prolymphocytic leukemia; CLL, chronic lymphocytic leukemia; FL, follicular lymphoma; HCL, hairy cell leukemia; MCL, mantle cell lymphoma; sIg, surface immunoglobulin; SLVL, splenic lymphoma with villous lymphocytes.

STAGING

Staging systems for CLL include Rai and Binet staging (Table 3–2).[19,20] The original Rai classification defined five stages from 0 to IV based on the presence or absence of lymphocytosis, lymphadenopathy, organomegaly, and cytopenia; this has been modified to three stages by defining Rai stage 0 as low risk, stages I and II as intermediate risk, and stages III and IV as high risk. Similarly, Binet stages A, B, and C are based on the number of lymph nodal areas involved and the presence or absence of cytopenia. The diagnostic workup that is undertaken in patients with CLL at initial presentation at The University of Texas MD Anderson Cancer Center (MDACC) is listed in Table 3–3.

TABLE 3–2 Staging of Chronic Lymphocytic Leukemia

Rai Stage	Modified Rai Stage	Description	Binet Stage	Description
0	Low risk	Lymphocytosis only	A	Hemoglobin ≥10 g/dL, platelets ≥100 × 10^9/L, and <3 enlarged lymphoid-bearing areas
1	Intermediate risk	Lymphocytosis and lymphadenopathy	B	Hemoglobin ≥10 g/dL, platelets ≥100 × 10^9/L, and ≥3 enlarged lymphoid-bearing areas
2	Intermediate risk	Lymphocytosis and splenomegaly and/or hepatomegaly with/without lymphadenopathy		
3	High risk	Lymphocytosis and anemia (hemoglobin <11 g/dL)	C	Hemoglobin <10 g/dL or platelets <100 × 10^9/L (irrespective of number of lymphoid-bearing areas)
4	High risk	Lymphocytosis and thrombocytopenia (platelets <100 × 10^9/L		

TABLE 3–3 Initial Evaluation of Patients with Chronic Lymphocytic Leukemia at MD Anderson Cancer Center

History and physical (close attention to lymph node areas, liver and spleen size)
Constitutional symptoms (fever, chills, weight loss, night sweats)
Assessment of performance status
CBC, electrolytes, BUN, creatinine, liver function tests, LDH, quantitative immunoglobulins, β_2-microglobulin
Examination of peripheral blood smear
Bone marrow aspiration and biopsy (in patients with cytopenias or those in need of treatment)
Immunophenotyping of peripheral blood or bone marrow lymphocytes to establish diagnosis
Prognostic marker assessment • Interphase FISH (assessment of deletion 17p, deletion 11q, trisomy 12, deletion 13) • *IGHV* mutation status • *TP53* sequencing • Flow cytometry for CD38 • Immunostaining or flow cytometry for ZAP-70
Imaging studies (only if presenting with significant adenopathy or needed treatment); many clinical trials are now incorporating CT scans as per new guidelines, but these are not standard of care outside of a clinical trial. • CT scan or PET scan (PET scan preferred if there is a suspicion of Richter transformation)

BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; FISH, fluorescent in situ hybridization; LDH, lactate dehydrogenase; MDACC, The University of Texas MD Anderson Cancer Center; PET, positron emission tomography; ZAP-70, zeta-associated protein 70.

PROGNOSIS

In the era of CIT, several factors were associated with poor prognosis. These factors included advanced Rai or Binet stage, male gender, older age, lymphocyte doubling time less than 12 months, presence of del(17p) or del(11q), complex karyotype, unmutated IGHV, higher CD38 expression, higher Zap-70 expression, elevated b2-microglobulin, elevated serum thymidine kinase, diffuse marrow involvement, and gene mutations (*TP53, BIRC3, NOTCH1, SF3B1*).[21–24] The CLL-International Prognostic Index (CLL-IPI) evaluated 3472 patients with treatment-naïve CLL and assessed for several demographic and CLL disease-related factors; five prognostic markers for OS were identified, which included *TP53* aberration, *IGHV* status, B2M, clinical stage, and age older than 65 years of age.[25] Based on these five markers, four separate prognostic groups were identified with 5-year overall survival (OS) ranging from 93.2% to 23.3%. It is important to note that the CLL-IPI was developed in patients who received CIT. Given improved outcomes with targeted therapies and overall decline in the use of chemotherapy for patients with CLL, the CLL-IPI will need to be reevaluated with the data from patients treated with targeted therapies. More recently, an international prognostic score to predict time to first treatment (TTFT) in patients with CLL with early, asymptomatic disease (International Prognostic Score for Early-stage CLL [IPS-E]) was developed.[26] A total of 4933 patients were analyzed. Three variables independently correlated with TTFT: unmutated IGHV, ALC greater than 15×10^9/L, and presence of palpable lymph nodes. Each of these variables was given a risk score of 1; patients were categorized into low risk (score of 0), intermediate risk (score of 1), and high risk (score of 2 or 3). The 5-year cumulative risks for treatment were 8.4%, 28.4%, and 61.2% among low-risk, intermediate-risk, and high-risk patients, respectively.

TREATMENT

Indications for Treatment

Unlike most leukemias, an unusual feature of CLL is that making the diagnosis is not necessarily an indication to initiate treatment. Early treatment of asymptomatic CLL with chemotherapy was not shown to prolong survival. In the current era of more effective CIT regimens and targeted therapies, this question is currently being evaluated in clinical trials. The 2018 IWCLL criteria for treatment of CLL are summarized in Table 3–4.

Up until recently, CIT was the standard first-line treatment for patients with CLL. With the significant advances in the field of CLL, targeted therapies have now become standard treatment for most patients with CLL.

Combination CIT such as fludarabine + cyclophosphamide + rituximab (FCR), bendamustine + rituximab (BR), and chlorambucil + CD20 monoclonal antibody (mAB) combination were the standard first-line treatments for patients with CLL.[1,27] In the original FCR study conducted at MDACC, a high overall response rate (ORR) of 95% was noted with a complete remission (CR) rate of 72%.[28] In the long-term follow-up of this trial, a 10-year progression-free survival (PFS) of about 55% was noted in patients with mutated IGHV.[11] The GCLLSG group conducted a phase III trial to evaluate the efficacy of FCR versus FC in first-line treatment of patients with CLL (CLL8 trial).[9] A total of 817 patients were randomized to receive six courses of either FC (409 patients) or

TABLE 3–4 Indications for Treatment in Chronic Lymphocytic Leukemia from the International Workshop on Chronic Lymphocytic Leukemia

Active disease should be confirmed before initiating treatment.
1. Evidence of progressive marrow failure as manifest by the development or worsening of anemia and/or thrombocytopenia
2. Massive (ie, >6 cm below the left costal margin) or progressive or symptomatic splenomegaly
3. Massive nodes (ie, at least 10 cm in longest diameter) or progressive or symptomatic lymphadenopathy
4. Progressive lymphocytosis with an increase of ≥50% over a 2-month period, lymphocyte doubling time of <6 months[a]
5. Autoimmune anemia and/or thrombocytopenia poorly responsive to corticosteroid therapy
6. Symptomatic or functional extranodal involvement (eg, skin, kidney, lung, spine)
7. Constitutional symptoms, defined as any one or more of the following disease-related symptoms or signs: a. Unintentional weight loss ≥10% within the previous 6 months b. Significant fatigue (ie, ECOG PS 2 or worse; cannot work or unable to perform usual activities) c. Fevers ≥100.5°F or 38.0°C for ≥2 weeks without evidence of infection d. Night sweats for ≥1 month without evidence of infection

<TFN>[a]In patients with a lymphocyte count of $<30 \times 10^9$/L, lymphocyte doubling time should not be used as a single parameter to define treatment indication. Factors contributing to lymphocytosis or lymphadenopathy other than chronic lymphocytic leukemia (ie, infections) should be excluded.
ECOG PS, Eastern Cooperative Oncology Group performance status.

FCR (408 patients). They reported a significantly higher CR rate (44% *vs* 22%; *P* <.0001), ORR (90% *vs* 80%; *P* <.0001), PFS (median PFS, 52 *vs* 33 months; *P* <.0001), and OS (3-year OS, 87% *vs* 83%; *P* =.012) with the addition of rituximab. This trial established the role of anti-CD20 mAB in the first-line therapy of patients with CLL. Bendamustine in combination with rituximab has also been evaluated as first-line treatment for patients with CLL. Fischer et al[29] reported on the outcomes of 117 patients with treatment-naïve CLL who received BR. The ORR was 88% with a CR rate of 23%. The median PFS was 34 months. Notably, one third of the patients had a creatinine clearance of 70 mL/min or less (these patients are typically excluded from the FCR trials), and these patients did equally as well as patients with a creatinine clearance greater than 70 mL/min.

The GCLLSG then conducted a randomized phase III study of FCR versus BR as first-line therapy for patients with CLL (CLL10 trial).[10,30] This trial included patients with CLL with good physical status (Cumulative Illness Rating Scale [CIRS] score ≤6 and creatinine clearance ≥70 mL/min). A total of 282 patients received FCR, and 279 patients received BR. The FCR arm had a significantly higher CR/CR with incomplete count recovery (CRi) rate (39.7 *vs* 30.8; *P* =.03) and significantly improved PFS (median PFS, 55.2 *vs* 41.7 months; *P* <.001). OS was not different between the two groups. Not unexpectedly, patients on the FCR arm experienced more grade 3 or 4 neutropenia (84.2% *vs* 59%; *P* <.001), more thrombocytopenia (21.5% *vs* 14.4%; *P* =.03), and increased risk of grade 3 or 4 infections (39.1% *vs* 26.8%; *P* <.001). However, the treatment-related mortality rate was similar in the two arms. This trial established FCR as a standard first-line CIT regimen for patients with CLL who are 65 years old or younger. Several studies have been conducted with the intent of modifying the FCR regimen by dose-intensifying rituximab,[31] adding mitoxantrone,[32] adding alemtuzumab,[33] adding granulocyte-macrophage colony-stimulating factor,[34] or using lower doses of FCR (FCR-Lite),[35] but these studies have not shown superior results compared with those seen with the standard FCR regimen.

Obinutuzumab is a humanized type II CD20 mAb with a glycoengineered Fc domain that leads to enhanced antibody-dependent cellular cytotoxicity compared with that seen with rituximab. This type II CD20 mAb is more effective at direct induction of CLL cell apoptosis, which leads to more effective B-cell depletion than rituximab. In the GCLLSG CLL11 trial, previously untreated patients with CLL with coexisting conditions (CIRS score >6 and/or creatinine clearance of 30–69 mL/min) were randomly assigned to receive chlorambucil monotherapy, chlorambucil plus rituximab, or chlorambucil plus obinutuzumab.[36,37] A total of 781 patients were enrolled. The median age was 73 years. Treatment with obinutuzumab–chlorambucil, compared to rituximab–chlorambucil, resulted in a higher ORR of 78.4% (CR 20.7% + partial remission (PR) 57.7%) versus 65.1% (CR 7% + PR 58.1%; *P* <.001). PFS was significantly longer with obinutuzumab–chlorambucil compared with that seen with rituximab–chlorambucil (median PFS, 29.2 *vs* 15.4 months; *P* <.001). Both antibody-containing regimens produced better outcomes than that seen with single-agent chlorambucil. This trial established the combination of chlorambucil with a CD20 mAb as a standard of care for first-line therapy in older patients with CLL who have comorbidities.

B-Cell Signaling Pathway Inhibitors

CLL cells receive growth and survival signals from the microenvironment of the bone marrow, lymph nodes, and spleen.[38] Bruton tyrosine kinase (BTK) is a central molecule in signal transduction for the B-cell receptor (BCR) as well as CD19, CD38, CD40, CXCR4 chemokine receptor, tumor necrosis factor receptors, and Toll-like receptors (TLRs). Other important signal transduction molecules include phosphoinositide 3-kinase (PI3K) and Syk.

Bruton Tyrosine Kinase Inhibitors

BTK is a nonreceptor tyrosine kinase of the Tec kinase family that plays a crucial role in BCR signaling. Ibrutinib is an oral, selective, and irreversible inhibitor of BTK. It forms a covalent bond with the cysteine-481 of BTK. Byrd et al[39] reported the outcomes of 85 patients with relapsed or refractory CLL who received ibrutinib monotherapy. This was a heavily pretreated population with a median of four prior therapies. The median age was 66 years (range, 37–82 years). Thirty-three percent of the patients had del(17p). The ORR was 90%, with 7% CR, 65% PR, and 9% PR with lymphocytosis (PR-L). The estimated PFS at 7 years was 34%.[40] In the treatment-naïve cohort of the same trial, 31 patients (65 years or older) with CLL received ibrutinib monotherapy. The estimated 7-year PFS rate was 83%. In a randomized phase III trial (RESONATE trial), patients with relapsed or refractory CLL were randomized to ibrutinib or ofatumumab.[41] The ibrutinib arm had a much higher ORR and superior PFS and OS compared with the ofatumumab arm. In a randomized phase III trial (RESONATE-2), 269 older patients with previously untreated CLL were randomized to ibrutinib versus chlorambucil.[42] The PFS was significantly longer in the ibrutinib arm (5-year PFS 70% vs 12% for chlorambucil; *P* <.001).[43] There was also an OS benefit for the ibrutinib arm (5-year survival rate, 83% vs 68% for chlorambucil arm; *P* <.001) despite crossover that allowed 57% of the patients receiving chlorambucil to receive ibrutinib at the time of disease progression. This trial led to the approval of ibrutinib for previously untreated patients with CLL. Common

adverse events with ibrutinib include diarrhea, arthralgia, hypertension, and atrial fibrillation.

It is important to note that most patients will develop lymphocytosis upon initiating ibrutinib. This is expected with all BCR inhibitors, and it generally resolves over the course of 6 to 9 months with continued treatment. Development of lymphocytosis is not detrimental to the long-term clinical outcomes The mechanism of resistance to ibrutinib include development of a mutation of *BTK* at cysteine-481 (C481S) and gain-of-function mutations in *PLCγ2*, a signaling molecule downstream of BTK.[44]

More recently, the ECOG1912 trial evaluated the activity of ibrutinib + rituximab versus FCR. A total of 519 patients (age 70 years or younger) with previously untreated CLL were randomized.[45] The PFS was significantly better with ibrutinib + rituximab than that seen with FCR (3-year PFS, 89.4% vs 72.9% P <.001). In a subgroup analysis, the PFS benefit of ibrutinib + rituximab over FCR was limited to IGHV-unmutated patients. The OS was also significantly improved with ibrutinib + rituximab versus FCR (3-year OS, 98.8% vs 91.5%; P <.001). As expected, there was more myelosuppression and infections in the FCR arm, and there were more atrial fibrillation and hypertension noted with ibrutinib + rituximab. Like the ECOG1912 trial, the investigators for the ALLIANCE group designed a first-line treatment trial for older patients with CLL. The older patients were randomized to BR versus ibrutinib + rituximab versus ibrutinib.[46] The PFS was significantly improved in the two ibrutinib-containing arms compared with that seen in the BR arm (2-year PFS, 74% for the BR arm vs 88% for ibrutinib + rituximab vs 87% for ibrutinib monotherapy; P <.001 for the BR vs ibrutinib arms). Notably, there was no difference in the PFS for the two ibrutinib arms, indicating no additional benefit with the addition of rituximab to ibrutinib. There was no difference in OS among the three treatment arms.

Acalabrutinib is a second generation BTK inhibitor currently approved for both first-line and relapsed CLL.[47] In the ASCEND phase III trial, patients with relapsed or refractory CLL were randomized to receive acalabrutinib monotherapy versus investigator choice therapy (idelalisib + rituximab or BR). Patients had received a median of two prior therapies.[48] After a median follow-up period of 16.1 months, the median PFS was significantly longer with acalabrutinib monotherapy (PFS not reached) compared with investigator's choice (16.5 months; P <.0001). In the ELEVATE-TN phase III trial, patients with previously untreated CLL who were 65 years or older or 18 years or older with either a CIRS score greater than6 or a creatinine clearance of 30 to 69 mL/min were enrolled. Patients were randomized to acalabrutinib monotherapy versus acalabrutinib + obinutuzumab versus chlorambucil + obinutuzumab. The estimated PFSs at 2 years were 93% with acalabrutinib + obinutuzumab, 87% with acalabrutinib monotherapy, and 47% with chlorambucil + obinutuzumab. These trials (ASCEND and ELEVATE-TN) led to the approval of acalabrutinib in both relapsed or refractory and frontline CLL. There is an ongoing head-to-head phase III trial of ibrutinib versus acalabrutinib in patients with relapsed or refractory CLL with either a del(17p) or del(11q).

BCL-2 Inhibitor

CLL cells express high levels of antiapoptotic proteins of the Bcl-2 family, rendering them long-lived and resistant to senescence and death. Navitoclax (ABT-263) is an orally administered small-molecule inhibitor of Bcl-2, Bcl-w, and Bcl-xL. A phase I/II trial of orally administered navitoclax reported antitumor activity in patients with CLL; however, the dose-limiting toxicity was thrombocytopenia.[49] Thrombocytopenia was secondary to the accelerated platelet senescence from inhibition of Bcl-xL in the platelets. Venetoclax (ABT-199) was designed as a molecule with greater affinity for Bcl-2 and reduced affinity for Bcl-xL.[50] Unlike BTK inhibitors, the treatment with venetoclax, especially in combination with CD20 mABs can lead to measurable residual disease (MRD)–negative remissions. Venetoclax was studied in a phase III study in relapsed or refractory CLL. In this study (MURANO trial), 389 patients with relapsed or refractory CLL were randomized to receive venetoclax + rituximab (2 years of venetoclax + 6 months of rituximab) versus six cycles of BR.[51] The 4-year PFS rate was higher with venetoclax + rituximab versus BR (57.3% vs 4.6% (P <.0001).[52] Similarly, 4-year OS was in favor of venetoclax + rituximab arm (85.3% vs 66.8%; P <.0001). In a landmark analysis, MRD at the end of 2 years of venetoclax treatment correlated with PFS. Venetoclax was investigated in a phase III trial in first-line CLL (CLL14 trial).[53] Eligible patients were aged 18 years or older with coexisting conditions (CIRS >6 or creatinine clearance of 30–69 mL/min). Patients received venetoclax + obinutuzumab or chlorambucil + obinutuzumab. Venetoclax and chlorambucil were given for 1 year; obinutuzumab was given for 6 months in both arms. A total of 432 patients were enrolled. At a median follow-up period of 39·6 months, patients in the venetoclax + obinutuzumab arm had a significantly longer PFS than that seen with chlorambucil + obinutuzumab (P<.0001).[54] The median PFS was not reached for the venetoclax + obinutuzumab arm and was 35·6 months for the chlorambucil + obinutuzumab arm. The OS were similar in the two arms.

Phosphoinositide 3-Kinase Inhibitors

PI3K-δ is a critical kinase for activation, proliferation, and survival of B cells and is hyperactive in many B-cell malignancies, including CLL. Idelalisib is a potent, selective, reversible inhibitor of PI3K-δ. A phase I trial of idelalisib was conducted in relapsed and refractory patients with CLL.[55] A total of 54 patients were enrolled with a

median of five prior therapies. The median PFS was 15.8 months. A phase III clinical trial evaluated the activity of idelalisib + rituximab versus rituximab + placebo in patients with relapsed or refractory CLL in whom rituximab monotherapy would be considered appropriate.[56,57] A total of 220 patients were enrolled. This trial demonstrated superior efficacy for combined idelalisib and rituximab over that seen with rituximab and placebo, with a hazard ratio (HR) for PFS of 0.15 (P <.001) and HR for OS of 0.28 (P = .02). Pneumonitis was seen in 4% of the patients treated on the idelalisib + rituximab arm. Because of immune-mediated side effects and risk of infectious complications, the development of idelalisib in first-line CLL has been halted.[58] Duvelisib is a PI3K-δ and -γ inhibitor and is also approved for relapsed CLL based on the results of the DUO trial.[59]

Chimeric Antigen Receptor T-Cell Therapy

Please refer to Chapter 16 for a detailed outline of chimeric antigen receptor T-cell (CAR T) biology, general principles of use, toxicities, and their management. Briefly, CARs are engineered immune receptors introduced ex vivo into T cells, usually autologous, that redirect these cells to react against CLL cells. The CAR is a recombinant protein composed of an antigen-binding domain derived from single-chain Ig variable genes and intracellular signaling domains derived from CD3ζ and costimulatory domains derived from CD28 and/or CD137. The transduced T cells are infused into the patient, where they bind to the target antigen and induce T-cell activation and proliferation, cytokine production, and killing of cells expressing the target antigen. CD19 is the most common target of the current CAR T-cell trials, although other targets are being explored as well (Table 3–5). CAR T products targeting CD19 are approved by the Food and Administration for the treatment of patients younger than 26 years of age with refractory pre-B-acute lymphoblastic leukemia (ALL) or second or greater relapse and for the treatment of diffuse large B-cell lymphoma (DLBCL) in patients who have received two or more prior therapies. In the pivotal study of tisagenlecleucel in pre-B ALL, the CR rate was 83%, and the event-free survival (EFS) was 50% at 1 year.[60] In DLBCL, the ORR with axicabtagene ciloleucel was 82% (54% CR), and 42% of patients remained in remission at 15.4 months.[61] In contrast, response rates in the CLL studies have generally been lower (ORR, 57%–71%; CR, 21%–28%).[62,63] Nevertheless, the treatment appears to have curative potential, as indicated by the fact that two of the original patients treated at the University of Pennsylvania[62] remain in remission 7 years after therapy.[64]

The underlying reasons for poorer responses in patients with CLL compared with those with ALL and DLBCL are not completely clear. In particular, the incidence of relapse because of loss of the CD19 target appears lower than in ALL and DLBCL.[65] One study, from the University of Pennsylvania,[66] demonstrated that the CAR T-cell phenotype in the apheresis product, before infusion, was strongly associated with response. Specifically, higher numbers of memory T cells and lower levels of immune checkpoint molecule expression and markers of T-cell exhaustion were associated with a higher likelihood of CR. This suggests that a patient's T-cell "fitness" may be important in determining the likelihood of responding to treatment with autologous CAR T cells. Attempts are being made to use novel combination

TABLE 3–5 Results of Some Selected Studies of Autologous Chimeric Antigen Receptor T-Cell Therapy Targeting CD19 in Chronic Lymphocytic Leukemia

	Patients (*n*)	Co-stimulation	Treatment Combination	Responses
Porter et al[62] (2015)	14	4-1BB	None	ORR, 57% CR, 28% MRD negative, 28%
Turtle et al[63] (2017)	24 (5 Richter transformation)	4-1BB	None	ORR, 71% CRR, 21% MRD negative, 58%
Gauthier et al[67] (2018)	17	4-1BB	Ibrutinib	ORR, 88% CRR, 83% (evaluable patients) MRD negative, 75%
Gill et al[68] (2018)	19	4-1BB	Ibrutinib	ORR, 71% CRR, 43% MRD negative, 78%
Siddiqi et al[105] (2019)	23	4-1BB	None	ORR, 82% CR, 46% MRD negative, 60%

CR, complete remission; MRD, Measurable residual disease; ORR, overall response rate.

strategies to enhance the response rates to CAR T-cell therapy in patients with CLL. Single-center experiences from the group at the Fred Hutchison Cancer Research Center and The University of Pennsylvania suggest that the combination of ibrutinib with CAR T may enhance response rates while simultaneously reducing the likelihood of severe cytokine release syndrome.[67,68] The combination of lisocabtagene maraleucel with ibrutinib is being explored in the ongoing phase 2, multicenter study TRANSCEND-CLL-04 (NCT03331198).

Stem Cell Transplantation

Because CLL is a disease of older adults, reduced-intensity conditioning (RIC) allogeneic stem cell transplant (allo-SCT) is the most common type of transplant offered to patients with CLL. RIC allo-SCT in CLL leads to 5-year EFS and OS rates of 35% to 45% and 50% to 60%, respectively.[69] Khouri et al[70] reviewed outcomes of 86 patients with CLL who underwent RIC allo-SCT at MDACC. The median age was 58 years. Eighty-three of the 86 patients experienced donor cell engraftment. Overall, the estimated 5-year PFS and OS rates were 36% and 51%, respectively. Notably, immune manipulation by withdrawal of immunosuppression or donor lymphocyte infusions enhanced clinical responses, indicating that CLL is a disease sensitive to immune manipulation. With the introduction of novel targeted therapies, such as BTK inhibitors and venetoclax, the numbers of allo-SCT procedures being performed for CLL are falling dramatically.[71] Nevertheless, allo-SCT will likely continue to remain an important strategy for selected group of patients such as those with high-risk CLL (del(17p) or *TP53* mutation) who are relapsed or refractory to novel agents. The European Research Initiative on CLL and European Society of Bone Marrow Transplant released a paper outlining a proposed risk assessment framework for CLL that includes cytogenetic and molecular features, as well as refractoriness to CIT, targeted agents, or both.[72] This framework assigns patients to high-risk I category if they have failed CIT *and* have a *TP53* abnormality (deletion of chromosome 17p or *TP53* mutation). High-risk category II comprises patients relapsed after CIT *and* a targeted agent, regardless of molecular features. The framework recommends consideration of cellular immunotherapy (CAR T or allo-SCT) for patients in high risk I or high risk II categories. In general, patients in the high risk II category should have a lower threshold for proceeding to allo-SCT. However, this remains a complex area and numerous factors need to be carefully considered when determining whether to proceed with cellular immunotherapy in an individual patient. When assessing patients in high risk I or II categories, the physician must weigh the risk of treatment-related morbidity and mortality from cellular immunotherapy (particularly allo-SCT) against the risk of unsalvageable CLL relapse or Richter transformation (Table 3–6). Complicating this decision is the lack of high-quality prospective data to guide the decision.

Patient Stratification for First-Line Treatment

Based on age, comorbidities, and CLL FISH, *TP53* mutation status, and *IGHV* mutation status, patients can be categorized into several groups:

- **Young patients (typically 65 years or younger) without major comorbidities and *IGHV*-mutated, no del(17p), and no *TP53* mutation:** For these

TABLE 3–6 Factors in Consideration for Cellular Therapy versus Targeted Therapy

Factors in Favor of Cellular Immunotherapy		Factors in Favor of Continuing the Targeted Agent	
Clinical Features (Predictive of Lower TRM)	Disease Features (Predictive of Higher Likelihood of Relapse in the Absence of Cellular Immunotherapy)	Clinical Features (Predictive of Higher TRM)	Disease Features (Predictive of Lower Likelihood of Relapse in the Absence of Cellular Immunotherapy)
Younger age	Refractory to multiple prior therapies	Older age	Received fewer lines of prior therapy
Few comorbid medical conditions	Complex karyotype	Frail, many comorbid medical conditions	Lack of complex karyotype
Well-matched donor (for allo-SCT)		Deep remission (eg, CR with U-MRD)	Deep remission (eg, CR with U-MRD)[a]
Access to CAR T-cell study		No well-matched donor or access to CAR T-cell study	

[a]Although patients who achieve deep remission with targeted therapy (eg, venetoclax + rituximab) are at lower risk of disease progression, these patients may also have better post-transplant outcomes than patients with significant disease burden.
Allo-SCT, allogenic stem cell transplant; CAR T, chimeric antigen receptor T-cell; CR, complete remission; TRM, Transplant-related mortality; U-MRD, undetectable measurable residual disease.

patients, treatment with FCR is appropriate given the very long-term benefit seen in about half of these patients after first-line FCR. Additionally, in the E1912 trial, there was no difference in PFS for FCR versus ibrutinib + rituximab for the *IGHV*-mutated group, at least with the median 4 years of follow-up. If a nonchemotherapy approach is desired, treatment with ibrutinib, acalabrutinib (+/- obinutuzumab) or the combination of venetoclax + obinutuzumab could be considered. Ibrutinib and acalabrutinib are given indefinitely. Venetoclax + obinutuzumab is a lime-limited therapy of 1 year.

- **Older adults or young patients with comorbidities or young patients with *IGHV*-unmutated (no del(17p), no *TP53*-mutation):** For these patients, a nonchemotherapy approach is preferred. Treatment with ibrutinib, acalabrutinib (+/-obinutuzumab), or the combination of venetoclax + obinutuzumab is appropriate.
- **Patients with del(17p) or *TP53*-mutation:** Treatment with a BTK inhibitor such as ibrutinib or acalabrutinib (+/- obinutuzumab) is preferred. Chemotherapy should not be used for these patients.

Supportive Care

Patients with CLL can have a host of complications ranging from immune cytopenias to infectious issues.

Autoimmune Complications of Chronic Lymphocytic Leukemia

Autoimmune hemolytic anemia (AIHA), autoimmune thrombocytopenia (ITP), and pure red cell aplasia (PRCA) develop in some patients with CLL. The incidence of AIHA is 4% to 11% and is 2% to 3% for ITP.[73] PRCA and autoimmune neutropenia (AIN) are both rare (<1%).[74] The pathogenesis is complex. The autoantibodies in autoimmune cytopenia (AIC) associated with CLL are typically polyclonal and usually IgG, indicating that they are not produced by the leukemic clone. Patients with unmutated *IGHV* and high-risk cytogenetics, as well as stereotyped B-cell receptor subsets 3 and 7, are more likely to develop AIHA or ITP.[75,76] Therapeutic agents, particularly purine analog monotherapy, may trigger AIC, possibly because of an imbalance in the ratio of T-regulatory cells to T helper type 17 cells.[77] The risk of treatment-emergent AIC during treatment with targeted agents appears lower. Prednisone is the usual treatment for patients with AIHA and ITP, with a high likelihood of response. However, the majority of patients relapse when treatment is stopped. Intravenous immunoglobulin (IVIG) produces response in 40% of patients, but these responses tend to be transient. CD20 mAbs, particularly rituximab, have also been used to treat patients with autoimmune complications of CLL either as monotherapy or in combination with cyclophosphamide and dexamethasone (RCD regimen).[78] Cyclosporine is another option for treatment of AIC and can produce responses even in patients with steroid-refractory immune cytopenias.[79] The thrombopoietin mimetic eltrombopag showed high response rates with good response durability.[80,81] Splenectomy is reserved for refractory cases.

The role of novel, targeted agents in the treatment of CLL-associated AIC is ill-defined, given patients with steroid-dependent or -refractory AIC were systematically excluded from clinical trials of these agents. However, a recent case series from the Mayo Clinic demonstrated improvement in cytopenias and ability to wean or discontinue immunosuppression in the majority of patients with CLL who had AIC at the time of initiation of ibrutinib.[82] An ongoing clinical trial (NCT03827603) is assessing ibrutinib plus rituximab treatment in the management of patients with steroid-refractory AIHA.

Hypogammaglobulinemia

Hypogammaglobulinemia is a frequent complication of CLL. The most common cause of morbidity in patients with CLL is infection, in part caused by hypogammaglobulinemia. A randomized study evaluated the use of IVIG versus placebo in patients with CLL showed significant reduction in bacterial infections but no difference in the number of life-threatening infections or nonbacterial infections.[83] Replacement therapy with IVIG is indicated for patients with hypogammaglobulinemia and repeated sinobronchial infections.

TRANSFORMATION

Richter Syndrome

The term *Richter syndrome (RS)* refers to the development of aggressive large-cell lymphoma during the course of CLL. Rarely, disease transformation to Hodgkin lymphoma is seen. RS is noted in approximately 5% of patients with CLL. RS is usually associated with worsening systemic symptoms, including B symptoms, elevated LDH, rapid tumor growth, or extranodal involvement. Diagnosis requires tissue biopsy. Positron emission tomography scans help identify sites to direct tissue biopsy, and every attempt should be made to biopsy the site with the maximum SUV.[84] In 80% of patients, the DLBCL is clonally related to the original CLL, which is a marker of poor prognosis (median survival time, ~1 year). In the other 20% of patients, the DLBCL is clonally

unrelated to the original CLL, possibly representing a new neoplasm and the prognosis is similar to that of de novo DLBCL (median survival time, ~5 years). Risk factors associated with development of RS in a patient with CLL include lymph node size greater than 3 cm, number of prior therapies, advanced Rai stage (III or IV), del(17p), del(11q), unmutated *IGHV* gene, short telomere length (<5000 bp), stereotyped B-cell receptors, and expression of CD38, CD49d, or ZAP-70.[85] The presence of a *NOTCH1* mutation is also associated with an increased risk of RS. *TP53* mutation is commonly acquired at the time of CLL transformation and is the most important negative prognostic feature, other than the clonal relationship to the underlying CLL.[85] Other common genetic abnormalities seen in patients with RS include activation of *C-MYC* and inactivation of *CDKN2A,* indicating possible cell cycle deregulation, and *NOTCH1* mutations (commonly in conjunction with trisomy 12).[86,87] The traditional treatment strategy has been intensive CIT such as OFAR (oxaliplatin, fludarabine, cytarabine, and rituximab), hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone), and R-CHOP (rituximab, cyclophosphamide, doxorubicin hydrochloride, = Oncovin, and prednisone).[88] No direct comparative data exist to guide treatment choice, and this should be individualized according to institutional experience and patient fitness. Allo-SCT remains the only potentially curative option for patients with RS. Two promising approaches to improve outcomes for this group of patients have recently been developed: the first is the use of programmed death 1 inhibitors, with or without ibrutinib. Pembrolizumab monotherapy achieved a 44% ORR (11% CR) among 9 patients with RS,[89] and ibrutinib + nivolumab achieved an ORR of 42% (33% CR) in 24 patients.[90]

Prolymphocytic Transformation

The NCI-IWCLL criteria allow a diagnosis of CLL to be made in the presence of 55% or less prolymphocytes. The presence of greater than 55% prolymphocytes indicates prolymphocytic transformation. PLL is characterized by a high number of circulating prolymphocytes, splenomegaly, minimal lymphadenopathy, and a median survival time of less than 3 years.

HAIRY CELL LEUKEMIA

Classical hairy cell leukemia (cHCL) is an uncommon B-cell lymphoproliferative disorder affecting adults and represents 2% of all leukemia. There is a marked male preponderance. Most patients have cytopenias; splenomegaly is also frequent at presentation. Hairy cells can be seen in the peripheral blood, but their numbers vary. Most typically, cHCL presents with pancytopenia, monocytopenia and a paucity of circulating malignant cells. Patients with large numbers of circulating cells may have hairy cell leukemia variant (HCL-v) or VH4-34 molecular variant (see later). Hairy cells are twice as large as normal lymphocytes, with the nuclei showing a loose chromatin pattern and villus-like cytoplasmic projections (Fig. 3–8) (best viewed under phase-contrast microscopy). Hairy cells typically show positive staining for tartrate-resistant acid phosphatase (TRAP) (Fig. 3–9). Hairy cells infiltrate the bone marrow in an interstitial or focal pattern, with clear zones between cells ("fried-egg"

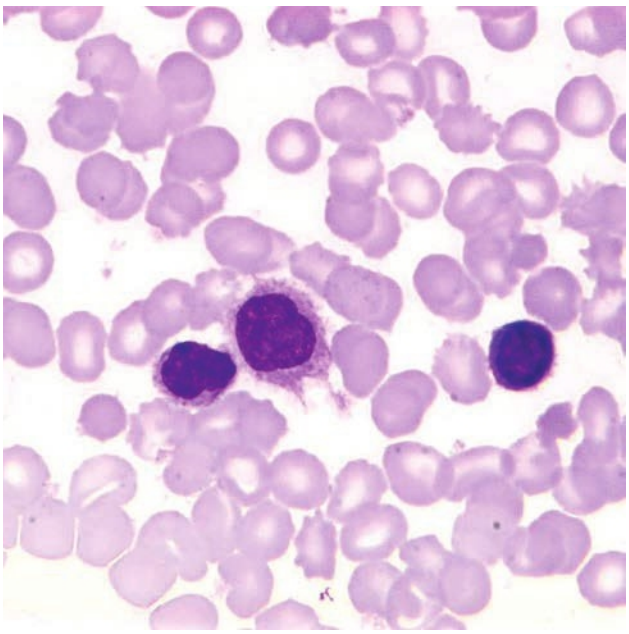

FIGURE 3–8 **Hairy cell in peripheral blood with cytoplasmic projections.**

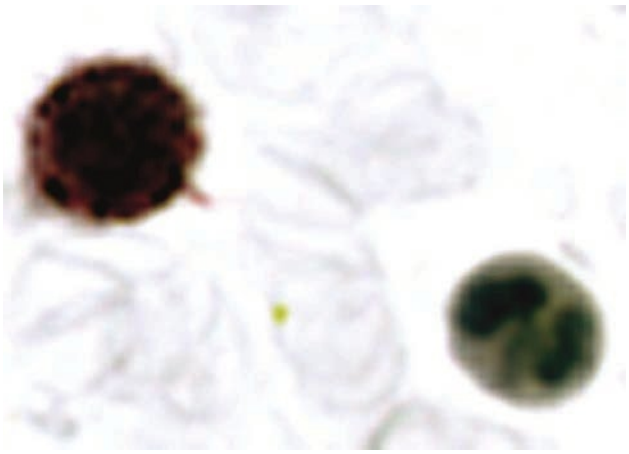

FIGURE 3–9 **Hairy cell staining for tartrate-resistant acid phosphatase (*left*). Note the absence of orange-brown staining in a neutrophil.**

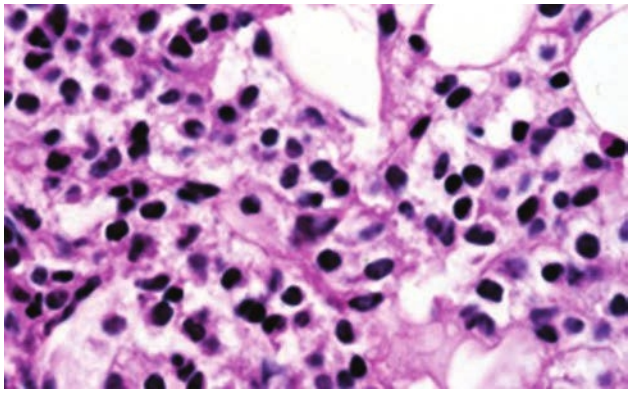

FIGURE 3–10 **Bone marrow involvement by hairy cell leukemia showing a "fried-egg" appearance (hematoxylin and eosin stain).**

appearance) (Fig. 3–10). Marrow reticulin is increased, and aspirates may result in a "dry tap."

Immunophenotypic analysis of hairy cells shows the presence of CD19, CD20, CD22, CD25, and CD103; in contrast to CLL, hairy cells are negative for CD5 and CD23. Hairy cells also stain strongly for surface Ig and FMC-7. HCL-v usually lacks CD25 and CD123 expression. CD200 is a specific marker, being highly expressed in cHCL but not in HCL-v or other morphologically similar lymphoproliferative disorders such as marginal zone lymphoma. Although CD200 is also expressed in CLL, the immunophenotype and morphology in CLL are sufficiently different from cHCL that diagnostic confusion is unlikely to arise.[91] The *BRAF V600E* mutation is present in most patients with cHCL.[92] Notably, patients with HCL-v and the VH4-34 molecular variant of cHCL lack *BRAF* mutations, instead often carrying *MAP2K1* mutations, which result in constitutive MEK1 phosphorylation and downstream ERK activation.[93] This may have implications for both diagnosis and treatment of HCL, and vemurafenib, a BRAF inhibitor, is currently in clinical trials as therapy for relapsed or refractory HCL.

Treatment decisions are usually based on the degree of cytopenia and accompanying complications (eg, bleeding, infections, anemia). Pentostatin and cladribine (2-CDA) are the nucleoside analogs that are the mainstay of treatment of HCL. Pentostatin is administered at 4 mg/m^2 every 2 weeks until maximum response and cladribine is given at 0.1 mg/kg/day as a continuous intravenous (IV) infusion for 7 days, or the same total dose can be administered as a 2-hour infusion over 5 days. Because cladribine offers a more convenient schedule (single course of therapy) and produces remission rates comparable to those achieved with pentostatin, cladribine is more frequently used. Estey et al[94] reported a CR rate of 78% with cladribine in patients who had newly diagnosed or previously treated HCL. One trial evaluated a strategy to improve the initial response to nucleoside analog therapy by adding additional doses of rituximab. Sequential therapy with 8 doses of rituximab 375 mg/m^2 weekly after completion of cladribine achieved a CR rate of 100% and increased MRD negativity from 14% to 74% (including 76% of untreated patients and 64% of patients in first relapse). Five-year failure-free survival (FFS) was 95%. Longer-term follow-up will be required to determine whether this translates into improved FFS for the first-line patients.[95,96] A CR rate of 100% was reported, and after a median follow-up period of 25 months, the median CR duration, PFS, and OS had not been reached. The majority of relapsed patients achieve second remission when retreated with pentostatin or cladribine. The choice of agent may depend on the duration of the first remission: if less than 3 years, use an alternate agent; if more than 5 years, use the same agent. Rituximab may improve results in relapsed cHCL and HCL-v. Of note, after a median follow-up period of 5 years, no patient has relapsed and FFS after second-line cladribine + rituximab was significantly longer (P = .004) than after initial monotherapy (in which median FFS was 6 years).[96] A more recent phase 2 randomized study has demonstrated that concurrent rather than delayed rituximab administration with cladribine is associated with a higher rate of CR. Splenectomy, although performed infrequently, can induce hematologic remission. The use of interferon-α is currently limited to patients unresponsive to nucleoside analogs. These latter two treatments are mainly confined to historical interest. A percentage of patients may relapse with cladribine-resistant disease. In addition, 10% to 20% of patients with the variant form of HCL have a poor response to nucleoside analogs.

Classic and variant hairy cells strongly express CD22. Recombinant immunotoxin, BL22, has been used in the treatment of chemotherapy-resistant HCL. Moxetumomab pasudotox (HA22 or CAT-8015) is derived from BL22, selected for high-affinity for CD22. A second-generation immunotoxin was developed, known as HA22/CAT-8015/moxetumomab pasudotox; this has greater binding affinity for CD22 and was demonstrated to have greater in vitro and in vivo toxicity against lymphoma cell lines and CLL/HCL cells.[97] A pivotal, open-label study demonstrated impressive activity in patients relapsing after at least two lines of prior therapy.[98] Among 80 patients treated, ORR was 75% and CR rate 41%; 85% of the patients in CR were MRD negative by multiparameter flow cytometry in bone marrow. Rapid improvement in hematologic parameters was noted. Median duration of CR and PFS have not been reached. Treatment was generally well-tolerated, with reversible hemolytic uremic syndrome occurring in 7.5% of patients and capillary leak syndrome in 5%.

The importance of constitutive BRAF-MEK-ERK signaling, induced by the *BRAF V600E* mutation in cHCL[92] led to two separate phase II studies being conducted with the BRAF inhibitor vemurafenib. This drug is approved for the treatment of metastatic melanoma,

which also carries the canonical *BRAF V600E* mutation, but is not currently approved for the treatment of HCL. The patient populations were either heavily pretreated or had early relapse after pentostatin therapy. In the Italian study, 6 patients had not responded to or relapsed within 1 year of purine analogue (PA) therapy, and 20 had either relapsed within 1 to 2 years of the first course or within 4 years of the second course of PA therapy. In the US trial, most patients were enrolled based on having received three or more prior courses of PA therapy. Patients received vemurafenib for 12 to 20 weeks in total and could be retreated at progression. ORR and CRR were 96% to 100% and 35% to 42%, respectively. In the Italian study, which had a longer follow-up, median relapse-free survival was 9 months; in the US study, 1-year PFS was 73%. Some patients responded to retreatment at relapse. Toxicity was generally manageable and was similar to that seen in studies of patients with melanoma; it included rash, photosensitivity, palmar or plantar fibrosis, warts, and arthralgias. Dose reduction was required in 50% to 58% of patients. Seven patients developed skin cancer (six nonmelanoma, one superficial spreading melanoma).[99,100]

PROLYMPHOCYTIC LEUKEMIA

PLL is characterized by splenomegaly, a high number of circulating prolymphocytes, minimal lymphadenopathy, and a median survival of less than 3 years. Prolymphocytes are larger and less homogenous than CLL cells; they have abundant clear cytoplasm, clumped chromatin, and a prominent nucleolus (see Figs. 3–7). Prolymphocytes can be of either B- or T-cell type. B-cell PLL cells usually do not express CD5 but stain strongly for surface Ig and FMC-7 (see Table 3–2). T-cell PLL demonstrates postthymic T-cell nature (TdT,$^-$ CD1a,$^-$ CD5+, CD2+, CD7+). A majority of the cases express CD4+ and are CD8.$^-$ Chromosomal abnormalities of chromosome 14 are present in more than 75% of patients. TCL-1 is commonly overexpressed and detectable by immunohistochemistry.

For T-PLL, IV alemtuzumab is the treatment of choice. Dearden et al[101] reported superior results in the first-line setting with IV alemtuzumab compared with results with subcutaneous alemtuzumab. With IV alemtuzumab, an ORR of 91% and CR rate of 81% were reported. Allo-SCT is the preferred consolidation regimen. Pentostatin should be considered for patients with poor response to alemtuzumab or relapsed disease. Retreatment with alemtuzumab is a reasonable option if the duration of the first remission was longer than 12 months.

LARGE GRANULAR LYMPHOCYTIC LEUKEMIA

Large granular lymphocytes (LGLs) are larger than normal lymphocytes and contain azurophilic granules in their cytoplasms (see Fig. 3–6). They normally comprise 10% to 15% of peripheral blood mononuclear cells. Clonal expansion of LGLs can arise from either of the normal cellular counterparts and so may have a natural killer (NK)- or T-cell phenotype; the T-cell phenotype composes 80% of LGL leukemias. T-cell LGL cells have a CD3+/CD57+/CD56$^-$ immunophenotype, and NK-cell LGL cells are CD3$^-$/CD56+/CD57$^-$.[102] T-cell receptor gene rearrangement studies can help establish the clonality. About 40% of patients with NK- and T-cell LGL leukemia were noted to have mutations in the *STAT3* gene.[103] Mutations in *STAT5b* were noted in a smaller subset (2%) of patients.[104] The clinical presentation of LGL leukemia is usually indolent. Cytopenias, including neutropenia with accompanying infections, thrombocytopenia, and anemia, are common. A small percentage of patients with LGL leukemia develop a more aggressive course; these patients tend to have an NK-cell phenotype. Several therapies, including low-dose methotrexate, oral cyclosporine, and oral cyclophosphamide with or without oral prednisone, have all been effective.

MD ANDERSON PRACTICE TIPS

- It is important to assess for *TP53* aberration by performing both FISH for del(17p) and sequencing for *TP53* mutation.
- Repeat prognostic marker testing (CLL FISH panel, *TP53* sequencing) at the time of disease relapse because patients may have acquired additional clonal abnormalities (clonal evolution). IGHV mutation status for an individual patient does not change over time, and therefore, there is no need to repeat, if already known.
- CIT is currently reserved for only young patients with no major comorbidities with mutated IGHV and no *TP53* aberration.
- Approved targeted therapies in first-line CLL include ibrutinib, acalabrutinib, and the combination of venetoclax and obinutuzumab. We generally do not combine BTK inhibitors with CD20 mAB in patients with CLL.
- Patients who have failed targeted therapies, especially those with *TP53* aberrant disease, should be referred for cellular therapies (allo-SCT, CAR T-cell therapies).
- Outcomes of CIT for Richter transformation remain dismal. These patients should be referred for clinical trials.

4 Chronic Myeloid Leukemia

Koji Sasaki
Elias Jabbour
Jorge Cortes
Hagop Kantarjian

KEY CONCEPTS

- The survival of patients with chronic myeloid leukemia (CML) has improved significantly since the advent of tyrosine kinase inhibitor (TKI) therapy. With the availability of TKI and proper management, the expected survival of patients with chronic phase CML (CML-CP) is approaching that of the general population.
- Any of the four TKIs approved for frontline therapy of CML-CP may be selected. These include imatinib, dasatinib, nilotinib, and bosutinib. Second-generation TKIs are superior to imatinib in achieving faster and deeper responses compared with imatinib, but survival is similar because of the availability of effective TKI salvage therapies.
- Factors considered in choosing TKI therapy in the frontline setting include patient age, comorbidities, adverse events profile, and disease risk score, as well as the TKI-associated schedule of administration and cost. Kinase domain mutation profile plays no role in selecting an initial TKI but becomes relevant in relapse.
- Most TKIs are reasonably well tolerated with close observation and supportive care. However, each TKI therapy has a distinct toxicity profile that should be considered when deciding on therapy.
- Second- and third-generation TKIs have not been compared head to head. Mutational analysis is required after failure of imatinib or second-generation TKIs, or after progression to accelerated phase CML (CML-AP) or blastic phase (CML-BP). Baseline mutational analysis are not recommended in newly diagnosed CML-CP because it does not help predict treatment outcome.
- Allogeneic stem cell transplant should be considered in patients who progress from CML-CP to CML-AP/CML-BP after TKI therapy failure and who fail second- or third-generation TKI while still in CML-CP.

Chronic myeloid leukemia (CML) is a myeloproliferative disorder of pluripotent hematopoietic stem cells. The Philadelphia (Ph) chromosome results from a reciprocal translocation between chromosomes 9 and 22 and constitutes the cytogenetic hallmark of CML. A critical milestone in CML research was the demonstration that this translocation involved the *ABL1* (v-abl Abelson murine leukemia viral oncogene homolog 1) gene on chromosome 9 and the *BCR* (breakpoint cluster region) gene on chromosome 22 and resulted in the formation of the chimeric *BCR-ABL1* fusion transcript that encodes the constitutively active BCR-ABL1 tyrosine kinase.[1] This in turn is responsible for cell growth and replication through downstream signaling pathways.[2–8] The discovery that *BCR-ABL1* plays a pivotal role in the pathogenesis of CML set the stage for the development of therapeutic strategies aimed specifically at inhibiting this kinase and its downstream signals. Herein, we summarize the current knowledge regarding the molecular biology of CML and the treatment modalities, including novel BCR-ABL1 tyrosine kinase inhibitors (TKIs).

EPIDEMIOLOGY

CML has an incidence of 1 to 2 cases per 100,000 adults. It accounts for approximately 15% of newly diagnosed cases of leukemia in adults.[9] The median age of onset of CML is 60 to 65 years, and the incidence increases with age. There are no known hereditary, geographic, familial, or ethnic associations. There are no known causal etiologies, although an increased risk has been noted with exposure to ionizing radiation.[10]

In 2020, it was estimated that there would be 8450 new cases of CML in the United States, and about 1130 people would die of this disease.[11] In the TKI era, the expected 5-year survival time of patients with CML chronic phase is comparable to that of the general population.[12] Since the introduction of imatinib in 2000, the annual mortality rate in patients with CML has decreased from 10% to 20% to 1% to 2%.[11] Consequently, the prevalence of CML in the United States, estimated at about 30,000 cases in 2000, has increased by approximately 7000 to 8800/year. It was previously estimated that the prevalence of CML cases would reach a plateau of 150,000 to 180,000 or more by the year 2030.[13] However, given the current number of new cases of CML in the United States, the prevalence plateau is now estimated to be 400,000 to 450,000 cases in the United States, which may not be reached until 2040 to 2050.

MOLECULAR BIOLOGY

CML is a clonal myeloproliferative neoplasm derived from an abnormal pluripotent hematopoietic stem cell that has acquired the *BCR-ABL1* fusion gene, usually through t(9;22)(q34;q11.2), also known as Ph, involving the long arms of chromosome 9 and 22. This is translated into a constitutively active oncoprotein, the BCR-ABL1 tyrosine kinase. This oncoprotein activates multiple downstream pathways, including PI3 kinase, nuclear factor-κB, JAK/STAT, RAS, RAF, ERK, MYC, and JNK. Depending on the breakpoint on the *BCR* gene, three main Ph variants can occur. In most patients with CML and in one third of those with Ph-positive acute lymphoblastic leukemia (ALL), the breakpoint maps to the major breakpoint cluster region (M-*bcr*), which spans *BCR* exons 12 to 16 (formerly called b1–b5), giving rise to a fusion transcript with either e13a2 (b2a2) or e14a2 (b3a2) junctions that translates into a 210-kDa protein ($p210^{BCR\text{-}ABL1}$). In two thirds of patients with Ph-positive ALL and rarely in CML, the breakpoints within *BCR* localize to an area of 54.4 kb between exons e2′ and e2, termed the minor breakpoint cluster region (m-*bcr*), giving rise to a fusion transcript e1a2, which translates to a 190-kDa protein ($p190^{BCR\text{-}ABL1}$). A third breakpoint cluster region (μ-*bcr*) has been identified giving rise to a fusion transcript e19a2, which translates to a 230-kDa fusion protein ($p230^{BCR\text{-}ABL1}$) associated with a more indolent CML course and with a phenotype more similar to chronic neutrophilic leukemia.

The Ph chromosome can be detected by conventional cytogenetics in 90% to 95% of the cases. In the remaining 5% to 10% of the Ph-negative cases by cytogenetics, *BCR–ABL1* rearrangement can be recognized with fluorescent in situ hybridization (FISH) technique and high-sensitivity reverse transcriptase polymerase chain reaction (RT-PCR). Additionally, when detected by conventional cytogenetics, 90% of patients have the typical t(9;22), and 5% to 10% of the patients have variant translocations, which can be simple (involving chromosome 9 and a chromosome other than chromosome 22) or complex (involving one or more chromosomes in addition to chromosomes 9 and 22). Patients with Ph-negative *BCR-ABL1* rearranged CML, as well as those with Ph variants have similar response rates to therapy and prognosis compared to patients with Ph-positive CML.

CLINICAL PRESENTATION AND NATURAL HISTORY

There are three separate phases of CML: chronic phase (CP), intermediate or accelerated phase (AP), and terminal or blastic phase (BP). Even though all three represent a stepwise progression of disease from the typically indolent CP to the most aggressive and frequently terminal BP, the natural course of the disease, particularly on adequate treatment with TKIs, may not include progression out of CP, nor will the disease always include all three phases when progressing. Approximately 85% to 90% of patients present in CP. About 50% of patients diagnosed with CML are asymptomatic. The diagnosis often occurs during routine physical examination or blood tests. When present, the symptoms mostly arise from low counts such as anemia and thrombocytopenia causing fatigue and bleeding. Splenomegaly is the most consistent physical finding, detected in 20% to 40% of cases, resulting in early satiety, weight loss, and left upper quadrant pain and fullness. In rare cases, patients may present with features of hyperviscosity from marked leukocytosis, including priapism, stroke, and retinal hemorrhages. Headaches, bone pain, arthralgias, pain from splenic infarction, and fever are more frequent with CML transformation. Most patients who transform to advanced phases evolve into AP before BP, but 20% transition into BP without AP warning signals. CML-AP might be insidious or present with worsening anemia, splenomegaly, and organ infiltration. CML-BP presents as an acute leukemia (myeloid in 60%, lymphoid in 30%, megakaryocytic or undifferentiated in 10%) with worsening constitutional symptoms, bleeding, fever, and infections. Involvement of extramedullary tissues such as the lymph nodes, skin, and soft tissues is generally limited to patients with CML-BP.

Various classifications were used to define the different CML phases. The European LeukemiaNet (ELN) classification defines CML-AP as the presence of any of the following features: 15% or more blasts

TABLE 4–1 Diagnostic Criteria of Accelerated Phase According to MD Anderson Cancer Center (MDACC), International Bone Marrow Transplant Registry (IBMTR), and World Health Organization (WHO)

	MDACC	IBMTR	WHO
Blasts (%)	15–29	10–29	10–19[a]
Blasts + promyelocytes (%)	≥30	≥20	NA
Basophils (%)	≥20	≥20[b]	≥20
Platelets ($\times 10^9$/L)	<100	Unresponsively high or persistently low	<100 or >1000 unresponsive
Cytogenetics	CE	CE	CE not at diagnosis
WBC count	NA	Difficult to control or doubling <5 days	NA
Anemia	NA	Unresponsive	NA
Splenomegaly	NA	Increasing	NA
Other	NA	Chloromas, myelofibrosis	Megakaryocyte proliferation, fibrosis

[a]In the WHO criteria, blastic phase is defined as a blast percentage of 20% or higher. In the MDACC and IBMTR, a definition of blastic phase requires the presence of at least 30% blasts.
[b]Basophils plus eosinophils.
CE, clonal evolution; NA, not applicable; WBC, white blood cell.

in the peripheral blood and/or the bone marrow, 30% or more blasts plus promyelocytes in the peripheral blood and/or the bone marrow, 20% or more basophils in the peripheral blood and/or the bone marrow, platelets 100×10^9/L or less unrelated to therapy, and cytogenetic clonal evolution (Table 4–1). The average survival period of patients in CML-AP was 1 to 2 years before the TKI era. With TKI therapy, the estimated 4-year survival has increased to 60% to 70%. In contrast to CML-AP after CML-CP, de novo CML-AP has a better prognosis with frontline TKI therapy, with an estimated 8-year survival rate of more than 80%, particularly when treated with second-generation TKIs.[14]

A diagnosis of CML-BP requires the demonstration of at least 30% blasts (20% in the World Health Organization classification) in the peripheral blood and/or the bone marrow or the presence of extramedullary blastic foci. The median survival of patients in CML-BP before the introduction of TKI therapy was 2 to 6 months; with TKI- based therapy, it improved to a median of 1 to 3 years, particularly when TKI is combined with chemotherapy.[15]

DIAGNOSIS AND CLINICAL WORK-UP

The typical presentation of CML involves leukocytosis with a left shift including myelocytes and metamyelocytes seen in the peripheral blood. Additionally, basophilia and in some cases eosinophilia can be predominant. The diagnosis of typical CML requires the presence of Ph abnormality, the t(9,22)(q34;q11) by routine karyotype, or the presence of BCR-ABL1 rearrangement noted by FISH or by RT-PCR.[16–18] A FISH analysis relies on the co-localization of large genomic probes specific to the *BCR* and *ABL1* genes. Comparison of simultaneous marrow and blood samples by FISH analysis shows high concordance. FISH studies may have a false-positive range of 1% to 5% depending on the probes used.

RT-PCR amplifies the region around the splice junction between *BCR* and *ABL1*. It is highly sensitive in detecting and monitoring minimal residual disease. Simultaneous peripheral blood and marrow RT-PCR studies show a high level of concordance. False-positive and false-negative results can happen with PCR. A 0.5- to 1-log difference in some samples can occur depending on testing procedures, sample handling, and laboratory experience.[16–18]

Although both FISH and RT-PCR can confirm the presence of the Ph chromosome, a bone marrow aspiration should be performed in all suspected cases of CML at diagnosis. This not only confirms the diagnosis (by cytogenetics) but also helps stage the disease (ie, percentage of blasts and of, basophils; and presence of additional chromosomal abnormalities [clonal evolution]). The Ph chromosome is usually present in 100% of metaphases, often as the sole abnormality. About 10% to 15% of patients have additional chromosomal changes, most frequently involving trisomy 8, isochromosome 17, additional loss of material from 22q or double Ph, or abnormalities involved of chromosome 3. Among these cytogenetic abnormalities, i(17)(q10), -7/del7q, and 3q26.2 translocations, are associated with a particularly poor prognosis.[19] Clonal evolution is considered a criterion of AP, particularly when it occurs during the course of the

disease. Corresponding molecular alterations that follow these changes include deregulation of p53, RB1, C-MYC, and AML-EVI1.

For correlative purpose and monitoring without necessarily performing marrow evaluation studies, a complete cytogenetic response (CCyR; 0% Ph-positive metaphases by cytogenetic) is grossly equivalent to a negative FISH test result (±2%) and *BCR-ABL1* transcripts by International Scale (IS) less than 1%. A partial cytogenetic response (Ph-positive metaphases 1%–35%) is approximately equivalent to *BCR-ABL1* transcripts 10% or less (IS).

The RT-PCR is an important diagnostic tool in CML and should be performed in all suspected CML cases. In patients with Ph-negative CML, which comprises 5% to 10% of the cases of CML, detection of *BCR-ABL1* rearrangement helps establish the diagnosis. RT-PCR also helps determine the type of transcript involved. This is helpful in monitoring disease status and response to therapy. Ninety percent of the cases have of the classical p210 transcripts, e13a2 (b2a2), and e14a2 (b3a2). Less common types include the p190 transcript, (e1a2) and the p230 transcript (e19a2). In 2% of the cases, patients may harbor other variant transcripts, such as e13a3 and e14a3. These variant transcripts along with the p230 transcript e19a2 are not detected by the routine RT-PCR probe. Hence, if RT-PCR is not performed at baseline, patients with these transcripts can be falsely considered to have undetectable transcripts because of treatment.

PROGNOSTIC TOOLS IN CHRONIC MYELOID LEUKEMIA

The different CML phases predict for very different survival probabilities. However, the prognosis is also variable among patients in the same phase of the disease. Several patient and disease characteristics have prognostic impact and were used to generate prognostic models. There are four different scoring systems: Sokal, Euro (Hasford), EUTOS (European Treatment and Outcome Study), and ELTS (EUTOS long-term survival score). Sokal was the first scoring system developed before the interferon (IFN) era. It included age, spleen size, platelet count, and peripheral blast count.[20] It segregated patients into three risk groups with hazard ratios (HRs) of less than 0.8, 0.8 to 1.2, and greater than 1.2, with respective median survival times of 105, 76, and 45 months, respectively. In 1998, the EURO or Hasford score was developed to identify risk groups in CML patients treated with IFN.[21] It included age, spleen size, platelet count, peripheral blood blast count, eosinophils, and basophils. It also stratified patients in low-, intermediate-, and high-risk groups with median survival times of 105, 65, and 45 months, respectively. The EUTOS score was developed in the imatinib era and included spleen size and basophils.[22] This score predicts likelihood of 18-month CCyR rate on imatinib therapy. Last, the ELTS was developed to assess the risk of CML-related death.[23] It includes the same prognostic variables as the Sokal score. Patients are separated into three risk groups with 8-year probabilities of dying from CML of 2%, 6%, and 11%, respectively.

RESPONSE DEFINITION

Response to therapy is initially assessed by measurement of hematologic response criteria. A complete hematologic response (CHR) is defined as normalization of white blood cell (WBC) count to less than 10 $\times$ 10^9/L with a normal differential, platelet count less than 450 $\times$ 10^9/L, and disappearance of splenomegaly and other symptoms of CML. Patients who achieve a CHR are further classified according to the type of cytogenetic response achieved (Table 4–2).

Cytogenetic responses are divided into complete, partial, and minor and are based on a banding karyotype with at least 20 metaphases counted. CCyR corresponds to 0% of all metaphases remaining Ph positive, partial cytogenetic response as 1% to 35% of metaphases being Ph positive, and minor as >35% to 95% Ph-positive metaphases. Although FISH results correlate well with the karyotypic evaluation, cytogenetic response criteria needs further validation with FISH.

Molecular response is assessed by RT-PCR in the peripheral blood or bone marrow.[24] A major molecular response (MMR) is considered when the *BCR–ABL1* transcript is 0.1% or less on the (IS). MR4.0 and MR4.5 are considered when the *BCR-ABL1* transcripts are 0.01% or less and 0.0032% or less on the IS, respectively. A molecular response 5 (MR5) represents achievement of undetectable transcripts of *BCR–ABL1* with at least 100,000 copies of ABL (or equivalent control gene).

FRONTLINE TREATMENT OPTIONS

Since 2000, the treatment of CML has changed dramatically. Conventional chemotherapeutic agents such as hydroxycarbamide (hydroxyurea) are no longer used, except to achieve transient cytoreduction. There are currently four commercially available TKIs for the frontline treatment of CML: imatinib, dasatinib, nilotinib, and bosutinib. Available guidelines support all four as viable

TABLE 4–2 Criteria for Hematologic, Cytogenetic, and Molecular Response and Relapse

Hematologic Response	
Complete	Normalization of peripheral blood counts; WBC count $<10 \times 10^9$/L; platelets $<450 \times 10^9$/L Absence of immature cells such as myelocytes, promyelocytes, or blasts in peripheral blood No signs and symptoms of disease with disappearance of palpable splenomegaly
Cytogenetic Remission[a]	
Complete	No Ph-positive metaphases
Partial	1%–35% Ph-positive metaphases
Minor	>35%–95% Ph-positive metaphases
None	>95% Ph-positive metaphases
Complete and partial cytogenetic responses together constitute major cytogenetic responses, ie, 0%–35% Ph-positive metaphases	
Molecular Remission (MR)[b]	
Early MR	*BCR-ABL1* (IS) ≤10% at 3 and 6 months
Major	*BCR-ABL1* (IS) ≤0.1% or ≥3-log reduction in *BCR-ABL1* mRNA from the standardized baseline
MR4.0	*BCR-ABL1* (IS) ≤0.01% or ≥ 4-log reduction in *BCR-ABL1* mRNA from the standardized baseline
MR4.5	*BCR-ABL1* (IS) ≤0.0032% or ≥ 4.5-log reduction in *BCR-ABL1* mRNA from the standardized baseline
MR5	*BCR-ABL1* (IS) ≤0.001% or undetectable *BCR-ABL1* transcripts with ≥100,000 copies of ABL (or equivalent control gene)
Relapse	
Any sign of loss of hematologic response or cytogenetic relapse	

[a]Cytogenetic response is based on routine karyotype analyzing at least 20 metaphases.
[b]Molecular responses is based on quantitative polymerase chain reaction (real-time polymerase chain reaction).
IS, international score; Ph, Philadelphia chromosome; WBC, white blood cell.

frontline options for the initial management of patients with CML-CP.

Imatinib Mesylate

Imatinib mesylate (STI-571, Gleevec) was the first TKI approved by the Food and Drug Administration (FDA) for the treatment of patients with CML-CP. It is a selective and potent competitive inhibitor of the ATP-binding site of the BCR-ABL1 oncoprotein, as well as c-kit, platelet-derived growth factor receptor α and β, and abl-related gene (ARG).[25] It is given orally with 98% bioavailability and a half-life of 13 to 16 hours. It was first used in patients who developed resistance or intolerance to IFN-α, and resulted in a CCyR of 60% and an estimated 5-year overall survival (OS) rate of 76%.[26]

Based on these results, the phase 3 randomized multinational IRIS (International Randomized study of Interferon-alpha plus cytarabine versus STI571) study compared imatinib 400 mg orally daily with IFN-α in combination with cytarabine (the standard of care at the time) in 1106 newly diagnosed patients with CML-CP.[27] After a median follow-up period of 19 months, outcomes for patients receiving imatinib were significantly better than in those treated with INF-α plus cytarabine. These included the rates of CCyR rate (74% vs 9%; P <.001) and freedom from progression to AP or BP at 12 months (99% vs 93%; P <.001). With a median follow-up period now of 10+ years, the estimated OS rate for patients assigned to imatinib was 83.3% with a cumulative CCyR rate of 83% and a 10-year MMR rate of 93%.[28] Despite the high rate of crossover among patients assigned to receive INF-α plus cytarabine (66%) and the short duration of therapy before crossover (median, 0.8 years), the 10-year survival rates favored the imatinib arm (83.3% vs 78.8%).[28]

Despite the impressive results with imatinib, approximately half of the patients had come off imatinib therapy at the 10-year follow-up time. This highlighted the need for additional treatment options in CML. The development of second generation TKIs helped address this issue, especially in patients who were intolerant to imatinib therapy.

Imatinib Dosage

The phase I imatinib study in patients who had failed prior IFN-α therapy established a clear relationship between dose and response.[29] No significant responses

were observed at doses below 300 mg/day. An arbitrary dosage of 400 mg/day for CP was selected in phase II studies despite the lack of dose-limiting toxicity at doses up to 1000 mg/day (maximum tolerated dose was not defined). Studies of higher dose schedules of imatinib (e.g. 400mg twice daily) were associated with more side effects and no longer term benefits.[30–33]

In a French Spirit study, 636 patients with newly diagnosed CML-CP were randomized to receive either imatinib 400 mg/day alone, imatinib 400 mg/day with cytarabine (20 mg/m^2/day on days 15–28 of each 28-day cycle) or pegylated (peg) IFN-α-2a (90 μg weekly), or imatinib 600 mg/day alone.[34] The 12-month CCyR rates were similar among the four groups, but the MMR and deeper molecular responses rates were significantly higher in patients receiving imatinib and peg IFN-α-2a compared with imatinib 400 mg alone arm (30% vs 14% respectively; $P = .001$). However, this high rate of early and deep responses did not translate into long-term improvement because of the poor tolerance of peg IFN-α-2a.

The CML-study IV was designed to investigate if treatment with imatinib 400mg/day ($n = 400$) could be optimized by doubling the dose ($n = 420$) or by adding IFN ($n = 430$) or cytarabine ($n = 158$) or by using imatinib after IFN failure ($n = 128$).[35] From July 2002 to March 2012, 1551 newly diagnosed patients with CML-CP were randomized into a five-arm study. The study was powered to detect a survival difference of 5% at 5 years. After a median observation time of 9.5 years, the 10-year OS rate was 82%, the 10-year progression-free survival (PFS) rate was 80%, and the 10-year relative survival rate was 92%. Despite a faster response with imatinib 800 mg, the survival difference between standard-dose and higher dose imatinib was only 3% at 5 years (<5%). In a multivariate analysis for survival, standard-dose imatinib was equivalent to other treatment arms. Patients who reached the 6-month *BCR-ABL1* transcripts (IS) less than 1% had a survival advantage of 6% after 10 years regardless of therapy.

Imatinib 400 mg/day is therefore the standard dose for treating patients with newly diagnosed CML-CP.

Imatinib Generics

Imatinib generics are now available. It has been questioned if these are comparable in safety and efficacy to the branded Gleevec. In a multicenter prospective study conducted by the Polish Adult Leukemia Group (PALG) imatinib generic registry, 726 patients with CML-CP were divided into two groups: group A ($n = 99$) consisting of patients who commenced therapy on generic imatinib after CML diagnosis, and group B ($n = 627$) consisting of patients who were switched to generic from branded imatinib.[36] Patients were observed for at least 12 months. In group A, the rates of early molecular response (EMR, *BCR-ABL1* transcript ≤10% at 3 months), CCyR at 6 months, and MMR at 12 months (65%, 53%, and 50% respectively) were comparable to those achieved by branded imatinib. In group B, 64% patients maintained their molecular response, but 15% had worsening of molecular response when switching to generic imatinib. Despite this, only 0.3% and 1.3% of the patients had loss of CCyR and MMR, respectively. Rates of adverse events were also similar between groups A and B and comparable to branded imatinib. Similar data were reported from India. Among 174 patients treated with imatinib generics, response and survival rates were similar to those observed among 1193 patients treated with the branded imatinib. Safety profile was similar as well.[37]

At MD Anderson 38 patients who switched therapy from branded imatinib to generics were evaluated. Before the switch, all patients were in CCyR, 36 (95%) were in MMR, and 28 (74%) in deep molecular response (MR4.5). Patients received generic imatinib for a median of 19.4 months. Molecular responses after switching were stable in 89%, improved in 8%, and worsened in 3% of patients. No patient lost MMR.[38] No significant changes in side-effects were observed after the switch to generic.

Management of Toxicity

Imatinib is overall well tolerated, although adverse events not requiring treatment interruptions or decrease in dosing may occur in 30% to 40% of patients. A list of the most frequently encountered side effects and suggestions for management are included in Table 4–3. Any grade 3 or 4 toxicities related to imatinib require treatment interruption and resumption upon resolution of toxicity or its decrease to grade 1 or less. Subsequent doses should be reduced if recurring or long-lasting side effects are encountered, keeping in mind that dosages below 300 mg/day are not recommended because of lack of adequate activity, unless the patient is already in deep molecular response. Only 2% to 3% of patients exhibit true intolerance to imatinib and require permanent discontinuation. Early recognition and intervention targeting toxicities greatly reduce the need for unnecessary treatment interruptions and dose reductions.

Myelosuppression is common and frequently seen within the first 2 to 3 months of therapy. It is generally self-limited, and dose interruptions are not recommended unless grade 3 neutropenia or thrombocytopenia (ie, neutrophils $<1 \times 10^9$/L, platelets $<50 \times 10^9$/L) develop. Anemia alone usually does not require interruptions or dose adjustments. Treatment is restarted when counts recover above specified thresholds. After treatment interruption, the WBC

TABLE 4–3 Recommended management of the Most Common Adverse Events Associated with Imatinib

Adverse Events	Management
Nausea or vomiting	Take with food or fluids
	Antiemetics
Diarrhea	Loperamide
	Diphenoxylate atropine
Peripheral edema	Diuretics
Periorbital edema	Steroid-containing cream
Skin rash	Avoid sun exposure
	Topical steroids
	Systemic steroids
	(Early intervention is important)
Muscle cramps	Tonic water or quinine
	Electrolyte replacement as needed
	Calcium gluconate
Arthralgia or bone pain	NSAIDs
Elevated transaminases	Hold therapy and monitor closely
	Dose reduction on resolution
Myelosuppression	
Anemia	Treatment interruption or dose reduction usually not indicated
	Erythropoietin or darbopoetin
Neutropenia	Hold therapy if grade ≥3 (ie, ANC $<1 \times 10^9$/L)
	Restart at lower dose if recovery takes >2 weeks
	Consider G-CSF if recurrent or persistent or sepsis
Thrombocytopenia	Hold therapy if grade ≥3 (ie, platelets $<50 \times 10^9$/L)
	Restart at lower dose if recovery takes >2 weeks
	Consider eltrombopag

ANC, absolute neutrophil count; G-CSF, granulocyte colony stimulating factor; IL-10, interleukin-10; NSAID, nonsteroidal antiinflammatory drug.

count should be monitored at least once weekly, and if recovery occurs within 2 weeks, treatment should be resumed with the same dose at which myelosuppression occurred. If recovery takes longer than 2 weeks, the dose could be reduced in increments (eg, from 400 to 300 mg). Hematopoietic growth factors may be beneficial with recurrent or prolonged myelosuppression (eg, erythropoietin or darbepoetin, filgrastim, and eltrombopag).[39,40]

Dasatinib

Dasatinib is a piperazinyl derivative oral second-generation TKI. It has an excellent oral bioavailability and is 350 times more potent in vitro than imatinib.[41,42] It exhibits significant activity against most imatinib-resistant BCR–ABL1 mutations, with the exception of T315I, and a few others, including V299L and F317L.[43] In contrast to imatinib, dasatinib binds to both the active and inactive conformations of BCR–ABL1 and inhibits the Src family of kinases, which may be important in suppressing critical cell signaling pathways.[44]

After evaluation in the salvage setting post imatinib failure, dasatinib was assessed in the frontline setting. The DASISION trial was a phase III, randomized study that compared imatinib 400 mg once daily to dasatinib 100 mg once daily in 519 patients with newly diagnosed CML-CP.[45,46] The primary endpoint was confirmed CCyR (cCCyR) at 12 months, which was higher with dasatinib (77% vs 66%; $P = 0.007$). The rates of molecular responses were significantly higher with dasatinib (MMR 76% vs 64 % $P = .002$; MR 4.5 42% versus 33 %, $P = .025$). Dasatinib induced deeper responses at early time points (3, 6, or 12 months) compared with imatinib. At 3 months, a higher proportion of patients treated with dasatinib achieved

BCR-ABL1 transcripts (IS) 10% or less (84% vs 64%; P <.0001). Meeting this threshold in either arm predicted better PFS and OS. The rate of transformation to AP or BP was lower in patients treated with dasatinib (4.6% and 7.3%, respectively). However, there was no PFS and OS difference at a minimum follow-up of 5 years when the study was terminated.[46] Relevant toxicities included a pleural effusion rate of 28% with dasatinib (mostly grade 1 or 2; 15 patients [6%] discontinued dasatinib because of pleural effusion). Arterio-occlusive events were higher with dasatinib (5% vs 2%). Pulmonary hypertension was reported in 14 (5%) dasatinib-treated patients, with 6 discontinuing the drug.

In another phase II, multicenter trial, patients with newly diagnosed CML-CP were randomized to either dasatinib 100 mg/day or imatinib 400 mg/day.[47] Similar to the DASISION study, higher rates of CCyR (84% vs 69%) and 12-month MMR (59% vs 44%; P = .059) were reported in patients receiving dasatinib. No difference in PFS or OS was reported. Grade 3 and 4 toxicities were most commonly hematologic, including thrombocytopenia, which was more common with dasatinib (18% vs 8%).

A third phase III randomized study, SPIRIT 2, compared dasatinib 100 mg/day with imatinib 400 mg/day.[48] More than 800 patients were treated. The primary endpoint was 5-year event-free survival (EFS). The 24-month CCyR rate was higher with dasatinib compared to imatinib (43% vs 32%). The cumulative incidence of MMR and MR4 were also higher with dasatinib (MMR 83% vs 63%; MR4 78% vs 57%). More imatinib-treated patients proceeded to stem cell transplant (SCT). Although the 5-year failure-free survival (FFS) rate was superior in the dasatinib arm (61% vs 53%), there was no difference in the EFS (91% vs 89%) or the OS (92% vs 91%) between dasatinib and imatinib.[49] Overall, more patients came off therapy because of suboptimal molecular response in the imatinib compared with the dasatinib arm (17% vs 2%), but more patients discontinued therapy because of intolerance in the dasatinib compared with the imatinib arm (30% vs 17%).

Dasatinib is well tolerated. Myelosuppression occurs frequently, with grade 3 or 4 neutropenia or thrombocytopenia in 20%. The most common nonhematologic grade 3 to 4 toxicities at the same dose were pleural effusion (9%), dyspnea (6%), bleeding (4%), diarrhea (3%), and fatigue (3%).

Lower Dose Dasatinib

In early clinical trials evaluating dasatinib, the drug was noted to be active at doses lower than those initially approved for second-line therapy, with a better safety profile.[50] In a randomized trial of four dose schedules of dasatinib (100 mg vs 140 mg/day; single-dose versus twice-daily schedule), dasatinib 100 mg single daily dose was as effective as 140 mg/day with a better safety profile.[51] Investigators from the DASISION trial have reported the ability to maintain the efficacy of dasatinib among patients who had their dose reduced, while improving its safety profile.[52] Based on this rationale, we conducted a phase II study evaluating the efficacy and safety of lower dose dasatinib 50 mg/day in 81 patients with newly diagnosed CML-CP. With a minimal follow-up of 12 months,[53,54] the cumulative rates of MMR, MR4, and MR4.5 by 12 months were 81%, 55%, and 49%, respectively. Twenty-one (25%) patients had treatment interruptions for a median of 13 days (range, 4–64 days). Five (6%) patients developed pleural effusions; four of them required a dose reduction. Two (2%) patients failed to achieve any cytogenetic or molecular response and were taken off study. At a median follow-up time of 24 months, none of the patients had disease transformation to an AP or BP.[54] The 2-year EFS and OS rates were 100%. Such a strategy may have a significant impact on our future practice because of equivalent efficacy, better safety, and a lower cost of care.[54]

Nilotinib

Nilotinib is a structural analog of imatinib with 50 times more potent affinity for the ATP binding site in vitro[55] and more selective activity against unmutated and most mutated forms of BCR–ABL1.[55,56] It is approved at a dose of 400 mg twice daily for patients with CML-CP and CML-AP with resistance or intolerance to imatinib. Nilotinib was also evaluated in newly diagnosed CML-CP. The ENESTnd trial was a large phase 3 international randomized study that compared two doses of nilotinib, 300 mg twice daily and 400 mg twice daily (the dose approved for CML salvage) with imatinib 400 mg once daily as initial therapy for patients with early CML-CP.[57] The primary endpoint was the MMR rate at 12 months, which was higher with both doses of nilotinib compared to imatinib (44% and 43% vs 22%; P <.001). The cumulative incidence of CCyR by 24 months was 87% with nilotinib 300 mg twice daily, 85% with nilotinib 400 mg twice daily, and 77% with imatinib 400 mg/day (P <.001).[57] Cumulative 10-year[58,59] MMR rates were 83% with nilotinib 300 mg twice daily, 80% with nilotinib 400 mg twice daily, and 70% with imatinib.[58] Cumulative 10-year MR4.5 rates were 64% with nilotinib 300 mg twice daily, 62% with nilotinib 400 mg twice daily, and 45% with imatinib, respectively.[58] The incidence of transformation to CML AP or BP was 3.9% with nilotinib 300 mg twice daily, 2.5% with nilotinib 400 mg twice daily, and 8.5% with imatinib. There was no significant difference in outcome among patients

treated with nilotinib and imatinib.[58] The estimated 10-year EFS rates were 92.0%, 96.2%, and 90.3% with nilotinib 300 mg twice daily, nilotinib 400 mg twice daily, and imatinib, respectively.[58] The estimated 10-year survival rates were 87.6%, 90.3%, and 88.3%, respectively.[58] Adverse events resulting in TKI discontinuation were highest with nilotinib 400 mg twice daily dose (35.4%) compared with nilotinib 300 mg twice daily and imatinib (24% and 20%, respectively). Cardiovascular events were noted to be significantly higher with nilotinib, particularly at the higher dose.[58] A second trial from China used the same design and enrolled 267 patients. The MMR rates at 12 months were 52% with nilotinib and 28% with imatinib. The rate of CCyR (84% vs 87%) and PFS (95% each) were similar at 24 months. The rates of progression to CML AP or BP and of survival were similar with nilotinib and imatinib.[59]

Although nilotinib is well tolerated overall, there is a cumulative increased risk of cardiovascular events on therapy. In the 10-year follow-up of the ENESTnd study, the cumulative cardiovascular event rates were 24.8%, 33.4%, and 6.3% with nilotinib 300 mg twice daily, nilotinib 400 mg twice daily, and imatinib 400 mg/day, respectively.[58] Other notable side effects include grade 3 or 4 myelosuppression (neutropenia or thrombocytopenia in 10%–20%). Nonhematologic toxicities include headaches, skin rashes (20%–30%; can be alleviated by dose reduction), elevated indirect bilirubin (10% to 15%), and asymptomatic elevation of lipase and amylase (10% to 15%). Rare cases (<1%) of pancreatitis have been reported. Diabetes may also be exacerbated with nilotinib (10% to 20%).

Bosutinib

Bosutinib is a potent dual SRC/ABL kinase inhibitor.[60] The drug was first approved for treating adults with CML and resistance or intolerance to prior therapy. In 2018, it was approved as first-line treatment of patients with CML-CP.[60] In the multinational phase III randomized BFORE trial, 590 patients with newly diagnosed CML-CP were randomized to bosutinib 400mg/day (n = 268) or imatinib 400mg/day (n = 268). The primary endpoint of the study was MMR at 12 months. Patients treated with bosutinib had a higher rate of MMR at 12 months (47% vs 37%; P = 0.02). Similarly, the 12-month CCyR rate was significantly higher with bosutinib (77% vs 66%; P = .0075). Early molecular responses (*BCR-ABL1* transcripts ≤10% at 3 months) were associated with superior PFS and OS and were achieved more frequently on bosutinib (75% vs 57%). At 2 years, six patients (2.2%) receiving bosutinib and seven patients (2.6%) receiving imatinib experienced disease progression to AP or BP. Among treated patients, 22% of patients receiving bosutinib and 27% of patients receiving imatinib discontinued treatment, most commonly for drug-related toxicity (13% and 9%, respectively). Grade 3 or greater diarrhea (8% vs 0.8%) and increased alanine aminotransferase (19% vs 1.5%) and aspartate aminotransferase (10% vs 2%) levels were more common with bosutinib. Cardiac and vascular toxicities were uncommon. The 2-year cumulative rates of CCyR were 76% and 66% among patients treated with bosutinib and imatinib (P = .0052), respectively. The 2-year cumulative rates of MMR, MR4, and MR4.5 were 57% and 34% (P = .0036), 27% and 10% (P =.0249), and 15% and 3% (P = .0542), respectively.[60] The estimated 2-year survival rates were similar (99% vs 97%).

The MD Anderson Cancer Center Experience

At MD Anderson, several frontline studies ran sequentially and in parallel and evaluated the outcomes of patients with newly diagnosed CML treated (July 2000–September 2013) with imatinib 400 mg/day (n = 68), imatinib 800 mg/day (n = 200), dasatinib 50 mg twice daily or 100 mg/day (n = 106), and nilotinib 400 mg twice daily (n = 108). An analysis of the total experience of 482 patients is summarized in Table 4–4.[55] The experience showed similar benefits with high-dose imatinib and second-generation TKIs in relation to early surrogate endpoints of long-term outcome (CCyR, MMR, MR4.5). Patients treated with imatinib 400 mg/day had a significantly inferior 5-year EFS compared with those treated with high-dose imatinib and second-generation TKIs (P = .009). However, 5-year transformation-free survival (TFS), FFS, and OS were not different by treatment strategy (P = .353, 0.078 and P = .381, respectively). As expected, among patients who achieved CCyR, there was no difference in outcomes regardless of whether MMR or MR4.5 were additionally achieved.[61]

The long-term results of frontline nilotinib and dasatinib therapy were recently published.[62,63] At a median follow-up period of 78 months, among the 122 patients treated with nilotinib 400 mg twice daily, the cumulative CCyR and MMR rates were 91%. Seventy-five percent and 59% of patients achieved MR4.5 and a sustained MR4.5 beyond 2 years, respectively. The estimated 5-year EFS and OS were 89% and 93%, respectively. The corresponding rates at 10 years were 85% and 88%, respectively.[62] At a median follow-up time of 6.5 years, among the 149 patients treated with dasatinib 100 mg/day or 50 mg twice daily, the cumulative CCyR rate at 11 years was 92.6%. The MMR, MR4.5, and sustained MR4.5 rates were 88.2%, 79.5%, and 55%, respectively. The 10-year OS, TFS, EFS, and FFS rates were 89%, 95%, 86%, and 65%, respectively.[63]

TABLE 4–4 The MD Anderson Cancer Center Experience with Frontline Tyrosine Kinase Inhibitors in Chronic Myeloid Leukemia

Outcome (%)	Imatinib 400 mg/day (*n* = 68)	Imatinib 800mg/day (*n* = 200)	Dasatinib 100 mg/day (*n* = 106)	Nilotinib 400 mg BID (*n* = 108)
CCyR	87	90	96	93
MMR	76	86	90	91
MR4.5	57	74	73	71
5-year EFS	71	84	93	84
5-year FFS	59	70	76	70
5-year TFS	87	94	96	88
5-year OS	89	93	98	89
Discontinued	43	43	21	25

BID, twice a day; CCyR, complete cytogenetic response; EFS, event-free survival; FFS, failure-free survival; MMR, major molecular response (BCR-ABL1 transcript [IS] ≤0.1%; MR4.5 BCR-ABL-1 [IS] ≤0.0032%); OS, overall survival; TFS, transformation-free survival.

Given the equivalent efficacy and lower toxicity of lower dose dasatinib in our phase II study, dasatinib 50 mg/day has become our standard of care for frontline therapy of patients with CML-CP.

Patient Age and Comorbidities

The patient's age plays a significant role in deciding TKI therapy. Younger individuals have a longer life expectancy. Therefore, in younger patients, the goal is more frequently durable deep molecular responses, preferably undetectable *BCR-ABL1* transcript levels, to allow for consideration of treatment discontinuation. This is more likely to be achieved with second-generation TKIs that induce rapid and significantly deeper molecular responses compared with imatinib. Therapy discontinuation might be less relevant in older patients in whom the goal is survival normalization with minimal adverse events, particularly serious ones (eg, arterio-occlusive events [AOEs], pleural effusions). Imatinib might be a more adequate initial therapy in older patients.

Most TKIs are reasonably well tolerated with close observation and supportive care. Each TKI therapy has a distinct toxicity profile that should be considered when deciding on therapy (Table 4–5). For patients with baseline cardiopulmonary comorbidities such as chronic obstructive pulmonary disease, congestive heart failure, or uncontrolled hypertension or pulmonary arterial hypertension,[64] a TKI other than dasatinib may be favored, given the risk of pleural effusions. Dasatinib also impairs platelet function,[65] and patients on concomitant anticoagulants may be at increased risk for hemorrhagic complications.[66]

Nilotinib has been linked with hyperglycemia and QT interval prolongation and should be used with caution in uncontrolled diabetics and in patients with baseline QT prolongation (routine monitoring of the QT interval is essential). Potassium and magnesium should be repleted to optimal serum levels before starting nilotinib. Nilotinib should be taken on an empty stomach to avoid excess drug exposure. Nilotinib has also been associated with significantly increased incidence of peripheral artery occlusive disease, cerebrovascular accidents, and cardiovascular events.[58] In the 10-year follow-up of the ENESTnd trial,[58] approximately 33.4% of patients experienced vascular events. Cardiovascular events are less common with bosutinib and with imatinib. It is therefore reasonable to choose these for patients with cardiovascular morbidities. Nilotinib may occasionally cause pancreatitis and should be avoided in patients with prior history or risk factors for pancreatic inflammation.

Imatinib is associated with the development of peripheral edema as one of its major side effects. Close monitoring and intermittent use of loop diuretics might mitigate the effects of fluid retention. Other common side effects associated with imatinib include weight gain, fatigue, periorbital edema, bone and muscle aches, and nausea. These are mostly mild to moderate. A decrease in glomerular filtration rate may occur in patients treated with imatinib, but fewer than 5% to 10% experience significant elevations in creatinine with long-term therapy.

Bosutinib is associated with gastrointestinal, hepatic, and renal toxicity. Among patients with such comorbidities, bosutinib should be avoided or used cautiously. Bosutinib should be avoided in patients with inflammatory bowel disease and renal dysfunction.[67]

Cost of Therapy

The prices of TKIs are of concern, given that patients can now remain on TKIs and expect to have a normal

lifespan. The cost of cancer drugs has risen drastically over the past decade.[68–73] Most are priced at over $120,000 to $160,000 annually.[68–70] When first approved in the United States, the annual price for imatinib was less than $30,000. Patients treated with imatinib are now living a "normal" life span. [70,71] Paradoxically, with a higher number of patients and a longer duration of therapy, the annual price of imatinib has quadrupled to $132,000. This price is comparable to the cost of second-generation TKIs, all priced above $150,000 per year of therapy.

Generic formulations of imatinib are now available in the United States, although at a higher initial cost than expected. Since 2017, there are several generic imatinib formulations available, and their wholesale price is decreasing rapidly. The price of generic imatinib is $3000 to $8000 per year in Canada and $400 per year in India. With the availability of generic imatinib at a relatively lower cost compared with second-generation TKIs, one may offer generic imatinib to patients in the frontline setting with low- and intermediate-risk disease and second-generation TKIs to those with high-risk disease.[73]

At MD Anderson, we assessed the treatment value of second-generation TKIs compared with imatinib to achieve treatment-free remission (TFR) in patients with CML using a decision analytical model.[73] Different modeled scenarios were considered. Incremental cost-effectiveness ratios (ICERs) were calculated, and cost effectiveness was assessed using two societal willingness-to-pay thresholds: $50,000 per quality-adjusted life-year (QALY) in all markets and $200,000 per QALY in the United States. None of the explored scenarios showed a good treatment value for using second-generation TKIs at the current prices in the United States or at the price of $30,000 to $40,000 per year elsewhere. The Austrian groups reported the frontline therapy with nilotinib yielded ICERs of 121,400 € per QALY compared with frontline imatinib without second-line TKI after imatinib failure; nilotinib followed by dasatinib yielded 152,400 € per QALY compared with imatinib followed by nilotinib after imatinib failure.[72] To be cost effective, the cost of second-generation TKIs should be less than $25,000 per year.[73–75] Under the same conditions in developing nations, the annual price of second-generation TKIs should not exceed $10,000 per year of therapy.

Finally, lower dose dasatinib and generic second-generation TKIs may constitute a cost-effective strategy by allowing the achievement of an optimal response as well as TFR at a lower cost.

Disease Characteristics and Risk Score

The CML risk score plays an important role in deciding the type of TKI therapy. Patients who score low by the Sokal[20] or Hasford[21] prognostic models responding optimally to all TKIs with higher rates of deep molecular response with second-generation TKIs. The outcomes differ with intermediate- and high-risk disease in which the use of second-generation TKIs demonstrate significantly higher deep molecular response (MR4.5) and with a lower risk of transformation. In the ENESTnd study, in which patients were categorized based on the Sokal scoring system, in the intermediate group, the rate of transformation was 10% in the

imatinib arm versus 1% to 2% in the nilotinib arm; in the high-risk group, the rate of transformation was 14% in the imatinib arm versus 5% to 9% in the nilotinib arm.[57, 58]

MONITORING RESPONSE

Monitoring includes routine complete blood counts with differential, cytogenetics, and molecular analysis for *BCR-ABL1* transcript levels and for BCR-ABL1 kinase domain mutations (Table 4–6). The monitoring of complete blood counts should be implemented every 1 to 2 weeks until complete hematologic response and later every 3 months, more frequently if clinically indicated.[36] Conventional cytogenetic testing should be performed to assess the presence of additional chromosomal abnormalities, particularly i(17)(q10), -7/del7q, and 3q26.2 rearrangements, associated with a relatively adverse prognosis.[19]

At diagnosis, all patients with leukocytosis suspected to be CML should undergo bone marrow aspiration and biopsy to establish the diagnosis, assess percentages of blasts and basophils, and evaluate the presence of clonal evolution. Currently, bone marrow evaluation is recommended at diagnosis, for failure to reach suggested response milestones, and for any sign of loss of hematologic and cytogenetic response.[76] An alternative technique to determine cytogenetic response is with the use of FISH or RT-PCR (or both) on peripheral blood. If a patient is responding optimally and the FISH study result is negative at 6 or 12 months or *BCR-ABL1* transcripts (IS) are less than 1%, it may be reasonable to omit further marrow examination because the patient is likely to be in stable CCyR.[77,78]

For patients in durable CCyR during TKI therapy, intermittent molecular monitoring every 3 to 6 months using quantitative RT-PCR is acceptable and useful but may lead to erroneous changes in treatment because of discordant results between laboratories or even within the same laboratory. The trend of quantitative RT-PCR is more reliable to avoid the overinterpretation of the variability of RT-PCR results. The additional benefit of the achievement of MMR among patients in CCyR remains unclear. Irrespective of MMR, a similar survival rate was reported in patients who received imatinib or second-generation TKI and achieved CCyR.[12,79–82]

The clinical impact of early molecular response has been shown in a number of studies. A *BCR-ABL1* transcript level <10% (IS) at 3 months of TKI therapy has been shown to divide patients into high- and low-risk categories for long-term outcomes (ie,, progression to BP, death).[79,83,84] The DASCERN, a randomized, open-label, international phase 2b trial, evaluated the impact of *BCR-ABL1* transcripts >10% (IS) at 3 months after initial treatment with imatinib 400 mg/day in patients with CML-CP who achieved complete hematologic response. Patients were randomized to receive dasatinib 100 mg/day or higher dose of imatinib.[85] Patients who switched to dasatinib 100 mg/day achieved a 12-month MMR rate of 29% compared with 13% among patients who continued imatinib ($P = .005$). However, the clinical outcome of PFS and OS were similar between groups with the median follow-up period of 30 months.[85]. A follow-up measurement at 6 months will help define patients clearly in need of a change in therapy.[87–96] Experts have suggested that a follow-up measurement at 6 months will help define patients clearly in need of a change in therapy.[93] This has been retrospectively analyzed by several large groups.[94–96] Two independent studies reported similar survival in patients who did or did not achieve *BCR-ABL1* transcript levels >10% (IS) at 3 months.[95,96] Patients who continued the same TKI therapy and achieved *BCR-ABL1* transcripts (IS) less than 10% at 6 months of TKI therapy maintained similar long-term outcome compared with patients with *BCR-ABL1* transcripts (IS) <10% at 3 months of therapy. The *BCR-ABL1* transcripts (IS) <10% at 6-month is the first milestone for survival. The 4-year OS rates were 100% and 74% in patients with the *BCR-ABL1* transcripts (IS) <10% and

TABLE 4–6 Main Features of the Monitoring Techniques Available for Chronic Myeloid Leukemia

>10% at 6-month of TKI therapy. Given the observed worse survival in patients on frontline imatinib, it may be reasonable to switch imatinib to a second-generation TKI for patients with *BCR-ABL1* transcripts (IS) >10% after 6 months of therapy. Although suboptimal response is associated with a statistically significant probability of worse survival, the consideration of allogeneic SCT should be deferred because patients with suboptimal response on second-generation TKI still had an estimated survival rate of 81%.[46]

WHEN TO SWITCH TYROSINE KINASE INHIBITOR THERAPY

Achievement of CCyR by 12 months and maintenance of CCyR thereafter is associated with improved survival, similar to that of a general population. With standard-dose imatinib, CCyR should be expected by 12 months of therapy, but it may be reasonable to expect CCyR with second-generation TKIs within 3 to 6 months of treatment.[98]

Patients who do not achieve a complete hematologic response by 3 months should be considered for a change in TKI treatment unless it is related to poor adherence. Considering a change in treatment at 3 or 6 months for *BCR-ABL1* transcript level >10% for patients on imatinib or second-generation TKIs, very early switching has not yet been shown to influence the long-term outcomes.[99] As such, it can be advocated that if the transcript level at 3 months is greater than 10%, providers should perform serial molecular monitoring between 3 and 6 months for definitive treatment response evaluation.[93] If patients retain >10% transcript levels (IS) at 6 months, a change in therapy is indicated because the chance of CCyR would be low. A 3-month value of 10% (IS) may not be accurate: in a report in one sample collected at 3 months and tested 96 times, the mean value was 11% (range, 5%–16%), with only 31% of tests being 10% or less.[100] This approach also applies to patients on second-generation TKIs.[99] Another study randomized patients in CCyR on imatinib for at least 2 years to continue imatinib or switch to nilotinib.[101] Switching to nilotinib induced deeper molecular responses but did not translate into an improvement in PFS or in other meaningful outcomes.

Patients who meet all the relevant benchmarks in the first 12 months are monitored periodically using molecular testing with or without FISH (molecular testing only if *BCR-ABL1* transcripts (IS) consistently <0.1%). If there are clear signs of possible failure, patients should undergo a bone marrow examination with cytogenetic analysis and molecular testing, including analysis for mutations. Any degree of cytogenetic relapse calls for a change of therapy. Fluctuating molecular levels during continuous CCyR would prompt closer monitoring and a compliance assessment. Some CML experts advocate a change of therapy for a documented consistent loss of MMR after 3 to 4 years of therapy (*BCR-ABL*1 transcripts (IS) >0.1%), particularly if transcript levels (IS) are consistently above 0.3% to 0.5%.

The new ELN 2020 recommendations and the National Comprehensive Cancer Network guidelines propose the achievement of TFR as an important goal of therapy in CML. This is discussed later.

Multiple studies consistently reported the association of CCyR within 1 year of therapy (or later) with improved survival compared with lesser degrees of response. Thus, the primary endpoint of TKI therapy is the achievement of CCyR. MMR (*BCR-ABL1* transcripts [IS] ≤0.1%) was not associated with improvement of survival, but was associated with improved EFS and stable CCyR. Treatment discontinuation can be considered for patients who achieved deep molecular response such as CMR (nonmeasurable *BCR-ABL1* transcripts). The use of allo-SCT and the switch to other TKI should not be considered for patients who achieved CCyR without MMR or CMR. The lack of major cytogenetic response (Ph-positive metaphases ≤35%; *BCR-ABL1* transcripts [IS] ≤10%) by 6 months may justify the TKI switch to a second-generation TKI. The achievement of CCyR within 3 to 6 months of frontline second-generation TKI therapy improved outcomes. Recommendations are summarized in Table 4–7, which are mostly consistent with the 2020 ELN recommendations.[93]

MANAGEMENT OF TYROSINE KINASE INHIBITOR RESISTANCE

Given that the survival of patients with CML is approaching that of the general population with long-term TKI therapy, and given that some patients may fail on a particular TKI therapy because of intolerance or resistance, the number of patients who have a history of at least one TKI resistance has been increasing. One of the mechanisms of TKI resistance is the acquisition of point mutations in the BCR-ABL1 kinase domain. The acquired mutation of kinase decreases the affinity of TKI, which impairs the activity of TKIs. Although second-generation TKI can overcome imatinib-resistant BCR-ABL1 kinase domain mutations, novel mutations resistant to second-generation TKI emerged through clonal selection. The gatekeeper mutation, T315I mutation, causes resistance to currently available TKIs except ponatinib.[102]

Although suboptimal response suggests TKI resistance or intolerance, TKI compliance and drug–drug interactions should be evaluated before the decision to switch TKI. The range of estimated rates of imatinib

TABLE 4–7 Response Definitions to Imatinib in Chronic Phase Chronic Myeloid Leukemia (2020 European LeukemiaNet Recommendations)

	Optimal	Warning	Failure
Baseline	NA	High-risk ACA, high-risk ELTS score	NA
3 months	≤10%	>10%	>10% if confirmed within 1–3 months
6 months	≤1%	>1%–10%	>10%
12 months	≤0.1%	>0.1%–1%	>1%
Any time	≤0.1%	>0.1%–1%, loss of ≤0.1%[a]	>1%, resistance mutations, high-risk ACA

For patients aiming at treatment-free remission (TFR), the optimal response (at any time) is BCR-ABL1 ≤0.01% (MR4).
A change of treatment may be considered if major molecular response (MMR) is not reached by 36–48 months.
[a]Loss of MMR (BCR-ABL1 > 0.1%) indicates failure after TFR.
ACA, additional chromosome abnormalities in Philadelphia chromosome–positive cells; ELTS, EUTOS long-term survival score; NA not applicable.

adherence was from 75% to 90% with worse outcome in patients with lower adherence.[103, 104] The monitoring of adherence is encouraged in younger patients, those with chronic toxicities, and those on higher dose of TKI therapy.[102]

SECOND- AND THIRD-GENERATION TYROSINE KINASE INHIBITORs

Second-generation TKIs were originally approved as second-line therapy for patients with CML-CP who failed frontline imatinib. Second-line TKI therapy with nilotinib, dasatinib, or bosutinib achieved high CCyR and MMR rates in patients who had suboptimal response or resistant to frontline imatinib therapy after initial optimal response. Although the dose escalation of imatinib to 800 mg/day may overcome resistance to standard-dose imatinib, the switch to second-generation TKI is a more effective strategy to achieve response.[105,106] In patients who failed frontline imatinib therapy, second-line second-generation TKIs, including nilotinib,[107,108] dasatinib,[106,108] or bosutinib,[89] achieved higher rates of major cytogenetic response, CCyR, and MMR compared with high-dose imatinib therapy.[109] The achievement of higher rates of CCyR and MMR translated into higher rates of PFS. These consistent results of second-generation TKI studies after imatinib failure suggest that an earlier switch from imatinib to a second-generation TKI may be more effective than a switch at the time of progression or at the time of losing hematologic or cytogenetic response. Patients in suboptimal response with frontline standard-dose imatinib had a higher rates of 12-month CMR when standard-dose imatinib was switched to nilotinib compared with high-dose imatinib.[110] Earlier change from standard-dose imatinib to dasatinib before the loss of MCyR resulted in higher rates of responses (CCyR and MMR) and improved clinical outcomes, including 2-year EFS, TFS, and OS.[106] Despite the limitations of various designs of clinical trials, the earlier intervention before the loss of major cytogenetic response (or equivalent) was associated with better outcomes.

Bosutinib was originally approved for the treatment of patients with imatinib-resistant or -intolerant CML.[89] The bosutinib dose of 500 mg/day was chosen with the potential for dose escalation to 600 mg/day for patients with suboptimal response on the phase 2 clinical trial. Among 288 patients enrolled, more than two thirds of patients had a history of imatinib resistance. Thirty-one percent of patients achieved MCyR within 6 months of bosutinib therapy (primary endpoint); 41% achieved CCyR. Although bosutinib does not have activity on T315I mutations, bosutinib has maintained activity in most imatinib-resistant mutations. Durable responses were observed in both imatinib-resistant and imatinib-intolerant groups. Common toxicities included gastrointestinal (GI) symptoms (diarrhea, nausea, and vomiting) and skin rash. Eighty-four percent of patients had all grades of diarrhea, and 9% had grade 3 diarrhea. Myelosuppression and liver function test abnormalities were common. A strategy of sequential dose escalation of bosutinib (200 mg/day for 2 weeks; 300 mg/day from 2 weeks to 3 months; 400 mg/day at 3 months if *BCR-ABL1* transcript level >1% [IS] at 3 months) and otherwise continue 300 mg/day may be considered in older patients with CML and frontline failure to one prior TKI (both resistance and intolerance).[111] Lower *BCR-ABL1* transcript levels were observed in 67% of patients. The dose-escalation strategy resulted in lower incidences of diarrhea (all grades, 16%; grade 3, 8%) and liver function test abnormalities (all grades, 22%; grade 3, 10%; and grade 4, 2%).[111]

Ponatinib is an FDA-approved third-generation TKI that exhibits activity against T315I mutation.[91] Preclinical studies showed ponatinib was 500 times more active in inhibiting *BCR-ABL1* than imatinib.[112] The FDA approved ponatinib at an initial dose of

45 mg orally daily for the treatment of patients with T315I-mutated CML and Ph-positive ALL and in patients for whom no other TKI therapy was indicated based on the results of the phase II PACE (Ponatinib Ph-positive acute lymphoblastic leukemia [ALL] and CML Evaluation) trial. The PACE trial included 449 patients with heavily pretreated all-stage CML (CP, AP, and BP) and Ph-positive ALL. Patients who had a prior history of intolerance or resistance to dasatinib or nilotinib and who had T315I mutation were eligible.[113] Patients enrolled were stratified by disease phase and T315I mutation status (absent or present). Among 267 patients with CML-CP, a 12-month MCyR was observed in 56% and 70% of patients overall and patients with a T315I mutation, respectively. There was a trend for higher rates of response in patients who received fewer prior TKI therapies. At the final 5-year result of the PACE trial, 60%, 40%, and 24% of patients achieved MCyR, MMR, and MR4.5, respectively; 82% and 59% of patients who achieved MCyR and MMR maintained response at 5 years.[102] The 5-year PFS and OS were 53% and 73%, respectively. AOEs, including cardiovascular, cerebrovascular, and peripheral vascular events, were observed in 84 (31%) patients and severe AOEs in 69 (26%). Common treatment-emergent adverse events (≥40%) in patients with CML-CP included skin rash (47%), abdominal pain (46%), thrombocytopenia (46%), headache (43%), dry skin (42%), and constipation (41%).[102, 113] Less common but notable adverse events were grade 3 or 4 skin rashes (4%), pancreatitis (7%), atrial fibrillation (6%), and grade 3 or 4 hypertension (14%).

As of June 2020, ponatinib labeling includes a warning for arterial thrombosis, including cardiovascular, cerebrovascular, and peripheral arterial thrombosis, and hepatotoxicity.[114] The PACE trial reported that AOEs were more frequent in older patients with previous history of cardiovascular events and with cardiovascular risk factors, including hypertension, diabetes, or hyperlipidemia. Patients with a longer history of CML since the diagnosis and patients taking higher doses of ponatinib were at higher risk for AOEs.[102]

A randomized, open-label, phase 2 trial of ponatinib in patients with resistant chronic-phase CML (OPTIC) evaluated the efficacy and safety of a range of ponatinib doses.[115] Patients were randomized to one of three starting doses of ponatinib at 45, 30, and 15 mg/day. Doses were reduced to 15 mg/day upon achievement of *BCR-ABL1* transcript levels <1% (IS). The AOEs and serious AOEs were 5% and 2%, 4% and 3%, and 1% and 0%, respectively. The achievement of *BCR-ABL1* 1% or less (IS) was observed in 38.7%, 27.4%, and 26.5% at the dose of 45 mg/day, 30 mg/day, and 15 mg/day, respectively; the achievement of MMR was observed in 14.7%, 17.8%, and 19.1%, respectively. To minimize the risk of AOEs, it may be reasonable to start ponatinib 30 mg/day (except in T315I-mutated CML where 45mg/D is better) and lower the dose to 15 mg/day when *BCR-ABL1* transcript <1% (IS) are achieved.

Novel Tyrosine Kinase Inhibitors

Although currently FDA-approved TKIs have shown significant survival improvement in CML-CP, the development of novel TKIs continues in order to overcome the resistance of T315I mutation and to pursue less toxic options. Asciminib is a novel allosteric BCR-ABL1 TKI that blocks BCR-ABL1 in an active conformation through binding a myristoyl site of the BCR-ABL1 oncoprotein.[116] The mechanism is different from all other TKIs and targets both the unmutated and mutated BCR-ABL1, levels including T315I mutation. In a phase 1 trial, adults with CML-CP or CML-AP who failed at least two TKIs (resistance or intolerance) were treated with asciminib. Among 150 patients enrolled, 141 patients had CML-CP and 9 patients had CML-AP.[117] Patients received asciminib once or twice daily at doses of 10 to 200 mg/day. Among 34 patients who lost hematologic response, 32 (92%) achieved a complete hematologic response; among 57 patients who lost cytogenetic response, 31 (54%) achieved CCyR. Among 91 evaluable patients, 44 (48%) achieved MMR by 12 months, including 8 (57%) ponatinib resistant or intolerant patients. In patients with a T315I mutation before asciminib, 5 (28%) patients achieved an MMR. Dose-limiting toxicities included asymptomatic elevations of lipase levels and clinical pancreatitis. A phase III randomized trial is ongoing in patients who failed two TKIs without T315I mutation and who are randomized to either asciminib or bosutinib.

Olverembatinib (HQP1315), a novel orally active potent third-generation TKI, enrolled 101 patients, including 87 patients with CML-CP and 14 patients with CML-AP who were resistant or intolerant to two or more prior TKIs or with T315I mutation after one or more prior TKIs. Sixty-two (61%) patients had T315I mutation.[118] Olverembatinib was administered every other day on a 28-day cycle; the dose escalation was 30, 40, and 50 mg. With a median follow-up period of 13 months, the rates of CHR, MCyR, CCyR, and MMR in patients with CML-CP were 94.5%, 69.1%, 60.5%, and 37.2%, respectively. Common adverse events included grade 3 or 4 thrombocytopenia and grade 1 skin pigmentation and hypertriglyceridemia. Two pivotal studies in patients with CML-CP and CML-AP are ongoing.

Vodobatinib (K0706), a novel third-generation TKI, was tested in a phase I trial in patients who failed 3 or more TKIs or who had comorbidities that limited the use of second-and third-generation TKI.[119] Among 35 patients, vodobatinib was given at dosage range of

12mg to 240mg daily. The recommended phase II dose was 174 mg/day. At 240 mg/day, two dose-limiting toxicities were grade 3 dyspnea, grade 2 noncardiac chest pain, and grade 2 shortness of breath caused by fluid retention. Among 27 patients treated 7 patients achieved CCyR. A phase 2 study of vodobatinib in patients who have received multiple prior TKIs is ongoing.

PF-114 is a fourth-generation oral TKI that has activity against wild-type and BCR-ABL1 mutations, including T315I.[120] A phase I trial in patients with CML-CP/CML-AP failing two or more TKIs or T315I mutations reported on 17 patients treated with PF-114 200 mg to 600 mg. The maximum tolerated dose was 600 mg (grade 3 psoriasis-like skin lesions). The recommended dose was 300 mg/day with 6 of 11 patients achieving MCyR; 4 of 11 patients achieved MMR.

Selection of a Second- or Third-Line Generation Tyrosine Kinase Inhibitor Option

Bone marrow examination should be performed at the time of treatment failure to evaluate the phase of CML and to document any evidence of clonal evolution. BCR-ABL1 kinase domain mutations should be examined to guide the selection of the salvage TKI option.[103,104,121,122] Among second-generation TKIs, the decreased sensitivity of TKI to BCR-ABL1 mutations were reported in vitro and in vivo.[103,104,121,122] In the presence of Y253H, E255K/V, and F359C/V, mutations either dasatinib or bosutinib are favorite options. In the presence of V299L and F317L mutations, nilotinib can be considered. In the absence of BCR-ABL1 mutations, patient comorbidities, toxicity profile, and cost should be considered.

Bosutinib has activity in most imatinib-resistant CML clones.[89] Bosutinib may be a reasonable salvage option in patients after frontline imatinib failure and who have comorbidities that may increase the risk of adverse events observed with dasatinib or nilotinib (eg, AOEs, pleural effusion, pulmonary hypertension). Common distinct adverse events include diarrhea and other GI complaints,[123] and liver function and renal abnormalities. Patients with underlying kidney dysfunction should be monitored closely.[67]

In T315I-mutated CML, ponatinib should be considered. Ponatinib can be considered in patient with at least one second-generation TKI resistance. Notable toxicities include AOEs, pancreatitis, hypertension, and severe skin rash. Although the risk of AEOs is not negligible, the treatment benefit from ponatinib outweighs the risks in most patients with a T315I mutation. The risks of AOEs can be minimized at reduced doses and optimal management of cardiovascular risk factors.

Second- and third-generation TKIs have not been compared head to head. Selection of one or the other is based on the side effect profiles, mutation profile, drug interactions, compliance issues, and the patient's preexisting medical conditions. Mutational analysis is required after failure of imatinib or second-generation TKIs or after progression to CML-AP or CML-BP.

Allogeneic Stem Cell Transplantation

TKI therapy has drastically changed the outcome of patients with CML-CP. Since 2000, the number of patients who underwent allo-SCT has decreased. Although the majority of patients who achieved deep molecular remission have a stable clinical course, approximately 1% to 2% of patients develop TKI-resistant CML every year. Given the increased prevalence of CML, the number of patients requiring allo-SCT may start to increase. Allo-SCT is an important curative option in patients who fail at least two TKIs or who harbor a T315I mutation if ponatinib is not effective.[124,125] Prior TKI exposure did not affect the outcome after allo-SCT lower burden of CML may have a better outcome.[125]

The financial burden and availability of allo-SCT and TKI therapy needs to be considered. The estimated cost of allo-SCT, a curative one-time procedure, is $500,000 in the United States but only $12,000 to $20,000 in developing countries.[126,127] Given the low annual cost of genetic imatinib of $400 to $1000 per year, allo-SCT should not be considered before TKI therapy since the survival of patients with CML-CP is approaching that of a general population[12]. Given the estimated survival of CML-CP for 30+ years from diagnosis, the total estimated cost would be $12,000 ($400 × 30 years), which is comparable to the lowest cost of allo-SCT in developing countries. Generic imatinib therapy has also significantly lower medical costs than allo-SCT. In patients with imatinib-resistant or -intolerant CML, the financial comparison of medical costs with second- or third-generation TKIs versus allo-SCT should be discussed.[127] In nations with financial constraints, allo-SCT could be offered as a salvage treatment option. Recommendations for the role and timing of allo-SCT in patients with CML are outlined in Table 4–8.[128]

TREATMENT-FREE REMISSION (TFR)

Multiple clinical trials of TFR evaluated the discontinuation of TKI therapy in patients who achieved deep molecular remission to aim at a functional cure of CML. The Stop Imatinib (STIM) trial evaluated treatment discontinuation in 100 patients on imatinib with undetectable transcripts for at least 2 years.[129]

TABLE 4–8 Recommendations Regarding the Role and Timing of Allogeneic Stem Cell Transplant (Allo-SCT) in Chronic Myeloid Leukemia

Status	TKIs	Allogeneic HSCT
AP, BP	Interim treatment to MRD	If in remission
Imatinib of first-line second-generation TKI treatment failure in CP, with T315I mutation	Ponatinib	If not responding well to ponatinib
Imatinib or first-line second-generation TKI treatment failure in CP, no clonal evolution, no mutations, good initial response to imatinib	Long-term treatment with TKI in second-line setting	Third line after second TKI treatment failure
Imatinib or first-line second-generation TKI treatment failure in CP, with clonal evolution, with mutations resistant to second-generation TKIs, no CyR to imatinib	Interim treatment with ponatinib eventually to MRD	As soon as possible if no response to ponatinib
Older patients (age older than 70 years), after imatinib treatment failure	Long-term treatment with TKI in second-line setting	Forego allo SCT for many years or for the patient lifetime (maximize quality of life)

AP, accelerated phase; BP, blast phase; CML, chronic myeloid leukemia; CP, chronic phase; CyR, cytogenetic response; MRD, minimal residual disease; TKI, tyrosine kinase inhibitor.

Molecular relapse was observed in 42 (61%) patients; 40 patients relapsed within 6 months of TKI discontinuation. At the time of molecular relapse, the reintroduction of imatinib achieved undetectable transcripts in 26 (62%) patients and decreased transcript levels in 16 (38%) patients. TFR was evaluated in multiple studies for patients with a frontline second-generation TKI with different criteria regarding the depth and duration of molecular remission.[130–133]

The European Stop Kinase Inhibitor (EURO-SKI) trial is the largest study of TKI discontinuation.[133] It included 821 patients with CML on frontline imatinib, nilotinib, or dasatinib in deep molecular remission, at least MR4 (*BCR-ABL1* transcript [IS] <0.01%). The molecular recurrence-free survival, defined as the time period from the date of TKI discontinuation to the date of the first event (loss of MMR or death) or censoring was 52% at 2 years. When the same TKI was resumed at the time of molecular relapse (ie,, the loss of MMR) among 321 patients, 81% reachieved a molecular response (MMR or MR4). A multivariate logistic regression showed the duration of MR4 for more than 3 years and the duration of TKI therapy for more than 6 years were prognostic factors. We have reported similar findings in our experience. With a median follow-up period of 30 months, a longer duration of TKI therapy was associated with higher TFR rates. In patients who achieved a sustained MR4.5 for more than 5 years, the TFR rate was 92%.[134] This suggests that longer duration of sustained MR4.5 may translate into improved TFR outcome.

A long-term periodic molecular monitoring is mandatory during TFR. With a follow-up over 15 years of a single institution experience of treatment discontinuation, 128 patients were treated with frontline imatinib (61%), frontline second-generation TKI (11%), and second line second-generation TKI (28%) and entering first TFR (TFR1).[135] With a median follow-up period of 6.5 years, 65 patients had a molecular relapse, including 9 (14%) relapses after 2 years; 1 patient relapsed at 6.4 years of TKI discontinuation. Patients with late molecular relapse had a long-term period of *BCR-ABL1* fluctuations between MR4 and MMR. We have reported an anecdotal case of sudden progression to myeloid BP under TFR.[136] The incidence of late molecular relapse and potential sudden progression to BP suggest the necessity of long-term follow-up of patients in TFR.

Initially, second-generation TKI therapy was reported to have a relatively higher TFR rate compared with that of first-generation imatinib. Successful TFR without TKI therapy over years will benefit younger patients given that their expected survival is longer.[137] However, the expected percentages of TFR was low; approximately 20% to 25% and 30% to 45% with imatinib and second-generation TKIs, respectively. Multiple randomized clinical trials have consistently reported that treatment with frontline second-generation TKIs achieved higher rates of deep molecular response, and more patients taking second-generation TKIs will be potential candidates for TFR compared with imatinib at the expense of financial costs and toxicities.[58,73] The use of second-generation TKI will cost $917,056 additionally over 10 years to achieve moderate improvement of QALY. The analysis of the incremental cost-effective ratio showed the use of second-generation TKIs will cost more than $22,000,000 to achieve a gain of 1 QALY from the replacement

of frontline generic imatinib with second-generation TKIs. The financial burden of the selection of TKI and the decision of frontline TKI should consider the potential cure fraction carefully.[73–75]

Novel combinations of TKI have been under evaluation in order to increase the fraction of functional cure. These combination strategies aim to target dormant CML stem cells in patients with deep molecular remission over years. CML stem cells may stay in a quiescent state, which may contribute to the relative resistance to TKI therapy.[138] The strategies include the combination of TKI with pegylated IFN-α2b,[139–142] Bcl-2 inhibitors such as venetoclax,[143] JAK2 inhibitors,[144] hypomethylating agents,[145] and immune-mediated treatments such as PD-1 inhibitors and dendritic cell vaccination.[146]

ADVANCED STAGE CHRONIC MYELOID LEUKEMIA

Second- or third-generation TKIs should be considered as initial therapy for patients with advanced stage CML followed by allo-SCT.[147–149] Although the addition of TKIs to chemotherapy improves survival in patients with CML-BP, survival remains suboptimal.[150] Combinations of TKIs and chemotherapy achieved response rates of 40% and 70% to 80% in nonlymphoid and lymphoid CML-BP. The median survivals are 6-12 months and 12-24 months, respectively. The median survival time of 477 patients with CML-BP treated with a TKI was 12 months.[15] Stem cell transplant confers the best outcome for patients in remission after the combination of TKI with intensive chemotherapy. The combination of fludarabine-high dose cytarabine-idarubicin with ponatinib 30 mg/day achieved responses in 11/16 (69%) patients with CML-BP.[151] Five patients achieved MMR after induction therapy; 9 patients proceeded to allo-SCT. The survival rate was 50% at 12 months.

Allo-SCT remains the only curative therapy for CML-AP and CML-BP (cure rates of 40% and 10% to 20%, respectively). The presence of clonal evolution as the only AP criterion is associated with EFS rates of 60%. In patients with CML-AP treated with TKI therapy, 80% achieved hematologic response; the estimated 4-year survival rate was 40% to 55%. In patients with CML-BP, the response rate was 40% and the median survival 9 to 12 months. TKI-naïve patients with de novo CML-AP have a higher survival rate with frontline TKI therapy than patients who progress from CML-CP to CML-AP. The survival rate of de novo CML-AP with TKI therapy were 60%.[14,149]

Allo-SCT should be considered in patients who progress from CML-CP to CML-AP after TKI therapy failure and who fail second- or third-generation TKI in case of de novo CML-AP. The combination of TKI with chemotherapy is an alternative treatment option for patients who are not optimal candidates for allo-SCT or as a bridge therapy to allo-SCT in remission. TKI therapy before allo-SCT does not increase the risk of transplant-related mortality.[152–154] When allo-SCT is performed in patients in CML-AP or CML-BP, posttransplant maintenance TKI therapy should be considered.

FUTURE PERSPECTIVES

Since the advent of TKI therapy, the survival of patients with CML is approaching that of the general population. In 2021, therapeutic options have expanded, including five commercially available TKIs (imatinib, dasatinib, nilotinib, bosutinib, and ponatinib), omacetaxine, and traditional agents, including hydroxyurea, IFN-α, cytarabine and hypomethylating agents. Optimal survival requires optimal monitoring for signs of resistance, optimal decisions regarding switching TKI therapy in case of resistance or intolerance, compliance and adherence to TKIs, and considering allo-SCT in case of multiple TKI failures. Once in deep molecular remission over years of TKI therapy, patients become potential candidates for TFR to aim at functional cure without TKI therapy. The increase in the fraction of functional cure without TKI therapy has a significant impact on the financial burden of patients and their families, as well as on the health care systems, given the prevalence of CML is expected to increase in the United States and worldwide. Therefore, it is important to continue the research aimed at long-term TFR in patients with CML. TKIs-based combinations with available (Bcl-2 inhibitors, JAK2 inhibitors, peg IFN-α2, omacetaxine, decitabine, immunotherapy) or other investigational therapies are in progress. These strategies may eradicate CML stem cells and obviate the need for indefinite TKI therapy to maintain optimal survival. Further understanding of the downstream pathways of *BCR-ABL1* signaling may help develop new strategies to target CML stem cells.

MD ANDERSON PRACTICE TIPS

- At diagnosis, all patients with leukocytosis and suspected for CML should undergo bone marrow aspiration and biopsy to establish the diagnosis, assess percentages of blasts and basophils, and evaluate the presence of clonal evolution.
- With multiple TKIs available for patients with newly diagnosed CML-CP, there are several considerations when choosing a starting agent such as patient status (age and comorbidities, TKI toxicity profile), cost of treatment, and disease characteristics and risk score.
- Given the equivalent efficacy and lower toxicity of lower dose dasatinib, dasatinib 50 mg/day has become our standard of care for frontline therapy of patients with CML-CP.
- To minimize the risk of arterio-occlusive AOEs, it may be reasonable to start ponatinib 45mg/day in T315I-mutated CML and 30 mg/day in other resistant CML-CP, and lower the dose to 15 mg/day when *BCR-ABL1* transcripts below 1% (IS) are achieved.
- The use of allogeneic-SCT and the switch to other TKI should not be considered for patients who achieve CCyR without MMR or deep molecular response.
- A long-term periodic molecular monitoring is mandatory during TFR. Patients with late molecular relapse had a long-term period of *BCR-ABL1* transcripts fluctuations between MR4 and MMR. The incidence of late molecular relapse suggest the necessity of long-term follow-up of patients in TFR.

Myelodysplastic Syndromes: The MD Anderson Cancer Center Approach

Kelly Chien
Carlos Bueso-Ramos
Guillermo Garcia-Manero

KEY CONCEPTS

- The term *myelodysplastic syndrome (MDS)* refers to a very heterogeneous group of myeloid disorders. In a majority of patients, MDS results from defects in a primitive hematopoietic stem cell compartment.
- Individuals with evidence of clonal hematopoiesis are at increased risk of developing MDS.
- Prognosis is calculated using a number of variables, including degree of cytopenia, percentage of blasts, cytogenetic alterations, and more recently genomic annotation.
- Using either the International Prognostic Scoring System or the Revised International Prognostic Scoring System, patients are divided into those with lower and higher risk disease.
- For patients with lower-risk disease, treatment approaches include growth factors, iron chelation, luspatercept, lenalidomide (for del5q- MDS), hypomethylating agents (HMAs; azacitidine or decitabine) or antithymocyte globulin–-based therapy (for patients with hypoplastic MDS). Allogeneic stem cell transplantation (allo-SCT) is reserved for younger patients with poor risk features.
- For patients with higher risk disease, the main treatment options include the HMAs and less frequently acute myeloid leukemia–like therapy. Allo-SCT should be considered in candidate patients early in the course of the disease in responding patients. Clinical trials should be considered for a majority of patients with MDS.

Myelodysplastic syndromes (MDSs) refer to a group of hematopoietic disorders characterized by ineffective hematopoiesis and increased risk of transformation to acute myeloid leukemia (AML). The median age of patients with MDS is 70 to 75 years. It is likely that environmental factors play an important role in the pathogenesis of this disease. MDSs are classified according to the World Health Organization (WHO) criteria, and a number of prognostic scores can be used to calculate survival and risk of transformation. Cytogenetic, genomic, and epigenetic alterations are common in MDS and help in the prediction of prognosis and potentially in the selection of therapy. Over the past decade, we have witnessed significant improvements in supportive care and therapeutic modalities for patients with MDS. These include growth factors, luspatercept, immune modulatory agents (lenalidomide), and hypomethylating agents (HMAs; 5-azacitidine and decitabine), with new oral formulations. We also better understand patient subgroups, such as those with hypomethylating failure disease. In this chapter, we summarize our knowledge of MDS and the treatment approach we use at MD Anderson Cancer Center (MDACC).

THE MD ANDERSON APPROACH TO PATIENTS WITH MYELODYSPLASTIC SYNDROMES

Approximately 350 to 400 patients are referred to MDACC annually with a diagnosis of MDS, and nearly 20% of these patients receive a different diagnosis. In most instances, the final diagnosis is AML or a form of higher risk MDS. Other benign and malignant conditions are also diagnosed. In a study of 915 patients referred to MDACC between 2005 and 2009,12% of patients were reclassified after evaluation at MDACC using very strict criteria.[1] This justifies our practice to repeat a confirmatory bone marrow aspiration and biopsy at the time of initial MDS evaluation at MDACC.

After the diagnosis is confirmed, the next important step is to calculate the "risk" of the patient. Many clinicians and investigators still use the International Prognostic Scoring System (IPSS)[2] score to perform such analysis, but more precise models, such as the Revised International Prognostic Scoring System (IPSS-R), have been developed.[3–5] Patients with low or intermediate-1 risk by the IPSS or those with less than 10% blasts in the bone marrow are considered as having lower-risk disease, and those with excess blasts or intermediate-2 or high-risk disease are considered as having higher risk disease. When using the IPSS-R, patients with very low, low, and some subsets of intermediate risk are considered as having lower-risk disease, whereas those with high, very high and some subsets of intermediate risk are considered as having higher risk disease.[6]

Patients with lower-risk disease can be candidates for a wide range of interventions, depending on their specific characteristics and transfusion needs. Patients with minimal cytopenias, who are transfusion independent, have a low percentage of blasts in the bone marrow, and have normal cytogenetics are more frequently observed because their 4-year survival rate is close to 80%.[4] At the other end of the spectrum, older patients with significant cytopenias and transfusion needs can have very poor prognoses, particularly if their cytogenetics are abnormal.[4] The median survival time of these patients is less than 12 months; around 60% to 70% of patients with MDS are in this category, but there are few interventions known to alter the natural history of these patients. Transfusion and growth factor support are usually initiated. Interventions, such as lenalidomide, have significant activity in improving red blood cell (RBC) counts in patients with deletion of chromosome 5[7] but are significantly less active in patients without this alteration.[8] The role of the HMAs 5-azacitidine and decitabine is less clear in this situation, although they are frequently used. allo-SCT is not frequently used up front in patients with lower-risk disease,[9] and delaying transplantation until the time of progression is associated with longer survival times even if transplant outcomes are poorer when performed at that time. A new subset of patients has emerged with lower-risk disease but also with hypomethylating failure.[10] The prognosis of these patients is poor, and new investigational strategies are needed.

Treatment decisions are relatively simpler for patients with higher risk MDS. The data with HMA indicate that treatment with these agents improves survival significantly compared with supportive care or low-dose chemotherapy approaches. The optimal approach for patients younger than age 60 to 65 years with MDS is unclear. These patients can be treated with HMA or an AML-like induction therapy or can be considered for up-front allo-SCT. No study has compared these treatments in younger patients. An approach followed by our group is to stratify patients based on cytogenetics. Younger patients with normal karyotypes are offered induction therapy with an AML-like approach followed when possible by allo-SCT. In contrast, younger patients with abnormal karyotypes receive HMA-based therapy followed by allo-SCT. It is not our routine to proceed with up-front transplant in patients with excess blasts. Older patients benefit significantly from the use of HMAs, and there is no upper age limit that may contraindicate their use.[11] Finally, the group of patients with higher risk disease and hypomethylating failure constitute a major unmet medical need.[12]

A comprehensive review of current knowledge in MDS is provided next. Current areas of intense research are the development of newer forms of therapy for patients with newly diagnosed disease and strategies for patients who have relapsed or not responded to HMA-based therapy.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of MDS increases with age. Most patients diagnosed with this condition are older than 60 years old; the median age at diagnosis is 75 years.[13] The incidence is higher in men than women, with a 2:1 ratio.[13] The incidence in the United States is 30 to 35 individuals per million per year with a relative yearly increase in the reported incidence, probably related to increase awareness of the disease and reporting efforts.[14]

The risk of developing MDS is related to the individual's racial background. In the United States, the incidence is highest in the white population.[13] Patients with MDS from Asia present at a younger age.[15] The underlying cause of this phenomenon is not known but may reflect genetic differences between different racial groups. Asian patients have a similar frequency of karyotype abnormalities as European and American cohorts, although they may have less frequent alterations of chromosomes 5 and 7.[15–17] The combination of younger age at diagnosis and lack of chromosome 7 alterations can explain the longer survival times observed in patients from Asia.

There is no known cause of MDS, but genetic or environmental risk factors may contribute. Genetic syndromes, such as Down syndrome, Bloom syndrome, and Fanconi anemia, are associated with an increased risk of MDS, which often presents earlier in life.[18,19] Genetic polymorphisms that influence the activity of enzymes responsible for metabolizing toxic chemicals or chemotherapy drugs may influence an individual's predisposition to MDS. Polymorphisms have been described in the cytochrome p450 3A, glutathione-*S*-transferase, and NAD(P)H quinine oxidoreductase enzyme systems that increase the risk of developing myeloid malignancies.[20–22]

Environmental agents may contribute to the development of MDS by causing toxic damage to hematopoietic stem cells. A causal relationship between occupational exposures to benzene and radiation and the development of myeloid malignancy has been demonstrated.[23] Exposure to organic solvents and pesticides has also been implicated in the development of MDS.[24–26] There is no correlation between MDS and socioeconomic status.[25]

The most significant risk factor for the development of MDS is previous exposure to chemotherapy or radiotherapy used to treat other cancers. Treatment-related MDS (t-MDS) constitutes a minority of MDS diagnoses but may be increasing in prevalence with improved survival rates after successful cancer therapies for tumors. Usually, t-MDS presents 5 to 6 years after initial cancer treatment and generally has a poor prognosis.[27] Patients treated for lymphoma are at risk of this long-term complication.[28] Patients who undergo autologous hematopoietic stem cell transplantation have a higher risk, approximately 10% to 15% of developing treatment-related MDS or AML, with incidence rates in some centers of up to 10%.[29] In our experience with t-MDS at MDACC in 281 patients, most of the risk was associated with complex cytogenetics or presence and alteration of chromosome 7.[30]

CLINICAL AND LABORATORY FEATURES

Most patients with MDS are diagnosed incidentally during routine complete blood cell count (CBC) analysis or because of nonspecific symptoms. Anemia is the most common cytopenia in MDS and is associated with fatigue. A lower percentage of patients presents with bleeding or bruising secondary to thrombocytopenia or with infections related to neutropenia. Physical examination is often normal. Hepatosplenomegaly may be present in patients with chronic myelomonocytic leukemia (CMML) or overlap myeloproliferative neoplasms. A change in the severity of cytopenia or rapid worsening of symptoms may indicate disease transformation. Patients suspected to have MDS transformation require prompt investigation because 20% to 30% of patients develop acute leukemia throughout their disease course.[2]

Initial assessment should include a CBC, reticulocyte count, and serum chemistry, including vitamin B_{12} and folate, iron studies with ferritin, and erythropoietin (EPO) level examination. Other causes of cytopenias or MDS-mimicking syndromes (eg, HIV [human immunodeficiency virus], other infections, autoimmune disorders, or copper deficiency) should be ruled out through appropriate tests. A bone marrow aspirate and biopsy with samples taken for an iron stain and cytogenetic and molecular studies are essential. Morphologic assessment of the disease is still required for MDS. Cytogenetic studies may confirm the presence of clonal hematopoiesis and provide additional important prognostic information. Analysis of specific gene mutations, such as *TET2*, *DNMT3A*, *ASXL1*, *TP53*, splicing factors, *NRAS*, *FLT3*, *IDH1*, *IDH2*, and *JAK2*, may improve our prognostic and predictive evaluation and allow for the use of targeted interventions using selective inhibitors (eg, *FLT3*, *JAK2*, or *IDH1/2* inhibitors) or earlier consideration of allo-SCT. However, it should also be noted that these molecular abnormalities[31] may be present in older individuals with or without cytopenias and may not necessarily point to an MDS diagnosis.

Clonal hematopoiesis of indeterminate potential is a phenomenon in which clonal somatic mutations are present in hematopoietic cells from older individuals with no evidence of a hematologic disorder.[32,33] These patients have been found to have an increased risk of hematologic neoplasms, therapy-related myeloid neoplasms, and cardiovascular disease.[34–37] Whereas the presence of a somatic mutation in the presence of cytopenias with no diagnostic criteria for MDS is considered clonal cytopenia of undetermined significance (CCUS),[38,39] individuals with cytopenias but no dysplasia are considered to have idiopathic cytopenia of undetermined significance (ICUS). The distinction between ICUS and CCUS is important because the risk of developing MDS and AML increases from 9% to 82% at 5 years in the presence of highly predictive mutation patterns.[39,40]

BONE MARROW FEATURES

Morphologic Analysis

Table 5–1 shows the different subsets of MDS under the 2016 WHO MDS classification.[41] Morphologic classification of MDS is based on a 500-cell differential count on the bone marrow aspirate and leukocyte

TABLE 5–1 Classification of Myelodysplastic Syndromes (MDS) According to 2016 World Health Organization Criteria

MDS with single-lineage dysplasia (MDS-SLD)
MDS with multilineage dysplasia (MDS-MLD)
MDS with ring sideroblasts (MDS-RS)
MDS-RS with single-lineage dysplasia (MDS-RS-SLD)

differential performed on the blood smear. This analysis determines the percentage of blasts present in the blood and bone marrow and provides an assessment of the number of myeloid lineages involved in the dysplastic process, and the iron stain determines the presence and number of ring sideroblasts.[42]

As shown in Figure 5–1, blood cell abnormalities on the peripheral blood smear are variable.[42] RBCs may be macrocytic and frequently display anisopoikilocytosis. Polychromasia or basophilic stippling may be present. Dysplastic granulocytes may show abnormal folding of the nucleus, and cytoplasmic granules are often reduced or absent. Platelets are of variable size and may also be hypogranular. The presence of circulating blast cells or an excess of monocytes is important for the classification of high-risk MDS and CMML, respectively.

Definitive diagnosis requires a bone marrow aspirate and biopsy. The bone marrow is usually normocellular or hypercellular, reflecting that hematopoiesis is ineffective. Abnormal maturation of hematopoietic cells results in a variable proportion of myeloblasts that are significantly increased in the more aggressive MDS. Morphologic abnormalities found in the nucleus of erythroblasts include nuclear budding, internuclear bridging, karyorrhexis, multinuclearity, and megaloblastoid changes (see Fig. 5–1). Cytoplasmic features include the presence of ring sideroblasts and abnormal vacuolization. Abnormal or absent granulation is a common feature of dysplastic granulocyte series. Aberrant nuclear folding of the neutrophil precursor can produce a dysplastic bilobed nucleus, the pseudo–Pelger-Huet anomaly. Megakaryocytes may have a very variable morphology, and a small dysplastic form called the micromegakaryocyte is a typical finding. A normal megakaryocyte has a polyploid nucleus that can be altered with dysplasia to produce hypolobulation or nuclei that are dispersed throughout the cell. The bone marrow biopsy provides the best assessment of the overall cellularity and allows examination of the architecture of the marrow and surrounding bone (Fig. 5–2). The presence of fibrosis can be assessed on biopsy with specific stains for reticulin and collagen. In normal bone marrow, the immature blast cells are frequently located near the endosteal surface. In MDS, these cells may be distant to this site and form aberrant clusters referred to as abnormal localization of immature precursors. Immunohistochemical staining of biopsies can aid diagnosis, with CD34 staining to identify blast and progenitor cells and CD42 or CD62 for quantitation and assessment of megakaryocytes (see Fig. 5–2).[43]

Nonclonal diseases may cause dysplastic morphologic changes in blood cells. Secondary causes of dysplasia should be excluded in the initial assessment and can potentially complicate the diagnosis. Blood cell dysplasia is seen with exposure to heavy metals or antituberculous therapies, vitamin B_{12} and folate deficiency, HIV infection, excessive alcohol consumption,[42] and occasionally normal aging.[44] Dysplastic features are commonly observed after chemotherapy or with the therapeutic use of granulocyte colony-stimulating factor (G-CSF). These diagnoses should be assessed in the history and may require exclusion with further laboratory testing. Diagnostic difficulties may occur in patients with marked hypocellularity of the bone marrow and in patients with prominent fibrosis because there are often very few cells in the aspirate sample to allow morphologic assessment of dysplasia. For patients with prominent hypocellularity of the marrow, it may be difficult to distinguish from aplastic anemia, for which morphologic dysplasia of the erythroid lineage may also be observed. In cases of marked fibrosis, bone marrow aspiration is often unsuccessful. Some patients with mild dysplastic changes in the bone marrow and a normal karyotype are difficult to definitively diagnose at initial presentation and may require a period of observation to confirm the underlying diagnosis. These patients require review with repeat investigations performed in 3 to 6 months.

Cytogenetic and Molecular Analyses

A cytogenetic abnormality is found in 40% to 50% of patients with primary MDS and lower-risk disease; it is higher in patients with more advanced MDS. Cytogenetic analysis of hematopoietic cells derived from the bone marrow aspirate provides important prognostic and predictive information and may direct therapy (eg, lenalidomide therapy with deletion 5q or earlier allo-SCT with complex or adverse karyotypes). A karyotypic abnormality provides evidence for the presence of a clonal blood disorder, which may be particularly important if the morphologic changes are not clear. Typically, cytogenetic analysis assesses 20 bone marrow metaphases.[43] Multiple different cytogenetic abnormalities have been described and are summarized in Table 5–2.[45] No specific cytogenetic abnormalities characterize MDS. Unlike AML and chronic myeloid leukemia, genetic translocations are rare in MDS, but deletions are common.

The presence or absence of a cytogenetic abnormality has a marked influence on prognosis.[45] The median survival time of patients with normal karyotypes is approximately 53 months compared with less than 12 months for patients with three or more cytogenetic abnormalities, known as a complex karyotype. Del(5q) and del(20q) are associated with a favorable prognosis. However, when these abnormalities are present in association with other cytogenetic abnormalities, especially as a component of a complex karyotype, the prognosis is poor. Abnormalities of chromosome 7, usually deletions, are associated with a poor prognosis regardless of the presence or absence of other abnormalities. Complex

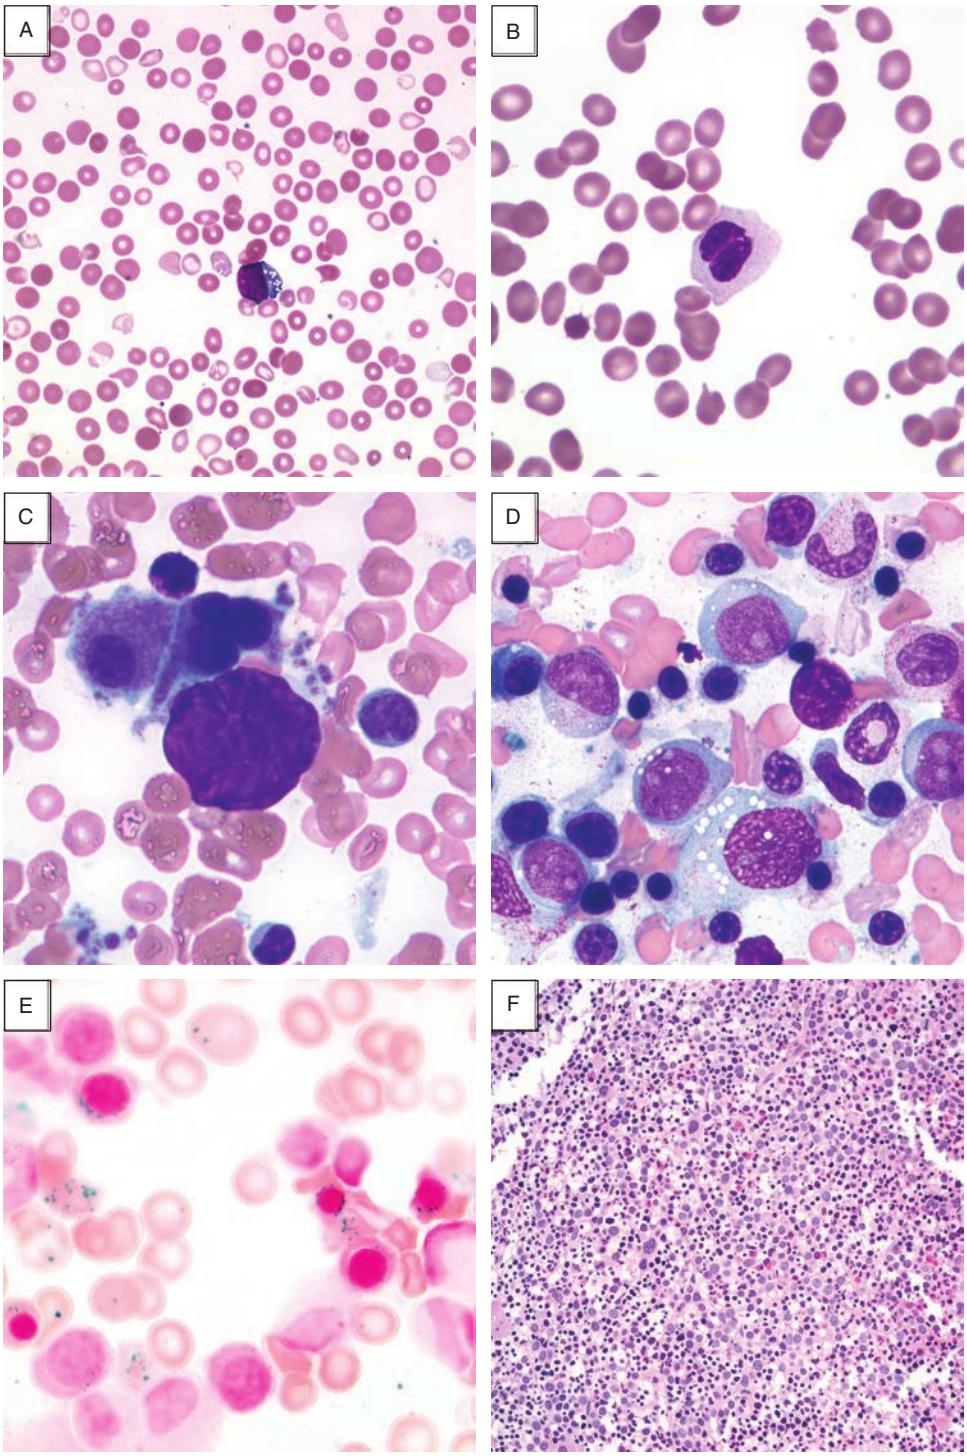

FIGURE 5–1 Morphologic features of peripheral blood and bone marrow in the myelodysplastic syndromes. **A.** Peripheral blood film from a patient with refractory anemia with excess blasts-1. The erythrocytes show hypochromasia, anisocytosis, and macroovalocytes. There is also an occasional blast (*center*). **B.** Peripheral blood film from a patient with refractory cytopenia with multilineage dysplasia demonstrating pseudo–Pelger-Huet cell (*center*) with hypercondensed chromatin and bilobed nuclei and hypogranular cytoplasm. **C.** Dysplastic small megakaryocytes, some with monolobated or with separated nuclei and mature granular cytoplasm in the bone marrow aspirate, from a patient with refractory anemia with excess blasts. **D.** Increased blasts, dysgranulopoiesis, and dyserythropoiesis in the bone marrow aspirate from a patient with refractory anemia with excess blasts. **E.** Ring sideroblasts and Pappenheimer bodies from a patient with refractory anemia with ring sideroblasts. **F.** Hypercellular (100%) bone marrow biopsy with increased immature cells and dysplastic megakaryocytes in a 70-year-old man with refractory anemia with excess blasts.

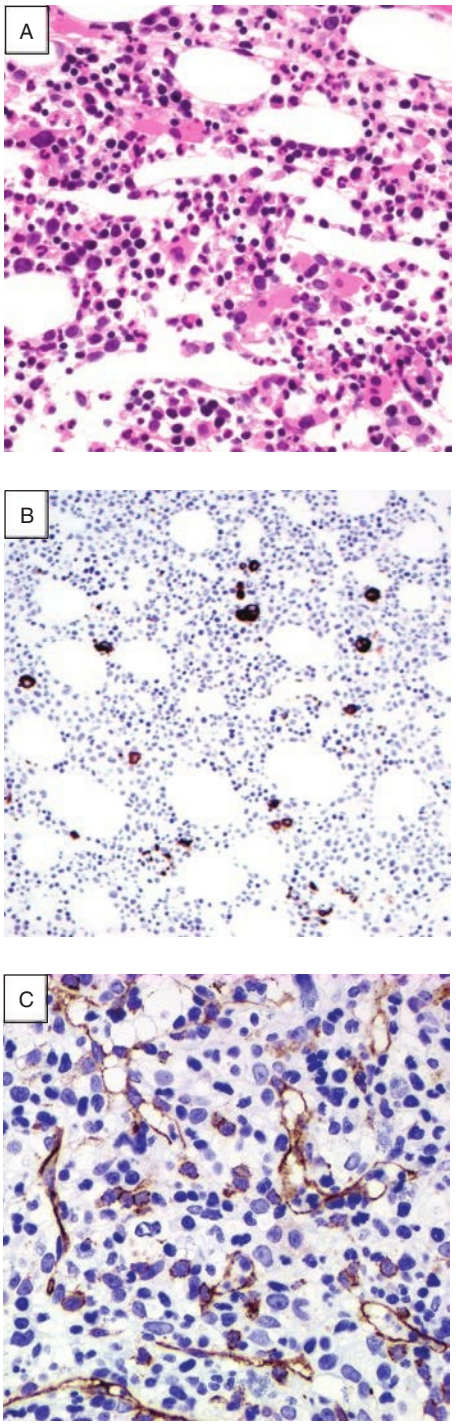

FIGURE 5–2 **Morphologic and immunohistochemical feature of bone marrow biopsy in the myelodysplastic syndromes. A. Trephine bone marrow biopsy with numerous dysplastic monolobated megakaryocytes in a 60-year-old female patient with refractory anemia with excess blasts type 1. B. CD61 immunohistochemical stain highlighting many dysplastic micromegakaryocytes. CD61 may be helpful in detecting dysplastic micromegakaryocytes to aid in confirming dysmegakaropoiesis and abnormal translocation of megakaryocytes to endosteal surfaces. C. CD34 immunohistochemical staining highlighting the presence of an increased number of blasts and increased blood vessels.**

cytogenetic abnormalities are more frequently observed in patients with increased marrow blasts. Progressively worse prognoses are observed with increasing karyotypic complexity. Patients with six or more abnormalities have a very poor median survival time of 5 months.[45] In 2012, a comprehensive scoring cytogenetic system was developed using data from 2902 patients.[46] This analysis resulted in 19 new cytogenetic categories and 5 prognostic subgroups, as shown in Figure 5–3, which serves as the basis for the IPSS-R scoring system.[5]

Treatment-related MDS has a particularly high incidence of cytogenetic abnormalities, with karyotypic changes observed in 70% to 90% of cases.[27,30,45] A high incidence of abnormalities is associated with an unfavorable prognosis for this group of patients. Abnormalities of chromosomes 5 and 7 are frequently observed after exposure to alkylating agents.[47,48] Translocations involving 11q23 are seen after treatment with topoisomerase II inhibitors.[47]

The high frequency of chromosomal deletions has prompted interest in the identification of epigenetic repressive alterations, such as aberrant DNA methylation in MDS. Aberrant DNA methylation of multiple promoter CpG islands has been associated with poor prognosis in MDS.[49] At this point, we do not have evidence of specific molecular pathways that are epigenetically inactivated in MDS.

An association between a genetic abnormality and disease phenotype was reported in a few specific subsets of MDS. An example is the 5q- syndrome.[50] A minority of patients with an interstitial deletion of chromosome 5q display an indolent anemia with relative preservation of the platelet count associated with hypolobated megakaryocytes in the bone marrow (Fig. 5–4). This array of findings is called the 5q- syndrome and is recognized as a separate diagnostic entity in the current WHO classification. The genetic defect within the deleted region that is responsible for the disease is not known. Research has focused on one candidate gene, *SPARC*, that may potentially contribute to the malignant phenotype.[51] *CTNNA1* is another gene on chromosome 5q identified to be important in MDS and AML but without specific features of the 5q- syndrome.[52] *RPS14* was identified as haploinsufficient in 5q- MDS and is involved in ribosomal biogenesis; its deficiency has a role in anemia in this syndrome.[53] It is likely that a complex network of genes cooperate in the pathogenesis of this syndrome. Indeed, microRNA 145 and 146a have been found to be involved in the biology of 5q- syndrome.[54]

A small number of patients have been described with a deletion of 17p associated with abnormalities in the *p53* gene. This specific disorder has a poor prognosis and may be suspected when morphologic characteristics of prominent dysgranulopoiesis, including neutrophils exhibiting the Pelger-Huet anomaly and abnormal vacuolization, are present.[55] Acquired

hemoglobin H disease produces RBC changes on the blood smear reminiscent of a-thalassemia. This RBC phenotype is secondary to decreased expression of a-globin within the bone marrow MDS clone and is associated with a mutation in the *ATRX* gene in most cases.[56] These rare syndromes represent a small minority of patients with MDS, and specific gene defects are not identified in most patients.

Several groups have used large-scale single-nucleotide polymorphism (SNP) arrays in MDS.[57] This has allowed the identification of areas of microdeletions and uniparenteral disomy in MDS.[58] It is likely

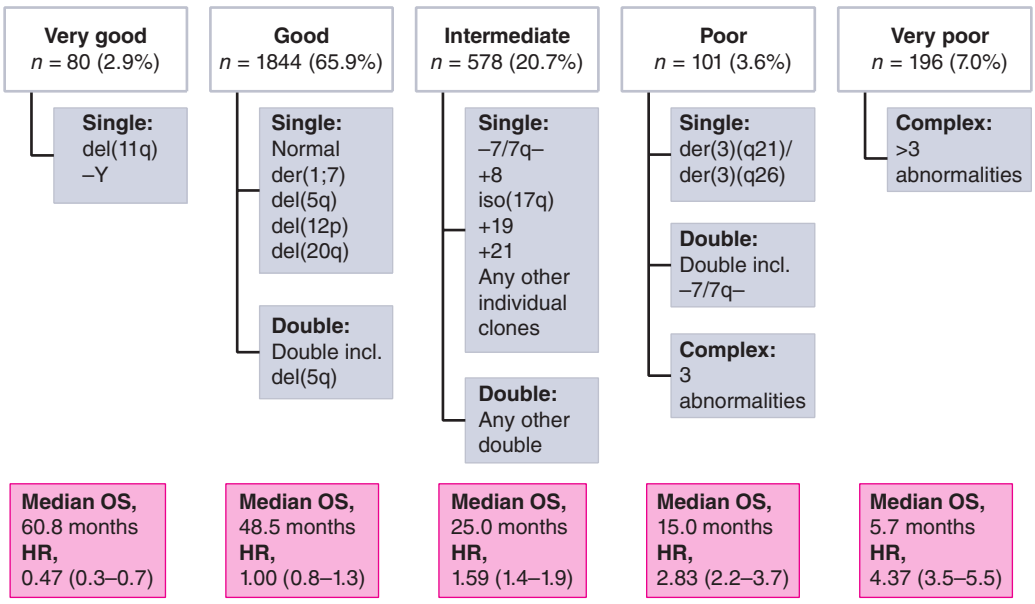

FIGURE 5–3 Cytogenetic score and corresponding prognoses. HR, hazard ratio; OS, overall survival.

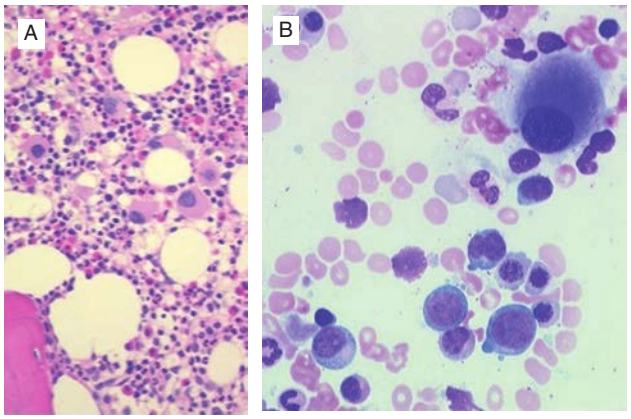

FIGURE 5–4 **A and B. Bone marrow morphology of myelodysplastic syndrome with deletion of chromosome 5.**

that these genomic regions harbor genes important in MDS, such as *c-CBL*.[59]

Over the past several years, we have accumulated significant information regarding genomic alterations in MDS, and the data are summarized in Figure 5–5.[31,60] Common mutations affect genes involved in gene splicing (eg, *SF3B1, SRSF2, U2AF1*), epigenetic regulators (eg, *TET2, DNMT3A, ASXL1,* and *EZH2*), and DNA repair and cell cycle control genes (eg, *PPM1D, TP53)*. The presence of mutations in *TP53* and *EZH2* is associated with poor prognoses.[31] Correlation of specific genomic alterations with gene expression patterns may explain some of the phenotypic features of the disease.[61]

Other Bone Marrow Studies

Flow cytometry is not required for the routine diagnosis of MDS, but it may sometimes provide valuable supplementary information. Flow cytometry can confirm the presence of specific myeloid lineages within the marrow and may also identify aberrant expression of cell surface markers indicative of a clonal cell population. This may have diagnostic significance in confirming abnormal hematopoiesis, particularly in the setting of inconclusive morphologic changes and a normal karyotype. Quantitation of the number of CD34-positive cells in the bone marrow may assist in the differentiation of hypoplastic MDS from aplastic anemia. In MDS, the number of CD34 cells is usually normal or increased, compared with aplastic anemia, for which it is frequently reduced.[62]

Fluorescent in situ hybridization techniques using probes specific for specific chromosomes (ie, covering chromosomes 5,7, 8, and 20) have not been fully standardized in MDS. Their use should not be consider standard of care in MDS and cannot yet replace conventional cytogenetics.

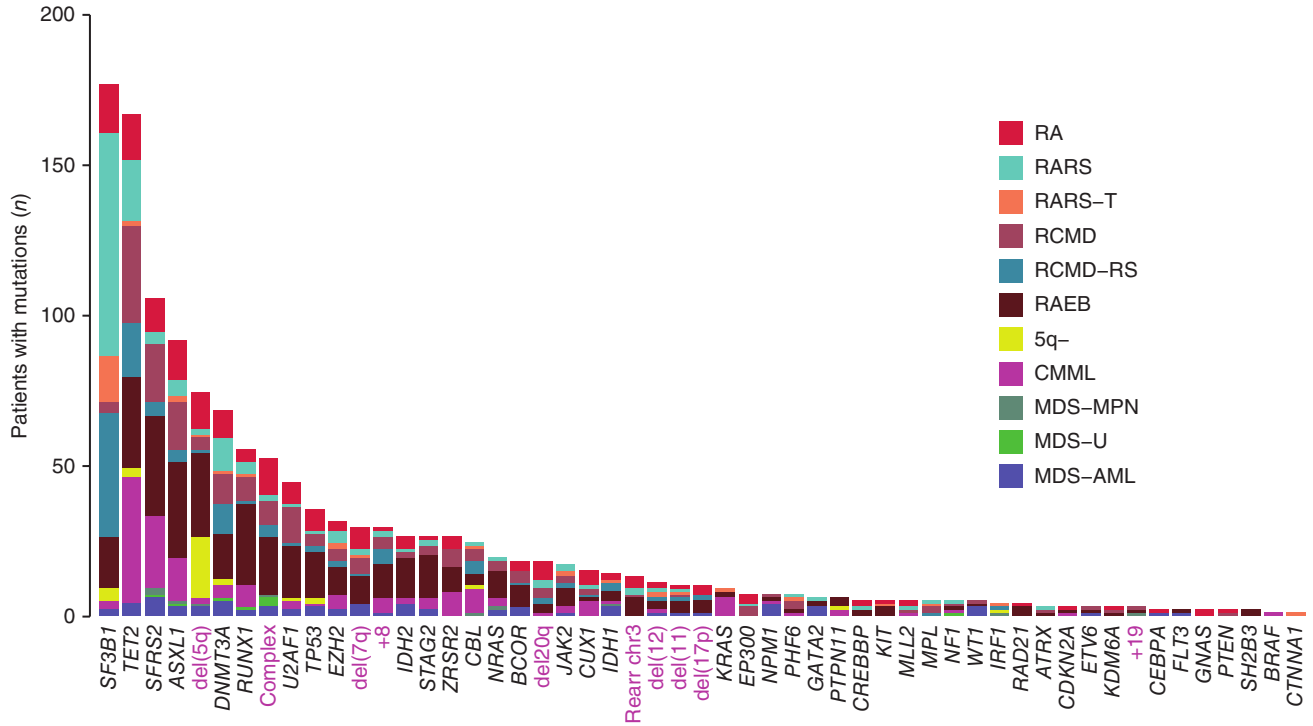

FIGURE 5–5 **Molecular data in myelodysplastic syndrome.**

DIAGNOSIS

The classification systems used to group different MDS have evolved over time with increased understanding of the biology and genetics of the disease. The first widely accepted classification was that proposed by the French-American-British (FAB) study group.[63] The FAB categorized MDS primarily on the percentage of blasts in the peripheral blood and bone marrow, with disease entities defined by increased numbers of blasts associated with a more aggressive clinical course. Patients with a bone marrow blast percentage greater than 30% were considered to have AML. This classification used only morphologic criteria to define disease groups and provided a framework that allowed the study of the natural history of MDS and its response to therapy.

The WHO classification of MDS was developed with the objective of using all features of disease biology, including morphology, cytogenetics, immunophenotype, and clinical behavior.[64] This classification was last updated in 2016 (see Table 5–1).[41] In the original WHO classification, the importance of morphologic assessment of blast percentage within the bone marrow and peripheral blood was retained, although the threshold level for the diagnosis of acute leukemia was altered. Patients with more than 20% bone marrow blasts were considered to have AML. Patients with 20% to 29% blasts had a similar prognosis as patients with greater than 30% blasts. Within the WHO MDS categories with an increased blast percentage, the magnitude of the blast elevation was quantified between MDS with excess blasts (MDS-EB) types 1 and 2, reflecting the worse prognosis of patients with an elevated blast count.[2,5] In patients with a normal proportion of blast cells within the bone marrow, the relatively indolent MDS with ring sideroblasts (MDS-RS) introduced in the FAB system were further delineated by assessment for the presence of multilineage dysplasia. Patients with dysplastic maturation limited to the erythroid lineage have a more favorable prognosis than patients with cytopenia and dysplasia present in multiple myeloid lineages. Also, the WHO introduced the 5q- syndrome as a separate diagnostic entity primarily on the basis of a genetic abnormality rather than morphologic features alone. Deletions involving chromosome 5q are relatively common in MDS, and the WHO classification tightly defined the syndrome as MDS with isolated del(5q) associated with anemia, a preserved or increased platelet count, and hypolobated megakaryocytes on the bone marrow biopsy (see Fig. 5–4). The WHO classification has been validated by a number of independent groups.[65,66] The 2016 WHO classification included the following changes: (1) replacing the terms "refractory anemia" and "refractory cytopenia" with "myelodysplastic syndrome" because of the minor impact of specific cytopenias and classification; (2) demonstrating 1% blasts on at least two separate occasions to diagnose MDS, unclassified (MDS-U); (3) changing the denominator for calculating blast percentage to all nucleated bone marrow cells rather than "nonerythroid cells"; (4) not including +8, -Y, or del(20q) as MDS-defining in the absence of morphologic features; and (5) excluding genomic data from classification but including specific mutations, such as *TP53* and *SF3B1*, on prognosis.[41]

PROGNOSIS

The prognosis of patients with MDS is heterogeneous. The development of clinical systems that allow accurate prognostication of individual patients into low- and high-risk categories has proven essential to guide rational management decisions and allow the introduction of investigational drug protocols. The IPSS, shown in Table 5–3, is the most widely used system for assessment of prognosis and treatment planning.[2] It provides an assessment of the prognosis of patients with primary MDS at the time of initial diagnosis. It was designed by the retrospective analysis of a large pool of 816 patients with MDS and followed the natural history of the disease to determine important factors related to patient outcome. Overall survival and the risk of transformation to acute leukemia were related to the number of blood cytopenias, the percentage of myeloblasts in the bone marrow, and the presence of specific cytogenetic abnormalities. The risk associated with cytogenetic abnormalities was determined to be good if a normal diploid karyotype, isolated del(5q), isolated del(20q), or isolated -Y were present. Poor-risk abnormalities were defined as abnormalities involving chromosome 7 or complex karyotypes with the presence of three or more karyotypic abnormalities. All other cytogenetic abnormalities were considered intermediate risk. The IPSS weighed these variables to produce a score that stratifies patients into four separate risk groups: low, intermediate-1, intermediate-2, and high risk (see Table 5–3). Survival and risk of transformation to acute leukemia are then predicted from cohorts of different ages, as illustrated in Table 5–3B. Patients classified as IPSS low and intermediate-1 risks are generally considered to have lower-risk MDS, and patients classified as having IPSS intermediate-2 and high are grouped into those with higher-risk MDS.

Lower-risk MDS is typically treated more conservatively than higher risk MDS. Prognostication in this lower-risk group may be particularly important because it is unclear at this time whether some lower-risk patients may benefit from early therapeutic intervention. To determine which lower-risk patients should be considered for treatment protocols investigating early

TABLE 5–3 International Prognostic Scoring System (IPSS)

A. IPSS Score: Sum of the Three Listed Prognostic Factors					
Score	**0**	**0.5**	**1**	**1.5**	**2**
BM blasts (%)	<5	5–10	—	11–20	21–30
Karyotype[a]	Good	Intermediate	Poor		
Cytopenias[b]	0/1	2/3

		Median Survival (years)			
Risk Group	**IPSS Score**	**≤60 years**	**>60 years**	**≤70 years**	**>70 years**
Low	0	11.8	4.8	9	3.9
Intermediate-1	0.5–1.0	5.2	2.7	4.4	2.4
Intermediate-2	1.5–2.0	1.8	1.1	1.3	1.2
High	≤2.5	0.3	0.5	0.4	0.4

[a]Good: normal, -Y, del(5q), del(20q); poor: complex (≤3 abnormalities) or chromosome 7 anomalies; intermediate: other abnormalities.
[b]Cytopenias are defined as hemoglobin concentration <10 g/dL, neutrophils $<1.5 \times 10^9$/L, and platelets $<100 \times 10^9$/L.
BM, bone marrow.

intervention, patients with lower-risk MDS at MDACC were analyzed to further stratify prognosis in low and intermediate-1 risk IPSS groupings (Table 5–4).[4] Factors associated with worse prognosis in this lower-risk group included thrombocytopenia (platelets $<50 \times 10^9$/L), anemia (hemoglobin concentration <10 g/dL), older age (older than 60 years), blast count greater than 4%, and a karyotype that was not diploid or del(5q) (Table 5–4A). This model stratified lower-risk patients into three subgroups by score—0 to 2, 3 to 4, and 5 to 7—with median

BM, bone marrow.

survival periods of 80, 27, and 14 months, respectively (Table 5–4B). Increased ferritin and β_2-microglobulin were also associated with worse survival, but these factors were not included in the prognostic model. Because patient survival was significantly different between these lower-risk categories, investigation of early intervention protocols in lower-risk patients with relatively poor survival may be warranted.

We described the cause of death of patients with lower-risk MDS.[67] Approximately 80% of patients died from a complication intrinsic to MDS and not because of disease progression, which only occurred in 10% to 20% of patients. The most frequent cause of death was infection followed by bleeding. Patients with increased percentage of blasts and monosomy 7 had an increased risk of transformation to AML.[67]

The IPSS determines risk at the time of initial diagnosis, but it does not provide information regarding changes in risk as patients progress through their disease course. A dynamic prognostication system has been developed to address this deficiency and provides a score that is predictive of survival and leukemic transformation over time. The WHO classification-based Prognostic Scoring System weighs three variables: WHO diagnostic classification, karyotype abnormalities categorized according to the IPSS criteria, and transfusion requirement.[3] This stratifies patients into five disease groups that demonstrate different survival and risk of evolution to acute leukemia over time. Very low-risk patients in this classification have an overall mortality rate that was not different from the general population. This model incorporates changes in the disease risk profile over time, allowing further refinement in prediction of survival and leukemic progression as the disease progresses. A model has been developed by MDACC that includes CMML and accounts for both de novo and secondary disease, allowing for prognostication at any time during the course of MDS.[68] The characteristics of this model are shown in Table 5–5.

The presence of fibrosis on the bone marrow biopsy occurs in a minority of patients with MDS, but this pathological feature is not incorporated into routine diagnostic classifications or prognostic systems. Fibrosis is more frequently observed in patients with multilineage dysplasia or with karyotype abnormalities and, when present, is associated with a more rapid progression to severe bone marrow failure and shortened survival.[69] In younger patients, it may warrant early consideration of allo-SCT.

An international consortium developed a new MDS classification known as the IPSS-R.[5] The basis for this effort was to improve on known limitations of the initial IPSS. IPSS-R includes a refined cytogenetic annotation and newer thresholds of cytopenias and blast percentages.[46] Table 5–6 shows the characteristics of this new classification. The IPSS-R divides patients into five categories (very low, low, intermediate, high, and very high risk). Algorithms have been developed to calculate expected survival and time to progression based on age and IPSS-R score. The IPSS-R should be considered the standard tool to calculate prognosis in patients with MDS and is now incorporated

in a majority of modern clinical trials. Furthermore, patients with intermediate-risk MDS by IPSS-R were further stratified based on age (66 years or older), peripheral blood blast count 2% or greater, and need for RBC transfusions (Table 5–7)[6]; patients with scores of 0 or 1 were considered intermediate-favorable risk, and those with scores of 2 to 4 were considered intermediate-adverse risk. Finally, it is likely that all these classifications will be modified with the incorporation of molecular genomic data.

Patients with MDS are older and may have other comorbidities. We have calculated the impact of comorbidities using the Adult Comorbidity Evaluation-27 (ACE-27) comorbidity score on the outcome of patients with MDS.[70,71] This analysis indicated synergism between the presence of comorbidity and disease score. The same was observed when ACE-27 was calculated with IPSS-R and in conjunction with genomic data.[71,72]

THERAPY

The number of effective drug treatments available to treat MDS has expanded in recent years, providing different management alternatives. Some treatments improve hematopoietic function and alleviate symptoms related to blood cytopenias; other therapies alter the natural history of the disease and improve survival. Both approaches may be appropriate in different clinical contexts, and many patients receive various combinations of treatments throughout their disease course.

The goals of therapy in MDS vary in different patient populations. A management plan should consider the patient's age, comorbidities, and disease risk. Patients with lower-risk MDS most commonly experience problems related to chronic anemia, and the disease may remain stable for prolonged periods. If these patients are older, they may best be managed with relatively nontoxic therapies that aim to maintain quality of life. Treatment options include transfusions of blood products, growth factor therapies (ie, EPO with or without colony-stimulating factors), iron chelation, luspatercept, and non–growth factor therapies with immune modulators (lenalidomide) and epigenetic drug treatment (azacitidine or decitabine). Higher risk MDS has a poor prognosis and forms a continuum with AML. Aggressive therapies may be warranted in these higher risk patients to eradicate the malignant clone and improve survival. Intensive therapies may include high-dose chemotherapy and consideration of allo-SCT in younger patients. Intensive treatment protocols are not suitable for all patients because they expose the patient to significant risks of treatment-related morbidity and mortality. An algorithm for treatment approaches at MDACC is shown in Figure 5–6, with specific therapies based on lower-risk and higher-risk MDS shown in Figure 5–7.[73]

Assessing response to treatment in MDS can be complex as treatment goals in low- and high-risk disease may be different. Clinical response criteria in

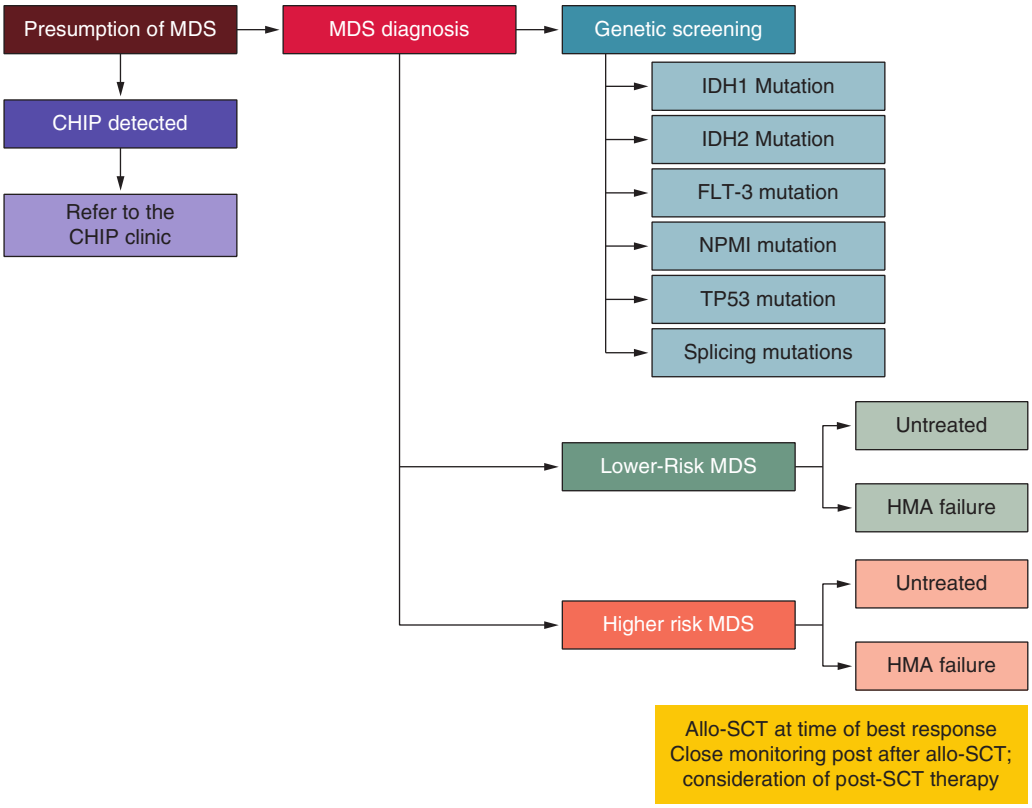

FIGURE 5–6 **A MD Anderson Cancer Center approach to the management of patients with myelodysplastic syndromes (MDSs). allo-SCT, allogeneic stem cell transplant; CHIP, clonal hematopoiesis of indeterminate potential; HMA, hypomethylating agent; SCT stem cell transplant.**

lower-risk disease usually measure improvements in peripheral blood cell counts and quality-of-life factors. Response in higher risk disease also requires improvement in bone marrow blasts. Standardized criteria by the International Working Group are available to assess response to treatment in MDS and are particularly useful to allow comparisons between drug trials,[74] with new hematologic response criteria recently proposed.[75]

Supportive Care

Chronic blood cytopenia is a principal characteristic of MDS. Therapies aimed at alleviating problems related to anemia, neutropenia, and thrombocytopenia are an essential component of management. Bacterial infections require aggressive treatment with antibiotics. Platelet transfusions are administered for episodes of bleeding or for prophylaxis in patients with severe thrombocytopenia. Transfusion thresholds at MDACC include a hemoglobin level of 8 g/dL (unless the patient is otherwise symptomatic) and a platelet count of less than 10 K/UL (unless there is evidence of bleeding). These transfusion thresholds have been challenged by the 2020 COVID-19 pandemia because of a lack of donors. Additional hemostatic support with the use of antifibrinolytic agents may be considered for problematic mucosal bleeding or for surgical procedures. The role of prophylactic antibiotics is less established in neutropenic patients. It is our practice at MDACC to use triple therapy (antibacterial with a fluoroquinolone, antiviral, and antifungal) in all patients with severe neutropenia who are receiving therapy.

Symptomatic anemia is often the major clinical problem in patients with lower-risk MDS. In this group, RBC transfusions are effective symptomatic therapies, but a prolonged transfusion program may cause problems with transfusion-related hemosiderosis, alloantibody formation, and volume overload in patients with impaired cardiac function. Deposition of iron in body tissues is treated with iron chelation. The efficacy of iron chelation therapy is best demonstrated in thalassemia major, in which regular deferoxamine therapy reduces iron deposition in organs and improves survival.[76] The parenteral administration of deferoxamine is inconvenient, and the development of effective oral iron-chelating drugs, such as deferasirox, has allowed iron chelation to be performed more easily.[77] In MDS, iron chelation was hypothesized to have similar advantages.[78] This was confirmed in the recently published randomized double-blind phase II TELESTO study,[79] which demonstrated an increased event-free survival with oral deferasirox compared with placebo. Iron chelation should start with parenteral deferoxamine or oral deferasirox after 20 to 40 units of RBC have been administered, particularly if there is an expectation of prolonged survival and continued transfusion therapy. Serum ferritin may be used as a guide to chelation therapy, with a ferritin concentration greater than 1000 µg/L typically attained after transfusion of 20 RBC units.[66] Iron chelation therapy should also be considered in younger patients who may be candidates for allogeneic transplantation. An elevated pretransplant ferritin has been associated with a lower overall survival after allogeneic transplantation and an increase in the hepatic transplant complication of veno-occlusive disease.[80]

Hematopoietic Growth Factors

Hematopoietic growth factors are the primary regulators of blood progenitor cell proliferation and are used therapeutically to promote effective hematopoiesis. EPO therapy has been explored as an alternative to RBC transfusion in patients with lower-risk MDS. Various forms of recombinant EPO (rEPO), including epoetin a, epoetin b, and the long-acting darbepoetin, have been studied in different cohorts of patients. Overall, erythroid responses in unselected patients were modest, in the range of 10% to 20%.[81] The best responses were identified in patients with low-risk MDS, a low serum EPO level (<200 IU/L), and no RBC transfusion requirement.[82] In this favorable subgroup of patients with MDS, an erythroid response to rEPO therapy was observed in 40% to 60% of patients.[82] The median duration of response was 2 years, and therapy was associated with improved quality of life.[83] Data suggest that patients who respond to growth factor therapy have better survival than historical control cohorts who received supportive care alone.[82]

EPO in combination with G-CSF is also effective, with response rates of 40% to 50% in selected cohorts.[61,83,84] The combination of these two hematopoietic cytokines appears to offer a synergistic clinical benefit and allow improvements in hemoglobin levels in some patients who fail to respond to EPO monotherapy. The benefit of this combination may be most marked in refractory anemia with ring sideroblasts (RARS) and refractory cytopenia with multilineage dysplasia (RCMD), but this has not been confirmed.[82] Disease transformation is a theoretical risk in patients receiving chronic hematopoietic growth factors, but long-term observations of these patients suggested that these cytokines do not promote leukemic transformation.[82,84] Hematopoietic growth factor therapy should be considered to treat anemia in patients with lower-risk MDS associated with a low serum EPO level. EPO can be initiated as monotherapy with the addition of G-CSF if there is no objective response in 2 to 3 months.

Thrombopoietin has been used to promote platelet production and minimize the bleeding complications related to severe thrombocytopenia. Initial trials with recombinant thrombopoietin were disappointing. New second-generation thrombomimetic agents are now being tested.[85–87] Potential concerns of increased blasts and fibrosis, leading to an elevated risk of progression to AML or death, led to discontinuation of the study drug in a phase II trial, though 5-year follow-up data did not show a difference.[87]

Transforming Growth Factor β Signaling Modulators

More recently, the use of luspatercept, a recombinant fusion protein binding transforming growth factor β

(TGF-β) ligands to decrease SMAD2- and SMAD3 signaling involved in ineffective erythropoiesis of MDS, has been studied.[88,89] A phase II study evaluating luspatercept in patients with lower-risk MDS showed an erythroid response rate of 63%, and 38% of patients had transfusion independence for 8 weeks or longer.[90] The double-blind, randomized, placebo-controlled phase III MEDALIST trial validated the previous observations that luspatercept reduced anemia severity in patients with lower-risk MDS-RS who were transfusion dependent and had disease that was refractory to EPO therapy,[91] leading to its Food and Drug Administration (FDA) approval in 2020. Limitations for the use of luspatercept include the cost of therapy and no clear evidence of improved survival, and longer follow-up times are needed to fully understand the effects of the compound on the natural history of MDS progression.

Lenalidomide

Lenalidomide is a chemical analogue of thalidomide with diverse biological actions that encompass immune modulation and antiangiogenic effects. Selective activity of lenalidomide against MDS associated with an interstitial deletion on the long arm of chromosome 5 was first suggested in a study examining the effects of this drug on anemia in patients with low-risk MDS.[92] Erythroid responses were noted in 56% of the cohort, with the most significant response found in the subgroup with a del(5q) abnormality. This observation was confirmed in a larger multicenter phase II study of lenalidomide.[7] This second trial demonstrated an overall erythroid response in 76% of patients with the del(5q) abnormality. Responses were prolonged and occurred rapidly, with a median time to a hematologic response of 4 to 5 weeks. A cytogenetic response was documented in 73% of patients, with 44% developing complete cytogenetic remission. Cytogenetic responses were observed in patients with the del(5q) abnormality alone and in patients with the del(5q) abnormality associated with additional cytogenetic defects. This clearly demonstrated that the activity of lenalidomide was not limited to patients with the 5q- syndrome but was also observed in patients with low-risk MDS. A randomized trial comparing different doses of lenalidomide versus observation further confirmed the activity of the drug at a dose of 10 mg/day.[93] Although none of these studies were powered to document improvement in survival, a recent analysis indicated that achieving a cytogenetic response with lenalidomide was associated with prolonged survival.[94]

Lenalidomide therapy in MDS is usually started at 10 mg/day. A favorable response is typically characterized by normalization of anemia and cytogenetic response.[7] The most important side effect of therapy with lenalidomide is myelosuppression, which may necessitate dose reduction in patients with persistent thrombocytopenia and neutropenia. Interestingly, the degree of myelosuppression has been associated with response. Thrombocytopenia at diagnosis (platelet count $<100 \times 10^9$/L) has been associated with a worse response to lenalidomide treatment. This may reflect repeated or prolonged treatment interruptions secondary to myelosuppression.

Lenalidomide and thalidomide also demonstrated activity in low-risk MDS without the del(5q) abnormality. Lenalidomide has been studied in 214 patients with low-risk MDS (IPSS low and intermediate-1) and predominantly a normal karyotype.[8] In this cohort, 26% of patients achieved transfusion independence, and 17% developed a reduction in transfusion requirement. The median duration of transfusion independence was 41 weeks, and cytogenetic responses were documented in 19% of patients with karyotypic abnormalities. These results were confirmed in a randomized trial.[95]

Hypomethylating Agents

5-Azacitidine and 5-aza-2′-deoxycytidine (decitabine) are chemically related drugs with a spectrum of activity that includes both lower and higher risk MDS. The mechanism of action of these drugs is uncertain, although both agents reverse abnormal promoter DNA methylation that surrounds the promoter of some tumor-suppressor genes in cancer cells. Aberrant promoter methylation is associated with transcriptional repression, or silencing, and may contribute to the loss of tumor-suppressor gene function in MDS. Decitabine and 5-azacitidine are both cytidine analogues that incorporate into DNA and form covalent bonds with DNA methyltransferase enzymes. Depletion of methyltransferase activity within the cell then causes newly synthesized DNA to be hypomethylated compared with the parent strand. After at least two cycles of cell division, DNA becomes globally hypomethylated with alteration in gene expression within the leukemic cell. Both agents display cytotoxicity at high doses, but hypomethylating activity remains prominent at lower doses. These biochemical changes are an attractive target for drug therapy because normal tissues have little gene promoter methylation, so hypomethylating therapy may have some degree of specificity for the malignant clone.

5-Azacitidine first demonstrated broad-spectrum activity in MDS. Comparison of azacitidine (75 mg/m^2 intravenously or subcutaneously for 7 days every 28 days) with best supportive care in a randomized control trial demonstrated an overall response rate of 48% with azacitidine compared with 5% with supportive care.[96,97] Azacitidine therapy was associated with a prolongation in the time to leukemic transformation and better quality of life. The median time to response

was three cycles, and response rates were independent of MDS classification. Complete responses were observed in relatively few patients, approximately 10%, with most patients experiencing hematologic improvement. A report of a multicenter phase III study of azacitidine in patients with higher risk MDS demonstrated an increase in overall survival of approximately 9 months for patients receiving azacitidine compared with other standard therapies.[98] This was the first drug trial that demonstrated a survival advantage in MDS. A subset analysis of the trial data suggested that azacitidine may have significant activity in MDS associated with abnormalities in chromosome 7, a cytogenetic abnormality associated with a poor outcome.

Decitabine has similar clinical activity to azacitidine and has been studied in various intravenous (IV) dose regimens in predominantly higher risk MDS and AML. Comparison of decitabine (45 mg/m^2 in three divided doses administered for three consecutive days every 6 weeks) with best supportive care in a randomized trial demonstrated an overall response rate of 17%, with complete remissions in 9% of patients with predominantly high-risk MDS.[99] Subgroup analysis revealed that patients who received decitabine had a longer median time to transformation to AML or death if they were treatment naïve or had high-risk MDS. Myelosuppression was the major drug toxicity. Data from this trial may underestimate the efficacy of the drug because a significant proportion of patients on decitabine received a small number of treatment cycles, which may have been insufficient to demonstrate a response. This is supported by previous phase II trial data that suggested decitabine had an overall response rate similar to azacitidine.[100] Subsequent clinical trial development with decitabine has focused on improving response rates by lowering the daily dose and lengthening administration schedules. One such schedule of IV administration of decitabine for 5 days every 4 weeks demonstrated a complete response rate of 39% in a high-risk MDS cohort.[101,102] Improvements in hematopoietic function are often delayed after the initiation of azacitidine or decitabine therapy, and drug treatment should continue for four to six cycles before cessation because of poor response.

Chemical modification of histone proteins by acetylation contributes to the regulation of gene expression and probably interacts with abnormal DNA methylation to cause transcriptional suppression of tumor-suppressor genes. Histone deacetylase (HDAC) inhibitors, such as valproic acid and pracinostat, alter chromatin structure to promote gene transcription, and their combination with HMA demonstrates significant in vitro synergy.[103] Initial clinical drug trials in MDS and AML at MDACC indicated increased clinical activity when combining either decitabine or azacitidine with valproic acid.[104,105] None of the randomized trials investigating a HMA with or without a HDAC inhibitor showed a survival improvement.[106–108]

Guadecitabine (SGI-110) is a next-generation HMA that, unlike decitabine, is relatively resistant to degradation, thus allowing for slow release of its active metabolite decitabine and consequently prolonged exposure time and reduced maximum plasma concentration.[109] A phase I study identified guadecitabine 60 mg/m^2 as the biologically effective dose and 90 mg/m^2 as the maximum tolerated dose,[109] and a phase II study showed better-than-expected outcomes in treatment-naïve patients with MDS compared with the first-generation HMA decitabine and azacitidine.[110]

HMA were previously only available as IV administrations, along with a subcutaneous form of azacitidine. However, oral administration of HMA would enhance patient convenience, avoid injection site reactions, and allow for the evaluation of alternative doses and schedules.[111,112]

The oral bioavailability of decitabine was limited due to its rapid degradation by cytidine deaminase (CDA) in the gut and liver, but simultaneous oral administration with the CDA inhibitor cedazuridine (E7727) resulted in increased bioavailability of oral decitabine and similar pharmacokinetics to IV decitabine.[113] A phase II study showed a similar safety profile and response rates between oral cedazuridine–decitabine (ASTX727) and IV decitabine.[114] Preliminary results from the phase III ASCERTAIN study comparing oral ASTX727 with IV decitabine in patients with higher risk MDS showed equivalent HMA exposure between the two arms, safety findings, and clinical activity,[115] and this led to the FDA approval of oral decitabine and cedazuridine for adult patients with MDS in July 2020.

Cytotoxic Chemotherapy

The relatively poor prognosis associated with higher risk MDS has initiated intensive treatment strategies incorporating high-dose chemotherapy in the same protocols used to treat AML. In higher risk MDS, AML-type treatments produce a complete response rate of about 40% to 60%, but remissions are brief.[116,117] This poor response to high-dose chemotherapy is caused, at least in part, by the relatively greater proportion of patients diagnosed with MDS-EB having poor prognosis cytogenetics involving complex changes of chromosomes 5 and 7. Older adult patients with significant comorbidities tolerate high-dose chemotherapy poorly.

Patients with higher risk MDS have been treated with a variety of intensive chemotherapy regimens at MDACC.[118,119] Studies have examined using intermediate- to high-dose cytosine arabinoside (ara-C) (A) in various combinations with idarubicin (I), cyclophosphamide (C), fludarabine (F), and topotecan (T), as regimens: IA, FA, FAI, TA, and CAT. The overall

complete response rate for these regimens was 55% to 58%. A short antecedent history of any hematologic disorder, a normal karyotype, performance status, age, and treatment in a laminar airflow environment were all predictive of attaining a complete response. This intensive approach was beneficial in some patients because those who developed a complete response within 6 weeks of chemotherapy obtained a survival advantage. However, these regimens were toxic, with a significant treatment-related mortality rate in the first 6 weeks, ranging from 5% with TA to 21% with FAI. Consolidation chemotherapy was used in most cases when a remission was achieved with a regimen containing the drugs used in induction but at a reduced intensity of 50% to 66% of the initial dose. Survival of patients treated with IA and TA therapies were comparable and superior to those patients treated with FA, FAI, and CAT regimens, but prognosis remained poor. Nevertheless, this approach does benefit some younger individuals (younger than 65 years) with a normal karyotype, achieving an encouraging 5-year survival rate of 27% with intensive treatment. For older patients, the TA combination can be considered because it has a relatively low treatment-related mortality rate, and it does not contain anthracycline drugs (relatively contraindicated in the presence of heart disease).

Immunosuppressive Therapy

Immune dysfunction contributes to blood cytopenias in some patients with MDS, producing a clinical overlap with aplastic anemia. Immunosuppressive therapy with antithymocyte globulin (ATG) with or without the addition of cyclosporine has been explored in small numbers of patients with MDS. Response rates of 30% to 50% have been observed in selected cohorts of patients with lower-risk MDS administered a course of ATG, with a minority of patients experiencing prolonged remission.[120–122] Features that may predict a good response to immunosuppressive therapy include younger age, HLA-DR status, shorter duration of RBC transfusions, low-risk IPSS, and bone marrow hypocellularity.[122–124] Selection of appropriate patients for immunosuppression is important because ATG therapy is poorly tolerated in an older population with low-risk MDS.[125]

Hematopoietic Stem Cell Transplantation

In MDS, allo-SCT is potentially curative, but the therapy carries significant risk associated with treatment toxicities, prolonged cytopenias, infections, and graft-versus-host disease. In young patients with suitable donors, the transplant procedure offers the best chance of cure, with a long-term disease-free survival rate of 30% to 50%.[126–130] Given the risks associated with this procedure, patient suitability and timing of the transplant are important issues.

Allogeneic transplantation with myeloablative conditioning has been examined exclusively in younger patients (median age in the mid-30s) in most studies. Patients with lower-risk disease have experienced the best survival rate. However, this is also the subgroup of patients predicted to experience prolonged survival without aggressive therapies. This procedure is associated with a significant treatment-related mortality rate of up to 30% to 50% in some studies.[128,129] Relapse after transplantation occurs in approximately 20%, and the relapsed disease has a relatively poor response to donor lymphocyte infusion.[128,129,131] Increased risk of allogeneic transplantation mortality in MDS is associated with older age, poor-risk cytogenetics (particularly abnormalities of chromosome 7 or a complex karyotype), the presence of excess blasts in the bone marrow, and longer duration of disease.[132,133] Patients with treatment-related MDS also have a poor transplant outcome, but this is related to the frequency of high-risk cytogenetic changes.[133,134]

The development of nonmyeloablative allogeneic transplantation with reduced-intensity conditioning has allowed allogeneic transplantation to be considered in older patients with MDS and in patients whose comorbidities or organ dysfunction would exclude them from myeloablative treatment.[135] This procedure has reduced transplant-related mortality, the major problem limiting the availability of this potentially curative therapy to older patients. This therapy aims to minimize organ toxicity related to initial chemotherapy or radiation therapy and allow stable engraftment of donor cells that provide the curative potential associated with the graft-versus-leukemia effect. Comparison of reduced-intensity conditioning transplantation with standard myeloablative conditioning showed reduced transplant-related mortality but increased relapse rate, resulting in comparable rates of overall survival between the two transplantation strategies.[132,136–138]

Statistical modeling based on historical allogeneic transplantation outcomes for matched sibling transplantation suggested that the maximal overall survival is achieved by different transplant strategies in different MDS risk groups.[139] Patients with lower-risk disease maximize overall survival by delaying transplantation after diagnosis until evidence of disease progression but before the development of overt acute leukemia. This delayed transplant approach provided the greatest survival benefit to younger patients (younger than 40 years).

Specific features of disease progression have not been defined, but evidence of new cytogenetic

abnormalities, progressive cytopenias, and increasing blast percentage in the bone marrow are suggested as potential triggers for transplantation. Patients with higher risk disease should ideally receive the transplant as soon as possible after diagnosis. The presence of bone marrow fibrosis delays engraftment in allogeneic transplantation, and its presence is an additional risk factor in transplant outcome in higher risk MDS. In this group, fibrosis considerably increases transplantation risk.

Early consideration of transplantation is suggested in a younger patient with significant MDS-associated fibrosis.[134] The outcomes of patients older than 60 years of age with MDS treated with either reduced-intensity transplantation or HMA were studied.[9] The results of this analysis indicated that transplant should not be considered as first-line therapy in lower-risk MDS. Of interest, in higher risk MDS, it appears that there is a benefit toward transplant compared with HMA-based therapy, but survival curves cross significantly later than after 24 months of therapy. This indicated that there is probably a specific group of patients, not yet defined, that derives the maximal benefit from transplantation.

Emerging Therapeutics

Other Oral Hypomethylating Agents

The bioavailability and safety of oral azacitidine (CC-486) was initially evaluated an open-label pharmacokinetic study of patients with MDS, AML, or solid tumors.[111] In a phase I study in patients with MDS, CMML, and AML, oral azacitidine demonstrated biologic and clinical activity with extended dosing schedules showing sustained epigenetic effects.[112,140,141] Its use in lower-risk MDS is being further investigated.[142–144] Furthermore, ASTX030, an oral combination of azacitidine and cedazuridine, is currently being researched after showing the same efficacy as parenteral azacitidine in mouse models.[145]

Immunotherapy

The PD-1 axis is expressed in patients with MDS, which may allow for the development of new forms of therapy and combinations using inhibitors of this pathway.[146] Single-agent pembrolizumab (anti–PD-1 antibody), nivolumab (anti–PD-1 antibody), and ipilimumab (anti–CTLA-4 antibody) did not show significant responses but had acceptable toxicity profiles.[147,148] Updated results from ongoing phase II studies investigating the combination of azacitidine with pembrolizumab, nivolumab, or ipilimumab indicate that combination therapy is safe and well tolerated with antitumor activity.[148,149] Azacitidine in conjunction with double immune checkpoint inhibitor blockade with nivolumab and ipilimumab has also shown a tolerable safety profile and clinical activity.[150] The combination of HMA with anti–PD-L1 antibodies has also been investigated.[151,152]

Recently, T-cell immunoglobulin mucin-3 (TIM-3), an inhibitory immune checkpoint receptor expressed on AML cells, is being studied as a potential therapeutic target with the combination of the anti-TIM-3 antibody MGB453 and HMA.[153,154] Furthermore, CD47 expression on blasts from lower-risk patients with MDS was found to be similar to normal cells, but increased expression was observed in higher risk patients with MDS,[155] leading to the hypothesis that increased CD47 expression could represent progression or transformation.[156] The use of magrolimab, an anti-CD47 antibody, in patients with MDS is currently being explored; data recently presented include an overall response rate of 92% with a complete response rate of 50%.[157]

Venetoclax

Venetoclax is a BH3-mimetic that inhibits the antiapoptotic Bcl-2 protein, leading to programmed cell death.[158] Preclinical studies show synergy between venetoclax and HMA in higher risk MDS and AML.[159,160] A phase Ib study evaluating azacitidine and venetoclax in treatment-naïve patients with higher risk MDS showed that combination therapy had a tolerable safety profile and potential efficacy.[161] Multiple studies evaluating different combinations of therapies with venetoclax are underway.

Targeted Therapies

With the incorporation of molecular and genomic analysis into the diagnostic bone marrow aspiration or biopsy, the use of therapies that target particular mutations is being studied. Many of these therapeutic targets have been studied in AML, and clinical trials are underway for their potential role in the treatment of MDS. Current genomic targets under investigation include *TP53*, *IDH2*, *IDH1*, and *FLT3*.

TP53 mutations are one of the most frequently occurring mutations in myeloid malignancies and often associated with complex karyotype and poor prognoses.[31] APR-246 covalently binds to p53 and restores wild-type proapoptotic activity.[162] A dose escalation phase 1b clinical trial showed the combination of azacitidine and APR-246 had manageable nausea and transient neurologic adverse events,[163] and a dose expansion phase II trial showed an overall response rate of 87% in patients with MDS and

oligoblastic AML.[164] Similarly, our French colleagues conducted a similar phase II trial with azacitidine and APR-246 showing a response rate of 66%.[165] A randomized phase III study of frontline azacitidine with or without APR-246 in *TP53*-mutant MDS is underway.

Although *IDH2* and *IDH1* mutations are less frequently observed in MDS,[166,167] studies involving targeted inhibitors are underway. Enasidenib (AG-221) is a selective oral inhibitor of mutant IDH2 enzyme that is FDA approved in patients with relapsed or refractory *IDH2*-mutated AML with response rates of approximately 40%.[168] Preliminary results from a phase II study of enasidenib in treatment-naïve patients with higher risk *IDH2*-mutated MDS showed a response rate of 85%.[169] Ivosidenib (AG-120) is an oral targeted inhibitor of mutant IDH1 enzyme. Studies in *IDH1*-mutant AML have shown transfusion independence, durable remissions, and some molecular remissions.[170,171] Very few patients with MDS have been treated with ivosidenib, but further exploration of this genomic targeted is necessary.

FLT3 mutations are rare in patients with MDS but can occur in 15% to 30% of patients who have failed HMA therapy.[172,173] A phase 2 study showed significant activity of the addition of sorafenib, a FLT3 inhibitor, to azacitidine in patients with HMA failure.[174] Several small studies using second- and third-generation FLT3 inhibitors in MDS are underway.[73]

SPECIFIC CLINICAL SITUATIONS

Despite the clinical activity of several agents described earlier, most patients with MDS will eventually succumb to their disease. This emphasizes the need to develop better strategies, both up front and in patients who have failed prior therapies.

Patients with Lower-Risk Disease and Poor Prognosis

It is now demonstrated that the prognosis of patients with lower-risk MDS is very heterogeneous, with a significant subset of patients having poor prognosis.[4] Because most of these patients decease as a consequence of MDS, introducing therapy early in this selected group of patients may help. This has significant implications not only for the role of allo-SCT in MDS but also for the incorporation of disease-modifying strategies. We have studied the role of very low-dose or oral schedules of HMA in this setting.[142,143,175,176] Randomized phase III trials are being conducted to investigate the impact of these interventions on survival.[144]

Failure of Hypomethylating Agents

One of the major problems is the treatment of patients who have failed therapy with HMA. Two different scenarios exist: primary (when the patient progresses while on HMA therapy without experiencing response) and secondary (when the patient has an initial response but progresses later in the course of treatment) HMA failure.[177] The survival of patients with lower-risk disease and hypomethylating failure is less than 17 months.[12] Data from MDACC indicated that the prognosis is very poor for patients with higher risk disease and hypomethylating failure with a median survival of less than 5 months. Currently, no therapy has shown significant activity for patients with HMA failure. In general, this group of patients is refractory to most conventional antileukemia agents available, such as cytarabine. These patients should be treated with investigational new agents, considered for allo-SCT as soon as possible, or both. Agents currently being investigated include guadecitabine, immunotherapy, venetoclax, targeted therapy, and rigosertib, among others.

The next-generation HMA guadecitabine has been shown to have activity in patients who have failed decitabine and azacitidine in a phase II trial,[178] leading to an ongoing phase III ASTRAL-3 study of single-agent guadecitabine. Its use in combination with the immune checkpoint inhibitor atezolizumab was found to be safe in patients with relapsed or refractory MDS,[179] and a phase II study is ongoing. Although investigative efforts into various immune checkpoint inhibitors with and without HMA therapy have not yielded significant survival advantages, single-agent ipilimumab had a 30% response rate in patients who previously failed HMA.[148] Further studies with immunotherapy in patients with relapsed or refractory MDS are warranted.

Furthermore, the use of venetoclax as monotherapy or in combination with azacitidine is undergoing investigation. A phase Ib study showed a response rate of 40% with venetoclax and azacitidine with only modest clinical activity observed with single-agent venetoclax,[180] and multiple phase II studies are underway to further explore this therapeutic option. Regarding targeted therapy options for *IDH2*- or *IDH1*-mutant MDS that were previously discussed, multiple studies evaluating enasidenib, ivosidenib, and ivosidenib with nivolumab in the setting of relapsed or refractory MDS are underway.[169,181,182]

Additional investigational agents of interest include telaglenastat (a glutaminase inhibitor), H3B-8800 (a splicing modulator), and various adjunct therapies to HMA. Recent studies with rigosertib have failed to demonstrate improvement in survival in patients with higher risk disease and primary HMA failure.

Total Therapy Incorporating Allogeneic Stem Cell Transplantation

Traditionally, therapy for MDS is viewed as a dichotomy between candidates for allo-SCT and those who are not candidates, and the need for bridge therapy before allo-SCT remains controversial.[183] Additionally, we also observe very high relapse rates after transplant in specific subsets of patients, such as those with *TP53* mutations or complex cytogenetics.[184] The introduction of powerful new combinations including APR-247, magrolimab, and venetoclax, argues for total therapy that results in minimal residual disease negativity pre-allo-SCT followed by posttransplant maintenance therapy with HMA or targeted approaches, and further investigation is warranted.

MD ANDERSON PRACTICE TIPS

- Analysis of gene mutations using next-generation sequencing assays is important in MDS. A small fraction of patients with MDS carry an NPM1 mutation. These patients can be cured with AML-like therapy followed by allo-SCT.
- Low-risk patients with diploid cytogenetics without thrombocytopenia and anemia, as sole cytopenia, can respond to lenalidomide.
- Around 20% of patients with higher risk MDS failure carry a Flt-3 mutation. Usually, these patients have leukocytosis. These patients can respond to the combination of HMA and Flt-3 inhibitor.
- Patients with mutations on IDH2 and IDH1 (~15% of patients) respond to IDH inhibitors as single agents or in combination with HMAs.
- A subset of patients with higher risk HMA failure have diploid cytogenetics. These patients can respond to combinations of lower doses of nucleoside analogues (clofarabine, cladribine) with low-dose ara-C.
- In patients with higher risk disease, we attempt to proceed with allo-SCT at the time of best response (morphologic, cytogenetic, molecular) in an attempt to minimize relapse posttransplantation.

6 Philadelphia Chromosome-Negative Myeloproliferative Neoplasms

Prithviraj Bose
Lucia Masarova
Hesham M. Amin
Srdan Verstovsek

KEY CONCEPTS

- Polycythemia vera (PV) is the most common of the Ph-negative myeloproliferative neoplasms (MPNs). Virtually all cases are driven by activating *JAK2* mutations, and elevation of all three cell counts is typical. Life expectancy is good but shorter than that of an age- and sex-matched population. Thrombosis is the major clinical concern, and prevention of the same is the principal goal of therapy. PV can progress to myelofibrosis (MF) or transform to acute myeloid leukemia (AML). All patients need aspirin unless it is contraindicated. Low-risk patients are typically treated with phlebotomy, whereas high-risk patients need cytoreductive therapy. The target hematocrit level for all patients is to be less than 45%. Leukocytosis is clearly associated with mortality and leukemic transformation; its relationship with thrombotic risk is less certain. Hydroxyurea (HU) and interferon (IFN) are both reasonable frontline options for cytoreductive therapy; ruxolitinib is approved for use after failure of HU.
- Essential thrombocythemia (ET) is the most indolent of the classic Ph-negative MPNs. Careful distinction of ET from prefibrotic primary myelofibrosis (pre-PMF) is necessary. Life expectancy in ET is the same as, or only slightly lower than, that of an age- and sex-matched population. Driver mutations in *JAK2* underlie approximately half the cases, with *CALR* and *MPL* mutations accounting for most of the remainder. ET can progress to MF and rarely transform to AML. Thrombosis and bleeding are the main clinical concerns, and the goal of therapy is to mitigate these risks. Patients are risk stratified for thrombosis by age, *JAK2* mutation status, thrombosis history, and cardiovascular risk factors. The platelet count does not correlate with thrombotic risk. HU or IFN are the cytoreductive agents of choice; anagrelide is commonly used as a second-line therapy. Aspirin is generally recommended, but should be avoided in the presence of acquired von Willebrand disease.
- Myelofibrosis can be primary (PMF) or arise as a complication of PV or ET (post-PV/ET MF). Overt MF is usually characterized by anemia, splenomegaly, a variety of symptoms, leukoerythroblastosis, and markedly reduced survival compared with PV and ET. Pre-PMF is more indolent but carries a worse prognosis than ET. The distribution of driver mutations in PMF is generally similar to that in ET, but mutations in "nondriver" genes are much more common. The risk of leukemic transformation is much higher in MF than in ET or PV. Accurate prognosis for patients with MF is critical for decisions about stem cell transplant (SCT) and depends on several clinical and genomic factors. JAK inhibitors represent the cornerstone of therapy; in some patients, anemia-directed therapy with or without JAK inhibitors may be appropriate.
- Chronic eosinophilic disorders/hypereosinophilic syndromes (CED/HES) are heterogeneous disorders characterized by hypereosinophilia in the blood and possible eosinophilic organ infiltrations. Diagnosis requires exclusion of secondary causes. Evaluation for end-organ damage is always needed. Primary CED/HES include myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRα*, *PDGFRβ*, *FGFR1*, or with *PCM1-JAK2*. Patients might have various nonspecific symptoms or serious organ involvement (gastrointestinal system, heart, skin, lungs). *PDGFRα/β* rearrangements are sensitive to the tyrosine kinase inhibitor imatinib, and these patients have favorable life expectancy. Secondary agents commonly used are steroids, IFN, HU, and, less frequently, chemotherapy. Patients with *FGFR1* rearrangement usually have aggressive disease with rapid progression to acute leukemia. Stem cell transplantation is needed for long-term survival. The novel tyrosine kinase inhibitor pemigatinib is being evaluated in clinical trials as of this writing and showing optimistic results.

- Chronic neutrophilic leukemia (CNL) is a very rare, atypical MPN characterized by overproduction of mature neutrophils and the presence of *CSF3R* mutation in nearly all patients. Patients have various, mostly nonspecific constitutional symptoms. The presence of *CSF3R* mutation with neutrophilia is pathognomonic for diagnosis. CNL usually has an aggressive course, with a median survival of approximately 2 years and the tendency to progress to acute leukemia. There are no standard therapies. Cytoreduction therapy, such as HU; IFN; or cladribine-based chemotherapy are used most often. The JAK inhibitor ruxolitinib is being explored in clinical trials. All patients with CNL be considered for stem cell transplantation.
- Systemic mastocytosis (SM) is a heterogeneous group of diseases characterized by clonal expansion of malignant mast cells and their accumulation in various organs. KIT^{D618V} mutation occurs in more than 90% of the patients. The most important step in prognosis is evaluation for organ damage (C findings), which defines an aggressive subtype of SM. Clinical presentation is mostly driven by release of vasoactive mediations from mast cells (such as itching, flushing, diarrhea, and others). Patients with indolent SM have a normal life expectancy, but those with the aggressive form have significantly decreased survival rates. Higher age, advanced clinical features (eg, anemia, thrombocytopenia, leukocytosis), and the presence of mutations in *SRSF2, ASXL1*, or *RUNX1* predict inferior outcome. In addition to symptom relief, the goals of therapy for aggressive SM are reduction of disease burden and prevention of organ damage. The multikinase inhibitor, midostaurin, represents the only approved targeted therapy. Avapritinib is a promising agent being evaluated in clinical trials as of this writing.

INTRODUCTION

The field of myeloproliferative disorders (MPDs) has evolved considerably since the sentinel observations made by William Dameshek in 1951. He commented in an editorial in the journal *Blood:* "To put together such apparently dissimilar diseases as chronic granulocytic leukemia, polycythemia, myeloid metaplasia and di Guglielmo's syndrome may conceivably be without foundation, but for the moment at least, this may prove useful and even productive. What more can one ask of a theory?"[1]

The central feature among the MPDs, now termed myeloproliferative *neoplasms* (MPNs), is effective clonal myeloproliferation without dysplasia. Other features shared by most MPNs include involvement of a multipotent hematopoietic stem/progenitor cell; marrow hypercellularity; predisposition to thrombosis, hemorrhage, and marrow fibrosis; and phenotypic "driver" mutations in tyrosine kinases (TKs), eg, JAK2 (Janus kinase 2)[2–5] and c-KIT[6]; or other cellular proteins that affect JAK-signal transducer and activator of transcription (STAT) signaling (eg, the thrombopoietin receptor c-MPL[7,8] and the endoplasmic reticulum chaperone CALR.)[9,10] When the concept of MPDs was first proposed, it consisted of five disorders: chronic myelogenous leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), chronic idiopathic myelofibrosis (CIMF), and erythroleukemia. Over the years, erythroleukemia was reclassified under acute myeloid leukemia (AML), and CIMF was renamed primary myelofibrosis (PMF). Prefibrotic (pre-) and overt PMF are now recognized as distinct entities in the most recent 2016 revision to the World Health Organization (WHO) classification of myeloid neoplasms.[11] Also included under the broad heading of MPNs are atypical MPNs, namely, chronic neutrophilic leukemia (CNL), chronic eosinophilic leukemia (CEL), and MPN-unclassifiable (MPN-U) (Table 6–1). The MPNs are, in turn, classified among the five categories of myeloid neoplasms, the others being: (1) AML; (2) myelodysplastic syndromes (MDS); (3) MDS/MPN "overlap" syndromes, which include chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia (JMML), atypical CML (aCML), *BCR-ABL* negative, MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T), and MDS/MPN-unclassifiable (MDS/MPN-U); and (4) mastocytosis, which is no longer grouped together with MPNs. There is also a separate WHO category for myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRα*, *PDGFRβ*, or *FGFR1*, or with *PCM1-JAK2*. Major changes to the WHO diagnostic criteria for PV were introduced in the 2016 revision, and are discussed below. CML, characterized by a balanced, reciprocal translocation between chromosomes 9q34 and 22q11, termed the "Philadelphia chromosome" (Ph), resulting in the BCR-ABL fusion protein that drives the disease, is discussed elsewhere. Here, we discuss the classic, Ph-negative (Ph-) MPNs (PV, ET, and PMF), as well as CEL, myeloid/lymphoid neoplasms with eosinophilia (MLN-Eo), CNL, and systemic mastocytosis, in which important advances have been made both in our understanding of its pathophysiology and its clinical management.

Table 6–1 2016 World Health Organization Classification Scheme for Myeloid Neoplasms

1.	Acute myeloid leukemia
2.	Myelodysplastic syndromes (MDS)
3.	Myeloproliferative neoplasms (MPNs)
	3.1 Chronic myeloid leukemia (CML), *BCR-ABL1*+
	3.2 Polycythemia vera (PV)
	3.3 Essential thrombocythemia (ET)+
32.	3.4 Primary myelofibrosis (PMF)
	• Prefibrotic primary myelofibrosis (pre-PMF)
	• Overt primary myelofibrosis (overt PMF)
	3.5 Chronic neutrophilic leukemia (CNL)
	3.6 Chronic eosinophilic leukemia, not otherwise specified (CEL)
	3.7 MPNs, unclassifiable
4.	MDS/MPN "overlap" syndromes
	4.1 Chronic myelomonocytic leukemia (CMML)
	4.2 Juvenile myelomonocytic leukemia (JMML)
	4.3 Atypical chronic myeloid leukemia (aCML), *BCR-ABL*$^-$
	4.4 MDS/MPN, unclassifiable (MDS/MPN-U)
	4.5 MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T)
5.	Myeloid/lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRα*, *PDGFRβ*, *FGFR1*, or with *PCM1-JAK2*
	5.1 Myeloid neoplasms with *PDGFRα* rearrangement
	5.2 Myeloid neoplasms with *PDGFRβ* rearrangement
	5.3 Myeloid neoplasms with *FGFR1* rearrangement (8p11 syndrome)
	5.4 *Provisional entity*: Myeloid/lymphoid neoplasms with *PCM1-JAK2*

Data from Arber DA, Orazi A, Hasserjian R, et al: The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia, *Blood* 2016 May 19;127(20):2391-2405.

POLYCYTHEMIA VERA

PV is a clonal disorder characterized by the accumulation of phenotypically normal red cells, granulocytes, and platelets. The word *polycythemia* is composed of the Greek words *poly* ("many"), *cyt* ("cells"), and *hemia* ("blood"), indicating the presence of too many blood cells (red, white, and platelets). The term *vera* is from the Latin word meaning true, making a distinction between PV and a host of other conditions that can result in an increase in the number of red blood cells (RBCs). The central feature of the disease is elevated red cell mass (RCM), associated with a predisposition to thrombosis. PV occurs mainly in older adults. The annual incidence of PV is around 1 case per 100,000 population,[12] and the US prevalence has been estimated to be 44 to 57 individuals per 100,000.[13] In a large observational study of 1638 patients with PV, the median age at diagnosis was 62.1 years, and only 4% of the patients were younger than 40 years.[14] The median survival is long, approximately 18.9 years (although inferior to that of the age- and sex-matched general population), as found in an international study of 1545 patients that used a more contemporary (2008 WHO) definition of PV.[15] However, other studies from referral centers with more complete follow-up have reported the median survival of patients with PV to be shorter, around 13.5 years.[16]

The JAK-STAT pathway has been known to play an important role in hematopoiesis, which is mediated in part by erythropoietin (Epo) and thrombopoietin (Tpo) via their cognate receptors. In 2005, four different groups identified an activating mutation in the *JAK2* gene in as many as 97% of patients with PV.[2–5] The JAK proteins are bound to the cytoplasmic domains of type I cytokine receptors (eg, the Epo and Tpo receptors), and the binding of cytokines or growth factors (eg, Epo and Tpo) to their cell-surface receptors induces dimerization and phosphorylation of the JAKs. The activated JAK then phosphorylates the cytoplasmic domains of

the cytokine receptors. STATs bind to these phosphorylated receptor sites and in turn are phosphorylated by the JAKs. These phosphorylated and activated STAT molecules regulate the transcription of the target genes in the nucleus. JAK2 has two domains: JH1 (the active kinase domain) and JH2 (the "pseudokinase" domain that autoinhibits the kinase domain). The most common mutation in PV (and in all 3 classic, Ph- MPNs) is a guanine-to-thymine substitution in exon 14, resulting in a valine-to-phenylalanine substitution at position 617 (*JAK2*V617F). This gain-of-function mutation, which renders JAK2 constitutively active, results in Epo-independent proliferation of erythroid precursors. The pathologic nature of this mutation has been illustrated by many studies, and *JAK2*V617F knockin mouse models resembling human PV have been created, showing that the mutation in hematopoietic stem cells is sufficient to initiate the disease.[17] In contrast to wild-type JAK2, mutated JAK2 allows for the Epo-independent growth of cell lines in culture.[3–5] The *JAK2*V617F mutation is present in approximately 95% to 97% of patients with PV and is not present in secondary polycythemia. Mutations in exon 12 of *JAK2* have been identified in most of the remaining patients with PV who are negative for the *JAK2*V617F mutation.[18] Therefore, with current sensitive testing, virtually all patients with PV should have mutations in either exon 14 or exon 12 of *JAK2*. Very recently, recurrent indels in exon 13 of the *JAK2* gene, also affecting the JH2 domain, have been described as giving rise to a novel MPN with features of both PV and CEL.[19] Loss-of-function mutations in *LNK*, a physiologic-negative regulator of *JAK2*, have been implicated in some cases of *JAK2*–wild type erythropoiesis.[20]

Clinical Features

Presenting symptoms include vasomotor manifestations such as headache, dizziness, trouble concentrating, blurry vision, tinnitus, erythromelalgia, and acral paresthesias, as well as constitutional symptoms such as fatigue, pruritus (especially after a hot shower or bath), bone and muscle aches, fever, weight loss, and drenching night sweats.[21] In an internet-based survey of 405 patients with PV, the most frequently reported constitutional symptoms were fatigue (85%), itching (65%), night sweats (49%), and bone pain (43%).[22] Thrombosis and hemorrhage are the most common serious complications. Palpable splenomegaly is found in about 40% of patients and may cause abdominal discomfort and/or early satiety.[21] The peripheral blood picture is typically one of "pancytosis." Thrombocytosis can be associated with ocular migraine and erythromelalgia (burning pain in the feet or hands associated with warmth and erythema). Some patients are asymptomatic and are diagnosed after abnormal findings on a routine blood examination. The bone marrow (BM) is typically hypercellular with panmyelosis and megakaryocyte pleomorphism.[11] Cytogenetic abnormalities are relatively infrequent but adversely affect survival.[15]

Thrombosis

Thrombosis is the most serious complication of PV (Table 6–2) and is a presenting manifestation in 15% to 20% of patients.[23,24] In a study of 1213 patients with PV, thrombosis (arterial and venous combined) occurred in 41% of patients overall (64% of thrombotic events occurred at presentation or before diagnosis and 36% occurred during follow-up).[23] In a more recent study of 1545 patients diagnosed using 2008 WHO diagnostic criteria, thrombosis occurred in 23.4% of patients at or before diagnosis and in 21% during follow-up.[15,25] Arterial thrombosis was more common overall than venous thrombosis, and was predicted by prior arterial events and hypertension, whereas venous thrombosis was predicted by prior venous events and age of 65 years or older. Ischemic stroke and transient ischemic attacks accounted for the majority of arterial thromboses at diagnosis.[23,25] The overall incidence of thrombotic events has been estimated at 2.62% to 4.4% of patients per year.[23,25,26] The rate of thrombotic events increases with age (1.8/100 patients per year for those <40 years to 5.1/100 patients per year for those >70 years).[23] Older age and a history of thrombosis are the two best established risk factors for thrombosis.[23,25] In the Polycythemia Vera Study Group studies, one third of the individuals who survived the initial thrombotic event had recurrent thrombosis.[27] Budd-Chiari syndrome (BCS) can be a presenting manifestation of PV. PV is the underlying cause in 50% of patients with BCS,[28] and the *JAK2* mutation has been found in 40% to 58% of patients with BCS.[29] Leukocytosis (white blood cells [WBCs] $>11 \times 10^9$/L or $>15 \times 10^9$/L)[30,31] has been found to be a risk factor for thrombosis in some, but not all, studies.[32,33]

Disease Evolution, Causes of Death, and Prognostic Models

Progression to myelofibrosis (MF; termed post-PV MF) and transformation to AML are the two major late complications of PV. Post-PV MF develops in 4.9% to 6% of patients with PV at 10 years and 6% to 14% at 15 years,[34] and is characterized by clinical features similar to PMF (anemia, serum lactate dehydrogenase elevation, leukoerythroblastosis, and progressive splenomegaly). Major diagnostic criteria include a history of PV and grade 2 or higher fibrosis in the BM.[35] Passamonti et al developed the Myelofibrosis Secondary to PV or ET Prognostic Model (MYSEC-PM) for prediction of overall survival (OS) and leukemia-free survival

Table 6–2 Thrombosis and Bleeding in Polycythemia Vera (at Diagnosis and at Follow-Up)

	At Diagnosis				At Follow-Up				
Study	No. of Patients	Asymptomatic	Major Thrombosis (%) (Arterial %, Venous %)	Bleeding (%)	Major Thrombosis (%) (Arterial %, Venous %)	Bleeding (%)	Major Thrombosis Rate	Deaths From Thrombosis (%)	Deaths From Bleeding (%)

[a]Data from Passamonti F, Brusamolino E, Lazzarino M, et al. Efficacy of pipobroman in the treatment of polycythemia vera: long-term results in 163 patients, *Haematologica* 2000 Oct;85(10):1011-1018.

(LFS) based on a cohort of 685 molecularly annotated patients with post-PV or post-ET MF.[36] In this cohort, the median OS for patients with post-PV MF was 8.1 years. PV transforms to blast phase (leukemic transformation) in 2.3% to 14.4% of patients at 10 years and 5.5% to 18.7% of patients at 15 years.[34] In the European Collaboration on Low-Dose Aspirin in Polycythemia Vera (ECLAP) study, AML/MDS developed from the diagnosis of PV in 22 of the 1638 patients (1.3%) after a median of 8.4 years. Older age and exposure to chemotherapy (^{32}P, busulfan, and pipobroman; $P = .002$), but not hydroxyurea (HU) alone, were associated with an increased risk of AML.[14] Very-long-term follow-up (median, 16.3 years) of the French Polycythemia Study Group study comparing HU with pipobroman in 285 patients also found a much higher cumulative incidence of AML/MDS in the pipobroman group.[37] In a prospective study of 338 PV patients, post-PV MF developed in 8 patients and AML developed in 10 after a median of 3.2 years. *JAK2*V617F allele burden was significantly related to the risk of development of MF but not AML.[32] Very recently, a retrospective study of 520 PV patients seen at 10 US centers found that persistent leukocytosis was significantly associated with disease evolution to MF, MDS, or AML.[33]

The most common causes of death in PV are thrombotic complications and leukemic transformation. In a study of 1213 patients, the most frequent fatal complications were thrombosis (30%) and cancer (15% acute leukemia, 15% other cancers).[23] In the ECLAP study (N = 1638), the most common causes of death were cardiovascular complications, leukemic transformation, and solid tumors in 45%, 13%, and 19.5%, respectively.[26] In the International Working Group for Myelofibrosis Research and Treatment (IWG-MRT) study (N = 1545), the most common causes of death were cancer (36% acute leukemia, 36% other cancers) and thrombotic complications (32%).[15] A prognostic model developed from this study included age (57–66 or ≥67 years), leukocytosis (≥15 × 10^9/L), and venous thrombosis as independent predictors of worse survival. Independent risk factors for shorter LFS included older age, abnormal karyotype, and leukocyte count ≥15 × 10^9/L. This study confirmed the associations of chlorambucil, pipobroman and ^{32}P, but not HU or busulfan, with leukemic transformation. A nested case control study from Sweden also found high exposures to ^{32}P and alkylating agents, but not HU, to be associated with significantly higher risks of transformation to AML/MDS.[38] More recently, targeted deep sequencing efforts have identified mutations in *ASXL1, SRSF2*, and *IDH2* as prognostically adverse in PV.[39] The mutation-enhanced International Prognostic Scoring System for PV integrates clinical and molecular information into a three-tiered (low, intermediate, and high risk) system to predict OS in PV built on hazard ratio–based points allocation to age more than 67 years, *SRSF2* mutation, leukocyte count ≥15 × 10^9/L, and thrombosis history.[40]

Diagnosis

The 2016 revision to the WHO classification of myeloid neoplasms and acute leukemia[11] saw major changes to the diagnostic criteria for PV (Table 6–3). These include lowering of the hemoglobin (Hgb) and hematocrit (Hct) cutoffs for diagnosis, largely based on the recognition that individuals with so-called "masked" PV (mPV) have worse outcomes,[41,42] at least in part because of less recognition and treatment,[43] and elevation of BM biopsy changes characteristic of PV to a major criterion, although BM biopsy is not required for diagnosis in cases that fulfill the 2008 WHO criteria for Hgb (>18.5 g/dL in men and >16.5 g/dL women) or Hct (>55.5% in men and >49.5% in women), are *JAK2*-mutated, and have a low serum Epo level. Compared with the Polycythemia Vera Study Group criteria, for which RCM measurement was mandatory, the WHO criteria have placed less reliance on direct RCM measurement and established Hgb and Hct cutoffs (Hgb >16.5 g/dL in men and >16 g/dL in women; Hct >49%

Table 6–3 2016 World Health Organization Diagnostic Criteria for Polycythemia Vera

Major criteria
• Hgb >16.5 g/dL in men and Hgb >16 g/dL in women or Hct >49% in men and Hct >48% in women, or other evidence of increased red cell mass
• Bone marrow biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleiomorphic, mature megakaryocytes (differences in size)
• Presence of *JAK2*V617F or *JAK2* exon 12 mutation
Minor criterion
• Subnormal serum erythropoietin level
Diagnosis: All 3 major criteria, or the first 2 major criteria and the minor criterion

Reproduced with permission from Arber DA, Orazi A, Hasserjian R, et al: The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia, *Blood* 2016 May 19;127(20):2391-2405.
Hgb, hemoglobin; Hct, hematocrit.

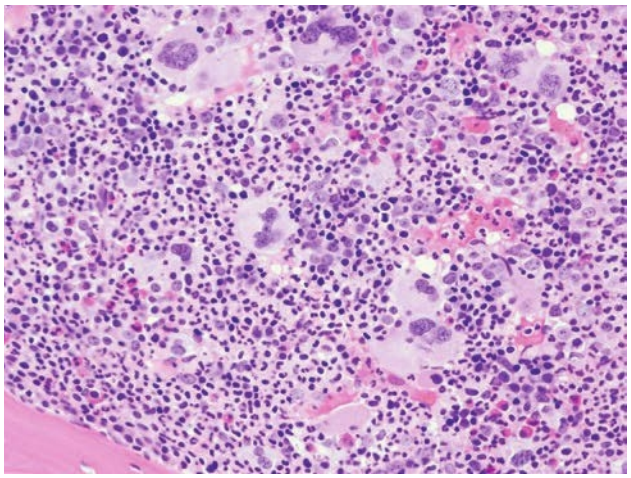

FIGURE 6–1 Bone marrow biopsy from a patient with PV shows remarkable hypercellularity because of myeloid hyperplasia and markedly increased megakaryocytes. Although some of the megakaryocytes morphologically demonstrate slight size variations, most of the megakaryocytes are unremarkable (×200).

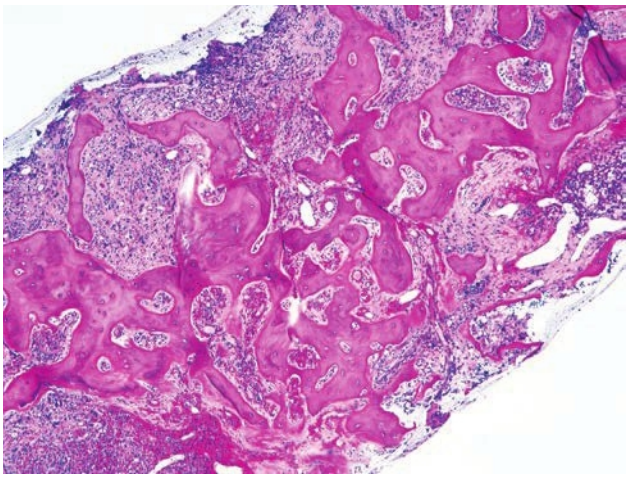

FIGURE 6–2 Extensive bone remodeling and osteosclerosis are occasional features encountered in bone marrow biopsies during the postpolycythemic myelofibrosis phase of PV (×40).

in men and >48% in women in the 2016 criteria) for diagnostic purposes. These cutoffs were found to discriminate best between mPV and *JAK2*-mutated ET.[44] This view is not universally held, however, and some experts still advocate use of direct RCM measurement for PV diagnosis[45]; however, RCM measurement is not available virtually anywhere in the United States, outside of a select few centers where this is still routinely performed. For patients suspected to have PV (based on elevated Hgb/Hct, presence of symptoms, or thrombotic/hemorrhagic complications), initial evaluation in most cases should include a BM biopsy with testing for the *JAK2* mutation (on either peripheral blood or BM)[46] and measurement of serum Epo. Because red cell proliferation is autonomous in PV, serum Epo is generally low but can be within the normal range. Classical morphologic features seen in BM biopsies in PV and post-PV MF are shown in Figs. 6–1 to 6–3.

Treatment

The main goal of therapy in PV is to prevent thrombotic events.[47] In general, this is achieved with the use of phlebotomy and low-dose aspirin in low-risk patients, and with cytoreductive therapy and low-dose aspirin in high-risk patients. The target Hct is <45%, established by the seminal Cytoreductive Therapy in Polycythemia Vera (CYTO-PV) study, discussed below.[48] Regular phlebotomy induces iron deficiency, which has not been shown to be detrimental in the absence of anemia. Patients with PV who become iron deficient as a result of phlebotomy use should not routinely receive iron supplementation. Although

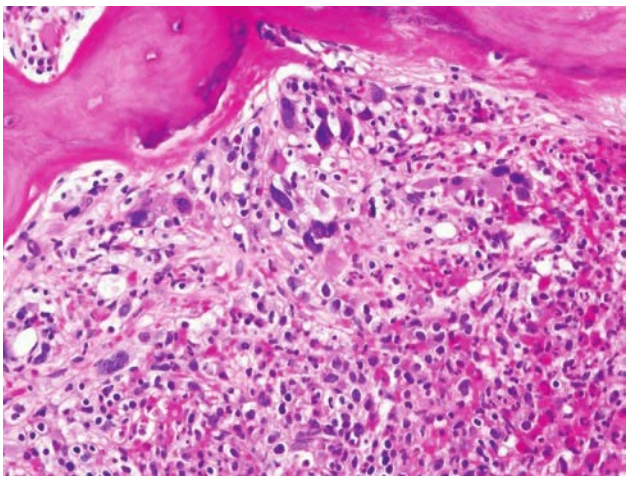

FIGURE 6–3 In contrast to the relatively normal megakaryocytes seen during the early stages of PV, megakaryocytes become markedly atypical during the postpolycythemic myelofibrosis phase. The atypical morphologic features include pronounced size variations, usually because of the presence of numerous small forms. Classically, megakaryocyte nuclei become hyperchromatic during this advanced stage of PV (×200).

the impact of therapeutic lowering of elevated WBC counts in PV is unclear, most clinicians try to control leukocytosis, given its known associations with inferior survival and risk of leukemic transformation, and possibly with thrombotic events.[15,30,31,33,40] Guidelines from the US National Comprehensive Cancer Network (NCCN) recognize the need for cytoreductive therapy in low-risk patients under certain circumstances—eg,

new thrombosis or disease-related major bleeding, frequent and/or persistent need for phlebotomy but with poor tolerance of phlebotomy, splenomegaly, symptomatic thrombocytosis, progressive leukocytosis, and troublesome disease-related symptoms such as pruritus, night sweats, and fatigue.[49] Hepcidin mimetics (NCT04057040) represent a novel class of agents that may have the potential to reduce the need for phlebotomy.[50]

Platelets from patients with PV have been shown to profoundly overproduce thromboxanes, and this can effectively be suppressed by low-dose aspirin.[51] In the ECLAP study, Landolfi et al randomized 518 PV patients of any age without a clear indication for, or contraindication to aspirin, to low-dose aspirin (100 mg daily) or placebo.[52] All patients continued to be treated with phlebotomy, cytoreductive therapy, and standard cardiovascular drugs; the median Hct was 46%. The use of aspirin resulted in a 60% reduction in the risk of nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, and death from cardiovascular causes (P = .03). The incidence of major bleeding episodes was not significantly increased in the low-dose aspirin group; virtually all excess bleeding in the aspirin group was caused by an 83% increase in the rate of minor bleeding episodes. Largely based on this trial, all patients with PV should receive low-dose aspirin unless contraindicated.

The CYTO-PV randomized controlled trial (RCT) evaluated the benefit of maintaining stringent control of Hct (target <45%) versus less intense treatment (target 45%–50%) in 365 adults with *JAK2*-mutated PV treated with phlebotomy or HU or both.[48] Patients with tight control of Hct (<45%) had a significantly lower rate of major thrombosis and death from cardiovascular causes (2.7% vs 9.8% after a median follow-up of 31 months).

Although not based on prospective RCT data, HU is the most preferred first-line cytoreductive therapy for patients with PV; however, weekly subcutaneously administered pegylated IFN-α-2a, which has been associated with high rates of both hematologic and molecular responses in single-arm, noncomparative phase 2 trials.[53,54] is also a reasonable option. The Myeloproliferative Disorders Research Consortium (MPD-RC) conducted a global phase 3 RCT, the MPD-RC 112 study, comparing HU with pegylated IFN-α-2a in 168 patients with high-risk PV or ET.[55] No meaningful differences were apparent between the two treatment arms at 1 or 2 years of follow-up, with respect to rates of complete response (CR) by IWG-MRT/European LeukemiaNet (ELN) criteria[56] or BM histopathologic or molecular responses. However, the rate of grade 3/4 toxicity was higher in the IFN group. Interferon's lack of leukemogenicity and teratogenicity makes it attractive for treatment of young patients and during pregnancy, but discontinuation rates are high (range, 20%–25%) because of side effects such as depression and flulike symptoms.[57] A newer, longer-acting form of monopegylated IFN-α (PEG-proline-IFN-α-2b, also called ropeginterferon-α-2b), which allows for subcutaneous dosing every two weeks, has recently been approved in Europe for patients with PV without symptomatic splenomegaly. In the pivotal PROUD/CONTINUATION-PV phase 3 RCTs,[58] ropeginterferon-α-2b was compared 1:1 with HU in 257 patients with PV who had never received cytoreductive therapy or had received HU for less than 3 years without achievement of CR or development of resistance/intolerance to HU (Table 6–4).[59] The primary end point of PROUD-PV, a noninferiority study—complete hematologic response (CHR) with normal spleen size at 12 months—was met (21% for ropeginterferon-α-2b and 28% for HU). One hundred seventy-one patients were rolled over into the CONTINUATION-PV trial. Fifty-three percent of the patients in the ropeginterferon-α-2b group versus 38% in the HU/standard therapy group (P = .044) met the coprimary end point of CHR with improved disease burden at 36 months. Tolerability of ropeginterferon-α-2b was good, and both hematologic and molecular responses to it improved over time, showing superiority over HU after two and three years of treatment. The histone deacetylase inhibitor givinostat is also in clinical development for PV.[60]

The oral JAK1/2 inhibitor ruxolitinib was approved by the FDA for HU-resistant/intolerant PV in December 2014, based on the results of a randomized phase 3 clinical trial, RESPONSE, in which 222 patients were randomized 1:1 to receive ruxolitinib (starting dose 10 mg twice daily) or standard therapy.[61] Twenty-one percent of the patients in the ruxolitinib arm achieved the primary end point (Hct control without phlebotomy through week 32 and a ≥35% spleen volume reduction [SVR] from baseline at week 32) versus 1% in the standard therapy arm (P < .001). Sixty percent versus 20% of the patients achieved Hct control, 38% versus 1% saw ≥35% SVR, 24% versus 9% achieved CHR and 49% versus 5% of patients in the standard therapy arm had a ≥50% improvement in the MPN-Symptom Assessment Form total symptom score (TSS), a validated measure of MPN patient-reported symptoms.[62] Herpes zoster reactivation was more common in the ruxolitinib arm. Crossover was permitted after week 32, and all standard therapy patients had crossed over to receiving ruxolitinib by week 80. A similarly designed phase 3 trial, RESPONSE-2, conducted in HU-resistant/intolerant patients without splenomegaly, produced very similar results.[63] The benefits of ruxolitinib were sustained after 5 years of follow-up, and no new safety concerns emerged.[64] Thromboembolic events were numerically

Table 6–4 European Leukemia Net (ELN) Definition of Hydroxyurea Resistance/Intolerance in PV

1. Need for phlebotomy to keep hematocrit <45% after 3 months of at least 2 g/day of hydroxyurea, **OR**
2. Uncontrolled myeloproliferation, ie, platelet count >400 × 10^9/L **AND** white blood cell count >10 × 10^9/L after 3 months of at least 2 g/day of hydroxyurea, **OR**
3. Failure to reduce massive[a] splenomegaly by >50% as measured by palpation, **OR** failure to completely relieve symptoms related to splenomegaly, after 3 months of at least 2 g/day of hydroxyurea, **OR**
4. Absolute neutrophil count <1.0 × 10^9/L **OR** platelet count <100 × 10^9/L or hemoglobin <10 g/dL at the lowest dose of hydroxyurea required to achieve a complete or partial clinico- hematologic response[b], **OR**
5. Presence of leg ulcers or other unacceptable hydroxyurea- related non- hematologic toxicities, such as mucocutaneous manifestations, gastrointestinal symptoms, pneumonitis, or fever at any dose of hydroxyurea

[a]Organ extending by more than 10 cm from the costal margin.
[b]Complete response was defined as: hematocrit <45% without phlebotomy, platelet count ≤400 × 10^9/L, white blood cell count ≤10 × 10^9/L, and no disease-related symptoms. Partial response was defined as: hematocrit <45% without phlebotomy, or response in three or more of the other criteria.
Reproduced with permission from Barosi G, Birgegard G, Finazzi G, et al: A unified definition of clinical resistance and intolerance to hydroxycarbamide in polycythaemia vera and primary myelofibrosis: results of a European LeukemiaNet (ELN) consensus process, *Br J Haematol* 2010 Mar;148(6):961-963.

lower in the ruxolitinib group than in the standard therapy group. A recent meta-analysis also found a numerically, but not statistically significant ($P = .098$), lower incidence of thrombotic events with ruxolitinib in patients with PV.[65]

Pegylated IFN-α-2a is also a therapeutic option after failure of HU in PV. In the single-arm, phase 2 MPD-RC 111 trial, the overall response rate (ORR) to pegylated IFN-α-2a at 12 months in 50 HU-resistant/intolerant patients with PV was 60% (22% CR + 38% partial response [PR]).[66] Retrospective studies have demonstrated that resistance/intolerance to HU (Table 6–4) has prognostic implications. In a Spanish registry study, resistance and intolerance to HU were found in 11% and 13% of patients with PV, and resistance to HU was associated with a higher risk of death and leukemic transformation.[67] In another such study, development of cytopenias at the lowest dose of HU needed to achieve CR or PR was an independent risk factor for transformation to acute leukemia, whereas the risk of progression to MF was higher in patients in whom cytopenia or massive splenomegaly developed.[68] Based on induction of murine double minute 2 (MDM2) by *JAK2*V617F,[69] MDM2 inhibition has been pursued as a therapeutic strategy for HU-resistant/intolerant PV. However, although clearly active,[70] the toxicity of these agents (eg, idasanutlin) has thwarted their clinical development for PV.

Treatment Conclusions

All patients with PV should receive low-dose aspirin unless contraindicated. Patients who are at high risk for thrombosis (age >60 years or a history of thrombosis) should receive cytoreductive therapy. The targeted Hct is <45% in all patients. We believe that when cytoreductive therapy is used, the goal should be to eliminate phlebotomy, although studies have arrived at opposite conclusions on whether persistent need for phlebotomies while receiving HU is associated with adverse outcomes.[71,72] Although HU is widely used as first-line cytoreductive therapy, data support the use of pegylated IFN-α-2a/ropeginterferon-α-2b up front as well. Both ruxolitinib and pegylated IFN-α-2a are reasonable options in the setting of HU resistance/intolerance.

ESSENTIAL THROMBOCYTHEMIA

Essential thrombocythemia (ET) is characterized by persistent thrombocytosis with a predisposition to thrombosis and bleeding. ET is not a cytogenetically or a morphologically defined disease entity and remains a diagnosis of exclusion, although the discovery of driver mutations in exon 9 of *CALR,* detected in the vast majority of *JAK2/MPL*-wild-type cases,[9,10] has substantially simplified the diagnosis. Generally, it is a disease of older adults; the median age at diagnosis is 55 to 60 years. ET is more common in women than in men. Survival in ET has been reported to be no different from to slightly worse (median, 19.8 years) than that of the age- and sex-matched general population in different studies.[16,73] The annual incidence of ET has been reported to be 0.21 to 2.27 per 100,000 population.[12] The US prevalence of ET has been estimated to be in the range of 38 to 57 individuals per 100,000.[13]

Reactive causes of thrombocytosis should be excluded. Most often, the underlying cause is apparent (postsplenectomy, acute infection, blood loss, iron deficiency). Other MPNs, such as PV or CML, can also present with thrombocytosis, as can MDS with isolated deletion 5q and the overlap syndrome, MDS/MPN-RS-T, and should be ruled out. The magnitude of elevation in the platelet count does not help distinguish between reactive and clonal causes of thrombocytosis. Reactive thrombocytosis, irrespective of the degree of

elevation of platelet counts, does not increase the risk of thromboembolic or bleeding complications. Such complications, if seen, are the consequences of underlying disease conditions (malignancy, iron deficiency from gastrointestinal bleeding) rather than of elevated platelets.

Pathophysiology

Approximately 50% of patients with ET harbor the *JAK2*V617F mutation, and 3% to 5% have a mutation in the thrombopoietin receptor (MPL) (W515L/K; tryptophan to leucine or lysine substitution at residue 515),[74] both of which lead to dysregulated JAK-STAT signaling. Most patients with ET are heterozygous for *JAK2*V617F, with allele burdens less than 50%, suggesting that lower *JAK2*V617F gene dosage may lead to the development of ET versus PV, in which the allele burden is generally higher.[75] The order of mutation acquisition has also been shown to influence disease phenotype, with *JAK2*-first mutation acquisition more likely to lead to a PV phenotype with a greater predisposition to thrombosis, as opposed to *TET2*-first mutation acquisition, which is associated with an ET phenotype.[76]

Recently, mutations in the gene encoding the endoplasmic reticulum chaperone protein calreticulin (CALR) have been found in nearly 70% of patients with ET negative for *JAK2* or *MPL* mutations (20%–30% of all patients with ET).[9,10] The *CALR* mutation may define a distinct subset of ET. In a series of 717 patients with ET, those with *CALR* mutations were younger and predominantly male and had a lower incidence of thrombosis, lower hemoglobin levels, lower leukocyte counts, and higher platelet counts than those with the *JAK2*V617F mutation.[77] Other studies have confirmed these observations and also noted that "triple-negative" ET patients (ie, those without detectable *JAK2*, *CALR*, or *MPL* mutations, ~10%–15%) share some of the same characteristics (ie, younger age, lower Hgb levels, lower leukocyte counts, and lower risk of thrombosis than *JAK2*-mutated patients).[78] Survival has been reported to be the longest for these "triple-negative" patients, and shortest for *MPL*-mutated patients.[78] There are data suggesting that the favorable impact of *CALR* mutations on thrombosis risk in ET might be confined to younger patients.[79]

There are two major types of *CALR* mutations: type 1 (52 base-pair deletions) and type 2 (5 base-pair insertions). Both result in an altered C-terminal of the mutant protein with loss of negative charge that impairs calcium binding, and in loss of the endoplasmic reticulum retention motif, culminating in JAK-STAT pathway activation. Several studies have shown that mutant CALR requires its altered C-terminal and needs to physically bind to the extracellular domain of MPL to exert its oncogenic effects.[80–85] Another function of mutant CALR shown to be essential for oncogenic transformation, termed its *rogue chaperone activity*, is its ability to stabilize and transport MPL and mutants thereof to the cell surface in states that would not normally pass quality control.[86] Types 1 and 2 *CALR* mutations occur at approximately equal frequencies in ET and do not appear to impact prognosis,[87] although one study has shown that type 1 *CALR* mutations may confer a higher risk of progression to post-ET MF.[88] *MPL* mutations have been associated with shorter myelofibrosis-free survival in ET.[87] Male sex may be associated exclusively with type 1 *CALR* mutations, and younger age with type 2; this study also found platelet counts to be significantly higher in type 2 than in type 1 *CALR*-mutated patients.[89]

Clinical Features

With the increasing use of automated blood counters and routine blood count screenings, more patients with ET are being diagnosed while they are asymptomatic. In an international, internet-based survey of 304 patients with ET, 72% reported fatigue, and about 40% of ET patients reported itching, night sweats, and bone pain.[22] Vasomotor manifestations such as dizziness, lightheadedness, acral paresthesia, livedo reticularis, and erythromelalgia were noted in 34% of patients in one study of 147 patients with ET.[90] Mild splenomegaly (<5 cm) was noted in up to 40% of patients, leukocytosis in 30% to 40%, and mild anemia in 10% to 20%. Thromboembolic and bleeding complications are the major cause of morbidity and mortality in ET. A series of 322 patients with ET from one institution reported a 26% incidence of major thrombosis and 11% incidence of major bleeding at diagnosis.[91] Hemorrhagic complications increase with extreme thrombocytosis (platelet count >1.5 million/μL) and with the use of antiplatelet therapy such as aspirin.

The most serious late complications of ET include transformation to AML and progression to post-ET MF. In a single-institution study of 605 patients with ET who were followed for a median of 7 years, the incidence of AML transformation was 3.3%.[92] Risk factors for transformation included anemia and platelet count $>1000 \times 10^9$/L. In a more contemporary large series from seven centers in Europe, the diagnosis of ET (per 2008 WHO criteria) was confirmed in 891 patients and revised to early/prefibrotic MF in 180 patients.[93] Among the patients with ET, the 10- and 15-year cumulative incidences of transformation to AML and progression to post-ET MF were 0.7% and 2.1%, and 0.8% and 9.3%, respectively. In another study of 292 patients with ET with a median follow-up of 17.3

Table 6–5 2016 WHO Criteria for Diagnosis of Essential Thrombocythemia

Major Criteria
1. Platelet count ≥450 × 10^9/L
2. Bone marrow biopsy specimen showing proliferation mainly of the megakaryocytic lineage with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei; no significant increase or left shift in neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibers
3. Not meeting WHO criteria for PV, PMF, *BCR-ABL1*$^+$ CML, MDS, or other myeloid neoplasm
4. Presence of *JAK2*, *CALR*, or *MPL* mutation
Minor Criterion
Presence of a clonal marker or absence of evidence for reactive thrombocytosis
Diagnosis of ET requires meeting all four major criteria or the first 3 major criteria and the minor criterion.

Reproduced with permission from Arber DA, Orazi A, Hasserjian R, et al: The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia, *Blood* 2016 May 19;127(20):2391-2405.

years, the cumulative incidence of AML was 3.8% and of progression to MF was 10.3%.[16] Overall, the risk of progression to post-ET MF has been reported in the literature to be 0.8% to 4.9% at 10 years and 4% to 11% at 15 years; the corresponding rates for post-ET AML are 0.7% to 3% at 10 years and 2.1% to 5.3% at 15 years.[34]

Diagnosis

The diagnostic criteria for ET did not change appreciably from the 2008 to the 2016 WHO classification, other than the addition of *CALR* mutations to the list of known driver mutations (Table 6–5).[11] An important change in the 2008 WHO classification was lowering the platelet count threshold for ET diagnosis from >600 × 10^9/L to >450 × 10^9/L.[94] BM biopsy is mandatory for diagnosis to rule out "masked" PV, PMF (especially pre-PMF), and MDS/MPN. A BM biopsy typically shows large but mature-appearing megakaryocytes with deeply lobulated or hyperlobulated nuclei (Fig. 6–4). The peripheral blood smear shows markedly increased platelets (Fig. 6–5). Reticulin staining should be done to rule out any underlying fibrosis; very rarely, a grade 1 increase in reticulin fibers is encountered.[11] The presence of megakaryocytic atypia in the BM biopsy suggests "prefibrotic" MF, which implies a higher risk of progression to overt MF and transformation to AML, and poorer OS.[93] Also, pre-PMF often exhibits decreased erythropoiesis and granulocytic proliferation, and some reticulin fibrosis (but not >grade 1).[11] CML should be ruled out by testing for the *BCR-ABL1* fusion gene. Beyond testing for *JAK2*, *MPL*, and *CALR* mutations, a myeloid mutation (targeted next generation sequencing) panel is recommended to establish the clonal nature of the disease, ruling out reactive thrombocytosis in "triple-negative" cases.

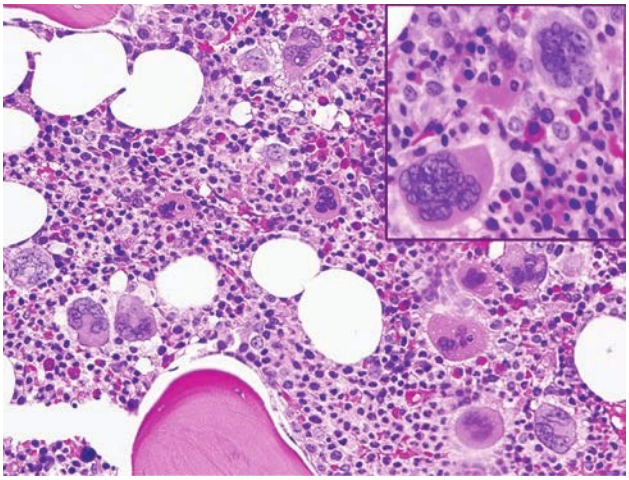

FIGURE 6–4 Essential thrombocythemia is characterized by increased bone marrow cellularity, myeloid hyperplasia, and notably increased megakaryocytes (×200). The megakaryocytes in ET tend to display larger than normal size, and they also contain large hyperlobulated nuclei (inset, ×400).

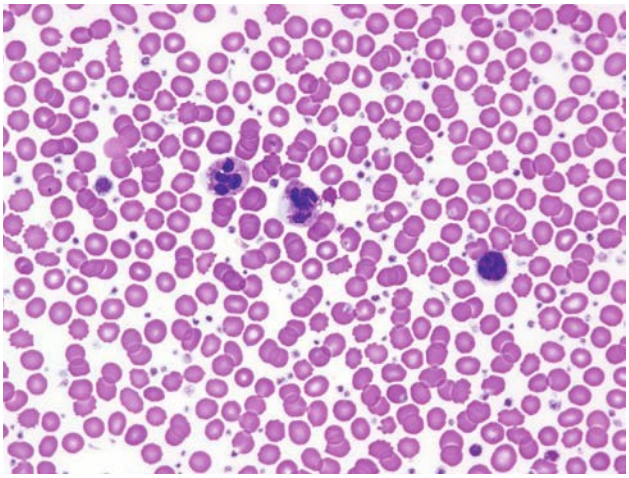

FIGURE 6–5 Peripheral blood smear from a patient with ET shows markedly increased platelets with scattered large forms (×400).

Thrombotic Risk Stratification and Survival Prediction in ET

As in PV, thrombosis and hemorrhage are the main complications of ET. Older age and a history of prior thrombosis have been shown to predict for future thrombotic events in most studies, whereas cardiovascular risk factors have been predictive in only some. As discussed previously, *CALR*-mutated and triple-negative patients with ET appear to be at lower risk of thrombosis compared with *JAK2*/*MPL*-mutated patients.[77,78] Platelet count does not correlate with risk of thrombosis in ET (Table 6–6). Some studies have found an inverse relationship between the platelet count and the thrombotic risk. This is thought to be the result of acquired von Willebrand disease (AVWD) with elevated platelet counts (eg, >1.5 million/μL), predisposing the patient to more bleeding and relative protection from thrombosis.

A study from the IWG-MRT on a cohort of 891 patients from seven centers in Europe diagnosed with WHO 2008–defined ET reported a 6% cumulative

incidence of major bleeding at a rate of 0.79 patients/year.[95] The cumulative incidence of thrombosis (fatal and nonfatal events) was 25% at a rate of 1.9% of patients/year.[93,96] The rate of nonfatal arterial events (1.2% of patients/year) was higher than that of venous events (0.6% patient/year).[96] Factors independently associated with bleeding included previous hemorrhage and aspirin therapy.[95] Factors independently associated with major thrombosis included age older than 60 years, cardiovascular risk factors (diabetes, hypertension, or smoking), previous thrombosis, and presence of the *JAK2V617F* mutation.[96] Leukocytosis (>11 × 10^9/L) was an additional independent risk factor for arterial thrombosis (though not when the analysis was restricted to *JAK2*-mutated cases), whereas male gender increased the risk of venous thrombosis. Extreme thrombocytosis (platelet count >1000 × 10^9/L) was independently associated with a reduced risk of arterial thrombosis.[96] This is thought to be caused by AVWD with elevated platelet counts, predisposing to more bleeding and relative protection from thrombosis, consistent with previous reports showing an inverse relationship between platelet count and thrombotic risk.[97] The link between leukocytosis, both at diagnosis and during follow-up, and thrombosis in ET has been confirmed in other studies.[98,99]

Using these risk factors, a prognostic model was proposed to predict risk of thrombosis in patients with ET (International Prognostic Score for Thrombosis in Essential Thrombocythemia [IPSET-thrombosis]).[100] The model assigned relative weights to the four risk factors, and the patients could be stratified into three risk categories, with an annual risk of thrombosis ranging from 1.03% of patients/year for the low-risk group to 3.56% of patients/year for the high-risk group (Table 6–7). *CALR* mutational status has been shown not to modify the IPSET-thrombosis score.[101]

In a more recent "practice-relevant" revision of the IPSET-thrombosis model, patients with ET were subdivided into four groups—very low, low, intermediate, and high—based on thrombotic risk, using age, thrombosis history, and *JAK2* mutation status as the

Table 6–7 International Prognostic Score for Essential Thrombocythemia (IPSET) and IPSET-Thrombosis[100,103]

Risk Factor	IPSET	IPSET-Thrombosis (IPSET-t)
Age >60 years[a]	2	1
Previous thrombosis	1	2
WBC count ≥11 × 10^9/L[†]	1	
Cardiovascular risk factors		1
*JAK2*V617F positive		2
Prognostic Score (Median Survival or Rate of Thrombosis)

Intermediate	1–2 points (24.5 y)	2 points (2.35% patients/y)
High	3–4 points (13.8 y)	>2 points (3.56% patients/y)

[a]≥60 years for IPSET, >60 years for IPSET-t.
[†]≥11 × 10^9/L for IPSET, >11 × 10^9/L for IPSET-t.

Table 6–8 The revised IPSET-t and Treatment Recommendations for Essential Thrombocythemia[102]

Risk Category	Description	Recommended Intervention
Very low	Age ≤60 years, *JAK2* WT, no h/o thrombosis	Observation, low dose aspirin[a] if CV risk factors
Low	Age ≤60 years, *JAK2* V617F+, no h/o thrombosis	Low-dose aspirin[a]; consider twice daily if CV risk factors
Intermediate	Age >60 years, *JAK2* WT, no h/o thrombosis	Cytoreductive therapy and low dose aspirin[a], possibly twice daily aspirin[a] without cytoreductive therapy
High	Age >60 years AND *JAK2* V617F+, or h/o thrombosis	Cytoreductive therapy and low-dose aspirin[a]

[a]Use aspirin with caution in patients with extreme thrombocytosis; always rule out acquired von Willebrand disease first. WT, wild type; CV, cardiovascular.

variables (Table 6–8).[102] Consensus guidelines from the NCCN recommend the use of this model to risk stratify patients with ET for disease management decisions.[49]

Data from the same cohort of patients were used to develop a prognostic score to predict OS of ET at diagnosis (IPSET).[103] The final prognostic score included age 60 years or older (2 points), leukocyte count 11 × 10^9/L or greater (1 point), and prior thrombosis (1 point) as independent risk factors for survival (see Table 6–7). The model stratified patients into three risk categories, with median survival not reached in the low-risk group to 24.5 years in the intermediate-risk group to 13.8 years for the high-risk group. Although the *JAK2* V617F mutation was associated with increased thrombosis risk,[93] it was not predictive of survival, which was consistent with findings from other studies.[16] In another study, *JAK2* V617F was identified as an independent predictor of pregnancy complications[104]; however, subsequent studies failed to confirm this observation.[105,106] Although cytogenetic abnormalities are uncommon in ET (<10% at diagnosis) and have not been correlated with survival or transformation risk,[107] targeted deep sequencing has identified some adverse mutations/sequence variants, *viz*. *SH2B3*, *SF3B1*, *U2AF1*, *TP53*, *IDH2*, and *EZH2*.[39] The recently published MIPSS-ET model integrates clinical and molecular information into a three-tiered (low, intermediate, and high) prognostic model for ET that allocates points, based on hazard ratios, to age older than 60 years, male sex, *SF3B1*/*SRSF2* mutations, and leukocytosis >11 × 10^9/L.[40]

Treatment

The goal of therapy in ET is to prevent the major cause of morbidity and mortality: thromboembolic events. Because the majority of patients have a normal life expectancy, aggressive treatments that could cause potentially dangerous side effects should be avoided. Cardiovascular risk factors should be aggressively managed in all patients. Smoking was an important risk factor for thrombosis in many studies; all patients should be counseled regarding smoking cessation. The two major classes of therapies used for the treatment of ET are antiplatelet drugs and cytoreductive drugs (Table 6–8).

Antiplatelet Therapy

Antiplatelet therapy with aspirin is useful in treating the microvascular symptoms of ET, such as erythromelalgia. The role of antiplatelet therapy in reducing thrombotic episodes in ET is less clear because no placebo-controlled, randomized trial is available. In a retrospective study, Van Genderen et al showed decreased thrombosis risk and improvements in microvascular symptoms with aspirin monotherapy.[108] Extrapolating from the ECLAP study results in PV,[52] the general consensus is to use low-dose aspirin (75–100 mg daily) in patients with ET unless contraindicated by bleeding history. Caution should be exercised in using aspirin in patients with a very high platelet count (>1500 × 10^9/L) because of the increased risk of bleeding from AVWD.[109] In the UK Medical Research Council Primary Thrombocythemia 1 (MRC PT-1) trial comparing HU and anagrelide in ET, all patients received antiplatelet therapy unless it was contraindicated.[110] An increased risk of bleeding was noted in the anagrelide arm compared with the HU arm, possibly because of the synergistic antiplatelet effect of aspirin with anagrelide. It has been suggested that low-dose aspirin given twice a day may be effective in patients whose symptoms are not controlled with once-daily dosing.[111] Several studies have shown that once-daily aspirin incompletely suppresses platelet thromboxane biosynthesis, possibly a result of accelerated renewal of platelet cyclooxygenase in ET,[112] and that twice-daily dosing more effectively inhibits platelet aggregation.[113–115]

Cytoreductive Therapy

Hydroxyurea, anagrelide, and IFNs are the main cytoreductive agents currently used in patients with ET. Hydroxyurea is a nonspecific, cytotoxic, and myelosuppressive drug that works through inhibition of ribonucleotide reductase. Anagrelide has a selective effect on the megakaryocyte lineage. Two randomized studies in ET have established HU as the frontline cytoreductive therapy of choice. In an Italian study by Cortelazzo et al, 114 patients with high-risk ET (age >60 years, history of thrombosis, or both) were randomized to receive either placebo or HU, with a goal platelet count of <600 × 10^9/L.[116] After a median follow-up of 27 months, 3.6% of patients in the HU group had thrombotic episodes compared with 24% in the placebo group (P = .003). This study established the antithrombotic effect of HU in ET. Harrison et al reported the results of the UK MRC PT-1 study of 809 high-risk patients with ET who were randomly grouped to receive HU plus aspirin or anagrelide plus aspirin.[110] The goal platelet count was <400 × 10^9/L. After a median follow-up of 39 months, anagrelide therapy was associated with higher rates of arterial thrombosis (P = .004) and serious hemorrhage (P = .008), but a lower rate of venous thromboembolism (P = .006) compared with the HU arm. Serious hemorrhage with anagrelide was likely the result of a synergistic antiplatelet effect of aspirin. The risk of developing post-ET MF was significantly higher in the anagrelide arm (5-year risk, 7% vs 2% in the HU arm, P = .01), and significantly more patients in the anagrelide arm withdrew from the study because of side effects (22% vs 11%, P < .001). The risk of developing MDS/AML was similar in the two arms. Largely based on this trial, HU has been widely adopted as the first-line treatment of choice in high-risk ET. However, the more recently reported ANAHYDRET study showed noninferiority of a controlled release preparation of anagrelide to HU in 259 patients with WHO-defined ET; aspirin was not allowed in either arm of this trial.[117] The utility of adding HU to aspirin in young patients (age 40–59 years) with ET without high-risk features (thrombosis, embolism, hemorrhage, hypertension, or diabetes requiring therapy) or extreme thrombocytosis (platelet count ≥1500 × 10^9/L) was assessed in a randomized trial (N = 382).[118] After a median follow-up of 73 months, there was no significant difference between the arms in the likelihood of patients reaching the primary end point (arterial or venous thrombosis, serious hemorrhage, or death from vascular causes, P = 1.0). There were also no differences in OS, the composite end point of disease evolution to MF, AML, or MDS; adverse event (AE) profile; or patient-reported quality of life (QOL). A recent pooled analysis of 1500 cases of MPN-associated thrombosis showed that although HU reduced the rate of recurrent arterial thrombotic events, this could not be conclusively shown with respect to recurrent venous thrombotic events, in particular, recurrent splanchnic vein thrombosis.[119]

The experience with IFN in ET generally mirrors that in PV. Response rates, both hematologic and molecular, are high,[54] but patients with nondriver mutations outside the JAK-STAT pathway have a lower likelihood of achieving complete molecular response.[120] Although pegylated IFN-α-2a is better tolerated and allows for weekly dosing, discontinuation rates because of AEs remain substantial.[57] As discussed in the section on PV, the MPD-RC 112 trial showed no meaningful differences between HU and pegylated IFN-α-2a after one or two years of treatment in patients with previously untreated high-risk PV or ET.[55] Interferon's lack of leukemogenicity and teratogenicity make it attractive for use in very young patients with ET in need of cytoreductive therapy,[47,49] and it is the cytoreductive drug of choice in pregnant patients.[121] Ropeginterferon-α-2b will be compared with anagrelide in patients with ET who are resistant to or intolerant of HU (NCT04285086). Pegylated IFN-α-2a has been studied in this setting and led to a 69.2% ORR (43.1% CR

Table 6–9 Consensus Criteria for Hydroxyurea Resistance or Intolerance in Essential Thrombocythemia

Platelet count >600,000/μL after 3 months of at least 2 g/day of HU (2.5 g/day in patients with a body weight >80 kg)
Platelet count >400,000/μL and WBC <2500/μL at any dose of HU
Platelet count >400,000/μL and Hgb <10 g/dL at any dose of HU
Presence of leg ulcers or other unacceptable mucocutaneous manifestations at any dose of HU
HU-related fever

Reproduced with permission from Barosi G, Besses C, Birgegard G, et al: A unified definition of clinical resistance/intolerance to hydroxyurea in essential thrombocythemia: results of a consensus process by an international working group, *Leukemia* 2007 Feb;21(2):277-280.

+ 26.2% PR) in 65 patients with ET; CR rates were higher in patients with *CALR* mutations.[66]

Ruxolitinib was compared with best available therapy (BAT) in 110 patients with HU-resistant/intolerant ET in the MAJIC-ET trial.[122] At one year, there was no significant difference in CR rates, and at two years, rates of thrombosis, bleeding, and disease evolution to MF or AML were not significantly different; however, some disease-related symptoms were significantly improved in the ruxolitinib arm. Other studies have suggested efficacy of ruxolitinib in providing sustained count control and symptom benefits in patients with HU-resistant/intolerant ET[123]. Table 6–9 lists consensus criteria for HU resistance/intolerance in ET.[124] The RUXO-BEAT study compares ruxolitinib with BAT in high-risk PV or ET (NCT02577926). Bomedemstat, an oral inhibitor of lysine demethylase-1, will also be studied in patients with ET in whom at least standard therapy has failed (NCT04254978).

Special Issues

Management of Extreme Thrombocytosis (Platelet Count >1.5 Million/μL)

Aspirin should be avoided because of the risk of bleeding secondary to AVWD. The use of cytoreductive agents is suggested, especially when bleeding is present, to lower platelet counts and decrease the risk of bleeding. Many experts regard extreme thrombocytosis as a high-risk category and treat all such patients with cytoreductive therapy; others reserve it for patients with bleeding complications or symptoms.[111]

Management of Essential Thrombocythemia in Pregnancy

Essential thrombocythemia is the most common of the Ph^- MPNs encountered in pregnancy. In a prospective study from the UK, pregnancies in 58 women with underlying MPN, 47 (81%) with ET, were identified.[125] The incidence of miscarriage was 1.7% and that of maternal complications was 9%; there were no maternal deaths or thrombotic events. Eighty-five percent delivered at term. There were no neonatal deaths; 22% of neonates were below the 10th decile for growth. Pregnant women with MPNs should be cared for in a multidisciplinary setting by both an obstetrician experienced in managing high-risk pregnancies and a hematologist.[121] In general, low-dose aspirin is recommended throughout pregnancy unless contraindicated (eg, by AVWD). Whether low-molecular-weight-heparin provides additional benefit is controversial,[126] but some experts recommend it for women with prior thrombosis or poor pregnancy outcome, and those with at least one other risk factor for thrombosis (besides pregnancy), with appropriate interruption around delivery.[121] When cytoreductive therapy is indicated, eg, by prior thrombosis or hemorrhage, or platelets >1500 × 10^9/L, IFN-α is preferred. Low-molecular-weight heparin should generally be offered postpartum for six weeks.

PRIMARY MYELOFIBROSIS

Primary myelofibrosis is a clonal disorder of a multipotent hematopoietic stem/progenitor cell of unknown etiology; it is characterized by myeloid cell proliferation, megakaryocytic atypia, BM fibrosis, a leukoerythroblastic peripheral blood picture, anemia, occasional extramedullary hematopoiesis (EMH), splenomegaly, and poor survival.[127] Primary myelofibrosis was previously known as CIMF, myelofibrosis with myeloid metaplasia, or agnogenic myeloid metaplasia. Myelofibrosis can occur either de novo (PMF) or as a late complication of PV or ET (post-PV/ET MF). In either case, it manifests as a stem/progenitor cell–derived clonal myeloproliferation accompanied by intense marrow stromal reaction, including collagen fibrosis, osteosclerosis, and angiogenesis. The US prevalence of MF has been estimated to be 4 to 6 individuals per 100,000 population.[13] The annual incidence of MF ranges from 0.1 to 1 per 100,000.[12,128]

Pathophysiology

Fibrogenesis and angiogenesis have long been thought to develop consequent to the release of growth-promoting factors (such as vascular endothelial growth factor, platelet-derived growth factor [PDGF], basic fibroblast growth factor, and transforming growth factor β) from proliferating atypical megakaryocytes in the BM.[129] More recently, however, fibrocytes, the fibrosis-driving cells in the BM of persons with PMF, have been shown to be clonal (neoplastic) and derived from blood monocytes.[130,131] The *JAK2* V617F mutation is found in 50% to 60% of patients with PMF. Persistent JAK-STAT signaling, resulting in the overproduction of proinflammatory cytokines, has been observed in all patients with PMF, regardless of driver mutation status.[132,133] Proinflammatory cytokines have been associated with many of the symptoms of MF, as well as splenomegaly, transfusion dependence, thrombocytopenia, and shortened survival.[134] Mutations in the thrombopoietin receptor (MPL) are found in 5% to 10% of patients, and *CALR* mutations are found in an additional 25%.[9,10] Approximately 10% of patients are "triple negative" (discussed previously in this chapter). Rare inactivating mutations in negative regulators of JAK-STAT signaling (eg, *LNK*, *SOCS*, and *CBL*) also contribute to the dysregulated JAK-STAT signaling in PMF.[135]

As in ET, disease phenotype appears to differ by driver mutation. In a study of 617 patients with PMF, those with *CALR* mutations had a lower risk of developing anemia, thrombocytopenia, and leukocytosis.[136] In another series of 428 patients with PMF, *CALR* mutations were associated with younger age, lower leukocyte count, and higher platelet count, whereas *MPL* W515K/L mutations were associated with younger age and lower leukocyte count when compared with *JAK2* V617F mutations.[16] A number of other mutations have also been found in PMF, albeit at much lower frequencies than *JAK2* and *CALR* mutations (eg, mutations in *ASXL1*, *EZH2*, *SRSF2*, *CBL*, *IDH1/IDH2*, *TP53*, *TET2*, and *DNMT3A*).[135] These "nondriver" mutations can be extremely helpful in establishing the clonal nature of the disease in triple-negative cases.

Clinical Features

PMF is a heterogeneous disorder with variable age of onset, presenting features, phenotypic manifestations, and prognosis. The incidence of PMF increases with age. In a series of 1054 patients, the median age at diagnosis was 64 years; 17% of patients were younger than 50 years and 5% were younger than 40 years.[137] Clinical presentation can range from no or minimal symptoms, where disease is discovered during a workup for leukocytosis or splenomegaly, to severe symptoms and poor QOL. Severe fatigue is the most common presenting symptom. Constitutional symptoms (fatigue, weight loss, pruritus, low-grade fever, night sweats) are a prominent feature of PMF and can be debilitating. In an internet-based survey of 456 patients with MF, 84% reported fatigue, 50% itching, 56% night sweats, and 47% bone pain.[22] Myeloproliferation is one of the major features of the disease and can lead to sequestration of immature cells and production of blood cells in sites other than the BM, a phenomenon known as extramedullary hematopoiesis (EMH). This commonly manifests as marked hepatosplenomegaly, with associated pain, early satiety, portal hypertension, anemia, and thrombocytopenia. Splenomegaly is present in 80% of the patients and may extend into the pelvis. Hepatomegaly is seen in 40% to 70% of patients. EMH might cause symptoms in various other organs, leading to respiratory distress, pulmonary hypertension, ascites, pericardial tamponade, cord compression, and paralysis. Teardrop red cells and a leukoerythroblastic picture (presence of immature myeloid cells including blasts in the peripheral blood) are characteristic of MF. Anemia is present in about one third of patients at diagnosis and eventually develops in all patients, many of whom require transfusion.[138] Some patients may present with leukocytosis and thrombocytosis; however, leukopenia and thrombocytopenia develops in later stages of the disease in most patients. Among the most feared complications of PMF is transformation to AML, with an actuarial probability of 20.6% in the first 100 months from diagnosis in one study.[139] The outcome after transformation is poor, with a median survival of 6 to 8 months, even with modern, targeted approaches.[140,141] Transformation to AML is the most common cause of death in MF, followed by MF progression without acute transformation, thrombosis, and cardiovascular complications, infection, bleeding, and portal hypertension.

As discussed previously, prefibrotic PMF is now a separate entity from overt PMF in the 2016 WHO classification.[11] The vast majority of patients now considered to have pre-PMF would previously have been categorized as having ET. Compared with ET, pre-PMF is characterized by significantly worse survival and higher rates of progression to overt MF (12.3% at 10 years and 16.9% at 15 years) and transformation to AML (5.8% at 10 years and 11.7% at 15 years).[93] Thrombotic risk is similar, and the IPSET-thrombosis model for ET has been found to accurately risk stratify patients with pre-PMF.[142] Bleeding risk is higher in pre-PMF than in ET. Compared with patients with overt PMF, patients with pre-PMF have lower rates of cytopenias, lower blast counts, fewer symptoms, and are less likely to exhibit large splenomegaly or unfavorable karyotypes.[143] The distribution of driver mutations is similar, but patients with overt PMF are enriched for "high molecular risk (HMR)" nondriver mutations (discussed below) and are more likely to be in higher

Table 6–10 2016 WHO Criteria for Diagnosis of Prefibrotic and Overt Primary Myelofibrosis (PMF)

Major Criteria
1. Megakaryocyte proliferation and atypia: a. without reticulin fibrosis >grade 1, accompanied by increased age-adjusted BM cellularity, granulocytic proliferation, and often decreased erythropoiesis (pre-PMF); b. accompanied by either reticulin and/or collagen fibrosis grades 2 or 3 (overt PMF)
2. Not meeting WHO criteria for PV, ET, *BCR-ABL1*$^+$ CML, MDS, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR*, or *MPL* mutation or in the absence of these mutations, presence of another clonal marker[a], or absence of (minor, in the case of pre-PMF) reactive bone marrow reticulin fibrosis[b]
Minor Criteria: Presence of At Least One of the Following, Confirmed on Two Consecutive Determinations
1. Leukocytosis ≥11 × 10^9/L
2. Serum lactate dehydrogenase level above upper limit of normal
3. Anemia not attributed to a comorbid condition
4. Palpable splenomegaly
5. Leukoerythroblastosis (this criterion is only applicable to overt PMF and is absent from the minor criteria for pre-PMF)
Diagnosis of PMF, whether overt or prefibrotic, requires meeting all three major criteria and at least one minor criterion.

[a]In the absence of any of the 3 major clonal mutations, the search for the most frequent accompanying mutations (eg, *ASXL1*, *EZH2*, *TET2*, *IDH1/2*, *SRSF2*, *SF3B1*) are of help in determining the clonal nature of the disease.
[b]BM fibrosis secondary to infection, autoimmune disorder, or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.
Reproduced with permission from Arber DA, Orazi A, Hasserjian R, et al: The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia, *Blood* 2016 May 19;127(20):2391-2405.

International Prognostic Scoring System (IPSS) risk categories. Median survival was 7.2 years for overt PMF and 17.6 years for pre-PMF in one large study.[143]

Diagnosis

The 2016 WHO criteria for diagnosis of both overt and prefibrotic PMF are listed in Table 6–10. Marrow fibrosis by itself is not specific for a diagnosis of PMF. Various degrees of fibrosis are observed in other MPNs, and MDS with fibrosis must be excluded. Morphologic features of the BM during the prefibrotic (cellular) phase of PMF are shown in Fig. 6–6, and those during the fibrotic phase are depicted in Figs. 6–7 to 6–9. Classical morphologic features consistent with PMF and seen in the peripheral blood smear are displayed in Fig. 6–10. BM histology, especially megakaryocyte morphology, is a critical diagnostic criterion for PMF. All patients suspected of having PMF should undergo BM biopsy with reticulin and collagen staining and molecular testing, first for *JAK2* V617F and then for *CALR* and *MPL* mutations. Myeloid mutation panels can support the diagnosis by uncovering mutations in nondriver genes in triple-negative cases. Diagnostic criteria for post-PV and post-ET MF appear in Table 6–11.

Prognosis

Survival in PMF is much shorter than in ET or PV; median OS was reported to be 6.5 years in a cohort of 368 patients diagnosed in four European countries between 1996 and 2007.[144] Median OS was 5.9 years in another cohort of 267 patients with PMF seen at the Mayo Clinic.[16] Over the years, many studies have

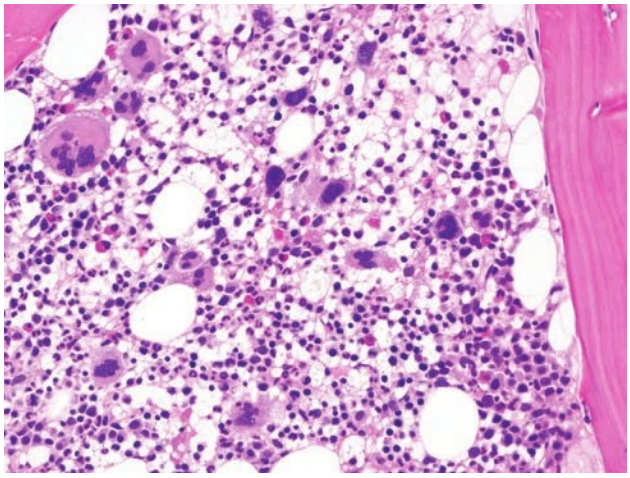

FIGURE 6–6 It is difficult to distinguish the prefibrotic phase of PMF from other types of chronic myeloproliferative neoplasms based on morphologic criteria alone. However, careful microscopic examination of the bone marrow biopsy usually reveals scattered atypical megakaryocytes with morphologic criteria classical for PMF in the fibrotic phase. As shown, some of the megakaryocytes in this bone marrow biopsy are remarkably variable in size and shape and characteristically contain markedly hyperchromatic nuclei (×200).

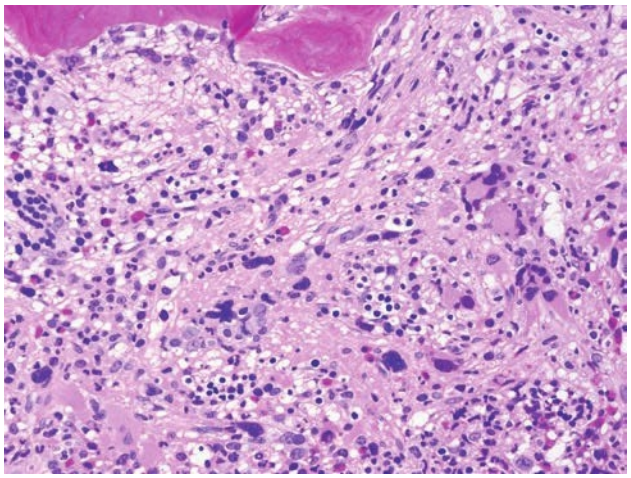

FIGURE 6–7 During the fibrotic phase of PMF, bone marrow hematopoietic cellular elements tend to decrease in number with interstitial infiltration of the bone marrow by fibroblasts, which leads to a streaming effect. Characteristically, the megakaryocytes demonstrate variability in size and shape, and megakaryocytes containing hyperchromatic and hyperlobulated nuclei are frequently encountered during the fibrotic phase of PMF (×200).

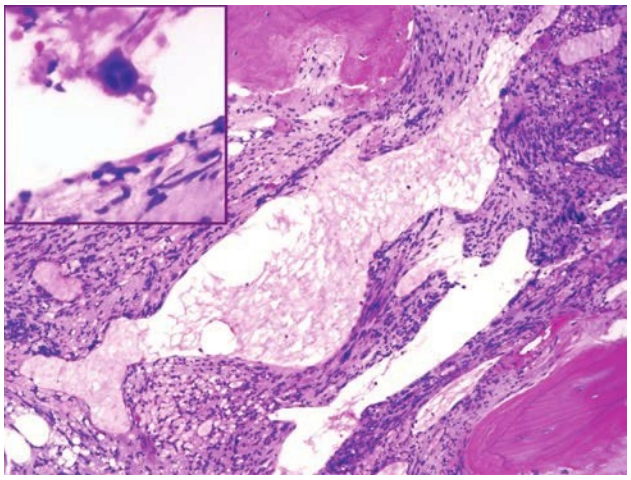

FIGURE 6–8 During the fibrotic phase, another common feature of the bone marrow is marked expansion of bone marrow sinusoids, which are usually rudimentary under normal conditions (×100). Hematopoietic cellular elements can be detected within the bone marrow sinuses; a megakaryocyte is shown, comprising what is known as intrasinusoidal hematopoiesis (inset, ×400).

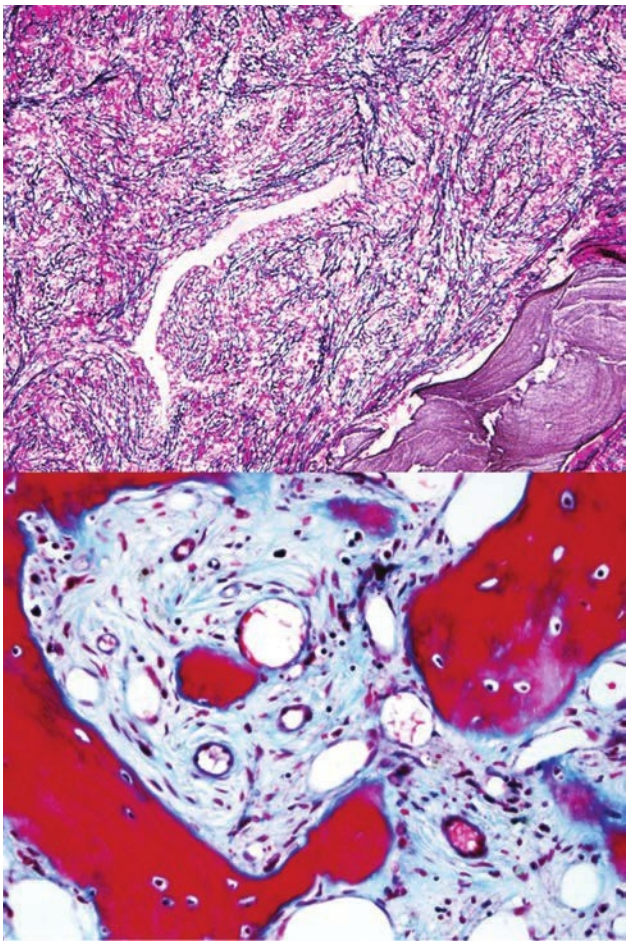

FIGURE 6–9 During the fibrotic phase of PMF, the bone marrow is characterized by increased interstitial reticulin fibrosis (upper panel, ×100), which might be associated with the abnormal presence of collagen fibers that are detected by trichrome staining (lower panel, ×200).

identified a number of clinical variables as adversely affecting survival.[145] These efforts culminated in the development of the IPSS in 2009, which uses five readily available pieces of information at the time of diagnosis—age, Hgb, WBC count, circulating blasts, and constitutional symptoms—to separate patients into four prognostic categories: low, intermediate-1, intermediate-2, and high risk.[137] The Dynamic IPSS (DIPSS), published in 2010, refined the IPSS by assigning two points, rather than one, to anemia (Hgb <10 g/dL), based on a higher hazard ratio for death, and was found to prognosticate patients accurately at any point in their disease course, not just at diagnosis.[146] The DIPSS was also shown to predict leukemic transformation.[147] Cytogenetic abnormalities associated with an unfavorable prognosis in PMF include complex karyotype, and a single or two of the following abnormalities: +8, i(17q), -7/7q-, -5/5q-, 12p-, inv(3), and 11q23 rearrangement.[148] A "very-high-risk" karyotype (single/multiple abnormalities of -7, i(17q), inv(3)/3q21,12p-/12p11.2,11q-/11q23, or other autosomal trisomies not including +8/+9 [eg, +21, +19]) has also been recently recognized.[149] The DIPSS-plus model adds a point each for thrombocytopenia (platelets <100,000/μL), RBC transfusion need, and unfavorable karyotype to the DIPSS score and can also be used at any time point in the patient's disease course.[150] These models are

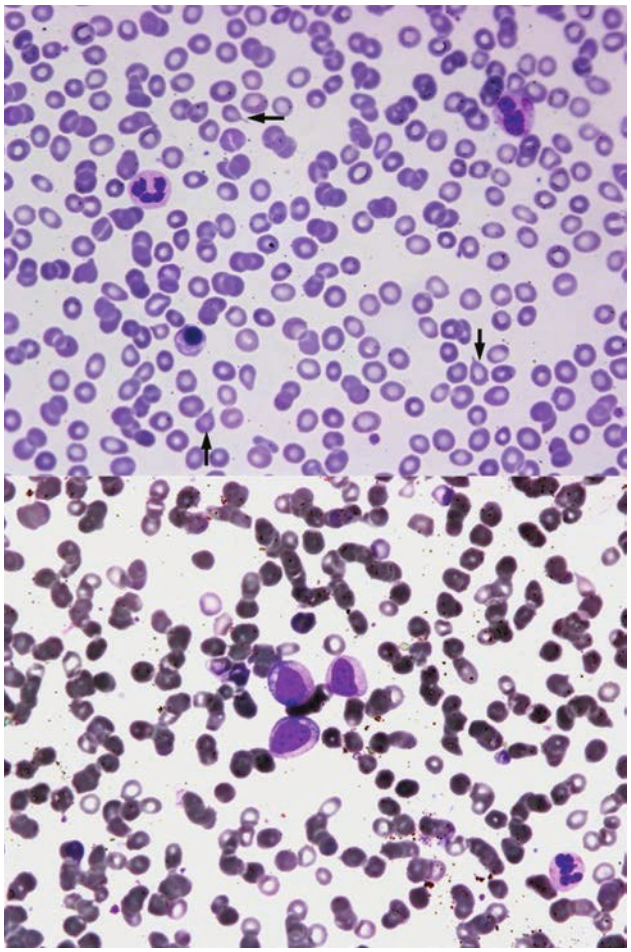

FIGURE 6–10 Careful examination of peripheral blood smears from patients with PMF usually reveals teardrop red blood cells (*arrows*, upper panel; ×400). In addition, nucleated red blood cells (upper panel) and left-shifted granulopoiesis (lower panel; ×400) are seen, two morphologic criteria collectively described as leukoerythroblastosis.

summarized in Table 6–12. Of note, all these models were developed for overt PMF, although the IPSS has been shown to effectively risk stratify patients with pre-PMF.[143] Growing recognition that these models do not work well for patients with post-PV/ET MF[151–153] led to the development of the MYSEC-PM, discussed further below.

Recent studies have explored the prognostic relevance of various mutations. In a study of 617 patients with PMF, *CALR* mutations were associated with longer survival (median, 17.7 years).[136] Patients with triple-negative PMF had a higher incidence of transformation to AML and a shorter survival (median, 3.2 years). Another study of 253 patients with PMF reported similar findings.[154] Patients with *CALR* mutations had the longest survival (median, 8.2 years), whereas patients without any of these mutations (triple negative) had the shortest survival (median, 2.5 years). Triple-negative patients also displayed inferior LFS. However, unlike in ET, the favorable prognostic impact of *CALR* mutations in PMF appears to be restricted to the much more common type 1/type 1–like mutations.[155–157] In 2013, in a seminal paper, Vannucchi and colleagues identified several nondriver mutations as being associated with worse OS and LFS in a cohort of 879 patients with PMF—these were termed HMR (high molecular risk) mutations and included *ASXL1*, *SRSF2*, *IDH1*, *IDH2*, and *EZH2*, although only *ASXL1* mutation status provided additional prognostic information beyond the IPSS or DIPSS-plus.[135] This group went on to show that the presence of two or more HMR mutations further reduced survival (median OS, 2.6 years for ≥2 mutations, 7 years for one, and 12.3 years for none).[158] Much more recently, the *U2AF1* Q157 mutation has been added to the list of prognostically unfavorable mutations in PMF.[159] This wealth of

Table 6–11 Diagnostic Criteria for Post-Polycythemia Vera/Essential Thrombocythemia Myelofibrosis[102]

Required Criteria
1. Documentation of a previous diagnosis of PV or ET as defined by the WHO criteria
2. Bone marrow fibrosis grade 2–3 (on a 0–3 scale) or grade 3–4 (on a 0–4 scale)
Additional Criteria (2 Required)
1. A leucoerythroblastic blood picture
2. Increasing splenomegaly defined as either an increase in palpable splenomegaly of ≥5 cm (distance of the tip of the spleen from the left costal margin) or the appearance of a newly palpable splenomegaly
3. Development of ≥1 of 3 constitutional symptoms: >10% weight loss in 6 months, night sweats, unexplained fever (>37.5 °C)
4. Anemia or sustained loss of requirement of either phlebotomy (in the absence of cytoreductive therapy) or cytoreductive treatment for erythrocytosis (for post-PV MF); Anemia and a ≥2 g/dL decrease from baseline Hgb level (for post-ET MF)
5. Increased serum LDH (for post-ET MF only)

Table 6–12 The IPSS, DIPSS, and DIPSS-plus Prognostic Models for Primary Myelofibrosis[137,146,150]

Factors	IPSS	DIPSS	DIPSS-plus
Age >65 years	1	1	Calculate DIPSS first[a]
Constitutional symptoms	1	1	Calculate DIPSS first[a]
Hemoglobin <10 g/dL	1	2	Calculate DIPSS first[a]
Leukocytes >25 × 10^9/L	1	1	Calculate DIPSS first[a]
Circulating blasts ≥1%	1	1	Calculate DIPSS first[a]
Platelet count <100 × 10^9/L			1
RBC transfusion need			1
Unfavorable karyotype			1
Risk stratification (Median Survival)			
Low	0 points (11.25 y)	0 points (not reached)	0 points (15.4 y)
Intermediate-1	1 point (7.9 y)	1–2 points (14.2 y)	1 point (6.5 y)
Intermediate-2	2 points (4 y)	3–4 points (4 y)	2–3 points (2.9 y)
High	3–5 points (2.25 y)	5–6 points (1.5 y)	4–6 points (1.3 y)

[a]To arrive at the DIPSS-plus score, calculate the DIPSS score first. Assign 0 points for DIPSS low risk, 1 point for DIPSS intermediate-1 risk, 2 points for DIPSS intermediate-2 risk, and 3 points for DIPSS high risk. Then add 1 point each for RBC transfusion need, platelets <100,000/μL, and unfavorable karyotype.
RBC, red blood cell.

genetic information that has become available in the last few years has since been integrated into a number of newer prognostic models for patients with PMF.[160] These include the mutation-enhanced IPSS and mutation-enhanced IPSS-plus for transplantation-age (≤70 years) patients with PMF (MIPSS70/MIPSS70-plus).[161] Compared with the MIPSS70, the MIPSS70-plus adds karyotypic information (unfavorable vs favorable), but omits BM fibrosis grade, leukocytosis and thrombocytopenia as prognostic variables, and classifies patients into four prognostic categories (the MIPSS70 model has 3 prognostic categories: low, intermediate, and high). There is also a version 2.0 of the MIPSS70-plus, which incorporates *U2AF1* Q157 status, very-high-risk karyotype, and sex- and severity-adjusted Hgb thresholds into the MIPSS70-plus to further enhance its power to discriminate between prognostic categories, of which there are five in this model.[162] Both the MIPSS70 and the MIPSS70-plus version 2.0 scores can readily be calculated in the clinic at http://mipss70score.it. Finally, the genetically inspired prognostic scoring system, distinguished by its reliance on genomic information alone for prognostication, is not widely used.[163]

Although managed similarly and characterized by the same general clinical features and complications, the underlying biology of post-PV and post-ET MF differs fundamentally from that of PMF. Passamonti and colleagues studied 685 molecularly annotated patients with post-PV/ET MF to develop a prognostic model, the MYSEC-PM, specifically for this population.[36] Median OS for the entire cohort was 9.3 years (8.1 years for post-PV MF and 14.5 years for post-ET MF). The model, which places a heavy emphasis on patient age, also allocates points for anemia (Hgb <11 g/dL), thrombocytopenia (platelets <150 × 10^9/L), circulating blasts (≥3%), driver mutation status (*CALR* wild type), and constitutional symptoms to assign patients to one of four prognostic categories: low, intermediate-1, intermediate-2, and high. The score can be calculated at www.mysec-pm.eu. The superiority of the MYSEC-PM over the IPSS for prognostication in patients with post-PV/ET MF has been independently validated.[164] Among patients with post-ET MF, the MYSEC study documented superior survival for *CALR*-mutated patients compared with *JAK2*-mutated patients, with no differences observed between type 1/-like and type 2/-like *CALR* mutations in terms of clinical presentation or outcome (in contrast to PMF); thrombosis incidence did not differ by driver mutation status, unlike in ET.[165]

Treatment

Before the approval by the FDA of the JAK1/2 inhibitor ruxolitinib in 2011, treatment of MF was largely unsatisfactory. Cytoreductive drugs such as HU or cladribine were used to control hyperproliferation, although their effects are transient and rarely result in complete spleen regression. Oral alkylating agents have also been used, but often induce severe myelosuppression and are associated with an increased risk of transformation to AML. Corticosteroids, erythroid-stimulating agents (ESAs), immunomodulatory drugs (IMiDs), and androgens have proven helpful in the treatment of anemia. Patients with low endogenous

serum Epo (<125 U/L) can benefit from ESAs; response rates range from 23% to 60% and median duration of response is about one year.[166] Oral danazol (200 mg 2 or 3 times daily) can be useful for both anemia (30% ORR) and thrombocytopenia.[167] Prostate cancer should be ruled out before starting danazol, and liver enzymes should be monitored in patients taking it. IMiDs (low-dose thalidomide and lenalidomide) have anticytokine and antiangiogenic effects and have been shown to reduce splenomegaly and improve anemia (in 20%–30% of patients).[166] They are usually used with tapering doses of prednisone for three months. Pomalidomide showed significant promise in a phase 2 study,[168] but failed to improve rates of transfusion independence in a phase 3 study.[169] Low-dose thalidomide (50 mg/d) may be particularly useful to treat thrombocytopenia.[170–172] Interferon-α has been used with some success, but significant toxicity prevents its use in many patients. It may slow disease progression in patients with early MF, as well as reverse BM fibrosis in some patients.[173] If used, IFN-α should be prescribed early in the disease because patients with HMR mutations tend not to respond well.[174] Splenectomy is used only rarely in the JAK inhibitor era. When performed, it should be performed in carefully selected patients, because perioperative morbidity and mortality can be substantial.[175] Splenic irradiation is effective for palliating splenomegaly, but its benefits are transient and it can result in prolonged and profound cytopenias and make subsequent splenectomy more difficult.[176]

JAK Inhibitors

Two pivotal phase 3 randomized trials provided evidence for the regulatory approval of the oral JAK1/2 inhibitor ruxolitinib. The COMFORT-I trial randomly assigned patients to receive ruxolitinib (n = 155) or placebo (n = 154),[177] whereas the COMFORT-II trial compared ruxolitinib (n = 146) with BAT (n = 73).[178] Patients in both trials had to have baseline platelets ≥100 × 10^9/L and IPSS intermediate-2/high-risk disease. Significantly more patients in the ruxolitinib arms had 35% or higher SVR (roughly approximating ≥50% reduction in spleen size by palpation) from baseline at week 24 (COMFORT-I) or week 48 (COMFORT-II). Both studies showed significant improvements in MF-related symptoms and QOL in patients treated with ruxolitinib. Thrombocytopenia and anemia were the most common toxicities associated with ruxolitinib therapy. These were most pronounced in the first 3 to 6 months of treatment and were managed with dose reductions or transfusions. Headaches, dizziness, and bruising are the most common nonhematologic adverse effects of ruxolitinib.

Long-term follow-up analyses have demonstrated that the effects of ruxolitinib are durable.[179,180] Response rates improved over time, although the median duration of spleen response was about 3 years. No new toxicity concerns emerged. Importantly, ruxolitinib improved survival, reducing the risk of death by 30% in a pooled analysis of 5-year data from both COMFORT trials (median OS, 5.3 vs 3.8 years).[181] Spleen responses to ruxolitinib are dose-dependent and correlate with survival.[182,183] Furthermore, anemia caused by ruxolitinib does not carry the adverse prognosis of disease-associated anemia, and ruxolitinib overcomes the negative prognostic impact of the latter.[184,185] For these reasons, we attempt to optimize ruxolitinib dosing whenever possible and manage the anemia with transfusions, ESAs, danazol, IMiDs, etc. However, although the ruxolitinib prescribing information suggests initial dosing based on the platelet count, an alternative dosing strategy of 10 mg twice daily for the first 12 weeks before escalating in anemic patients is also reasonable.[186,187] Although the recommended starting dose for patients with 50–99 × 10^9/L platelets is 5 mg twice daily, studies support using the more effective 10 mg twice daily dose in this population.[188,189] Patients taking ruxolitinib should be vaccinated against shingles and be monitored regularly for weight gain and hyperlipidemia. Although the US approval of ruxolitinib is restricted to patients with intermediate- and high-risk disease, NCCN guidelines support its use in symptomatic low-risk patients when required.[190] There is no guidance for or published experience with the use of ruxolitinib in patients with platelets <50 × 10^9/L.

The JAK2 inhibitor fedratinib was approved by the FDA for patients with intermediate-2/high-risk MF in August 2019. In the placebo-controlled JAKARTA trial, fedratinib produced rates of 35% or greater SVR and 50% or higher TSS improvement at week 24, which were significantly superior to those observed with placebo and similar to those seen with ruxolitinib in the COMFORT trials.[191] Apart from anemia and thrombocytopenia (expected from inhibition of JAK2), fedratinib was also associated with a relatively high incidence of gastrointestinal side effects, likely because of its inhibition of fms-like tyrosine kinase 3 (FLT3). JAKARTA enrolled patients with baseline platelets ≥50 × 10^9/L, and while the numbers were small, there were no significant differences in response rates between the ≥50–99 × 10^9/L and ≥100 × 10^9/L platelet groups.[192] Fedratinib dosing is not based on platelet count. Development of fedratinib had been halted owing to concerns over Wernicke encephalopathy but was recently resumed given that this complication is very rare and of uncertain relationship to fedratinib[193]; however, thiamine levels must be checked before fedratinib initiation, repleted if low, and monitored during therapy. In the setting of ruxolitinib failure, fedratinib yielded a 35% or higher SVR rate of 30% and a 50% or higher TSS reduction rate of 27% at 24 weeks in a

relatively small trial (JAKARTA-2),[194] and is being studied further in the FREEDOM trials (NCT03755518, NCT03952039).

Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplant (alloSCT) is potentially curative in MF; however, few patients undergo alloSCT because of older age or severe comorbidities. Reduced-intensity conditioning regimens are an option in older patients and those with comorbidities.[195] In general, patients in a risk category with a predicted median OS of fewer than 5 years should be considered for alloSCT.[47] Indeed, the primary goal of prognostication in MF is to inform selection of patients for alloSCT. This typically includes patients younger than 70 years with intermediate-2 or high-risk disease by the IPSS, DIPSS, or DIPSS-plus.[196] AlloSCT should also be considered in patients younger than 65 years who have intermediate-1–risk disease but have refractory, transfusion-dependent anemia, more than 2% circulating blasts, adverse cytogenetics (as defined in the DIPSS-plus model), are triple negative for driver mutations, or have *ASXL1* mutations. Our practice is to transplant patients at best response to ruxolitinib. Consensus recommendations are to initiate ruxolitinib at least two months before transplant and optimize the dose for best spleen response.[196] Ruxolitinib should then be tapered over 5 to 7 days to avoid a "flare" and stopped the day before conditioning. The recently published myelofibrosis transplant scoring system incorporates a number of clinical and genomic pretransplant variables (age, performance status, platelet count, leukocyte count, donor type, driver mutation, and *ASXL1* status) to predict outcomes after alloSCT.[197]

Combination and Novel Therapies

Momelotinib, a JAK1/2 inhibitor that can improve anemia, and pacritinib, a JAK2/FLT3 inhibitor that is relatively nonmyelosuppressive, are active agents that are reentering phase 3 pivotal studies with new end points and eligibility criteria (NCT04173494, NCT03165734) after previous phase 3 trials showed mixed results.[198–201] Regulatory approval of these agents would fulfill important unmet needs in the JAK inhibitor space. The activin receptor ligand trap luspatercept has shown promise for the treatment of anemia, both as a single agent and in combination with ruxolitinib.[202] Imetelstat, a telomerase inhibitor, has demonstrated an intriguing apparent OS benefit in the "ruxolitinib failure" setting.[203] A phase 3 trial of this agent and one of the antifibrotic drug PRM-151[204] are planned. Many other novel agents are being studied in the ruxolitinib failure and/or suboptimal response settings.[205] Encouraging results have been reported with some laboratory-based synergistic combinations, eg, those with the BH3-mimetic navitoclax[206] and the bromodomain inhibitor CPI-0610[207]; these combinations are moving into phase 3 trials in the JAK inhibitor–naïve setting.

Treatment Conclusions

Patients with MF should first be assigned to a risk category using one of the standard prognostic models. For patients with low-risk disease, a watch-and-wait approach is acceptable, although ruxolitinib may be needed for symptom control. Patients in the intermediate- and high-risk groups should be treated based on their clinical needs, eg, anemia, splenomegaly, symptoms, EMH, and increased blasts. For younger patients in the intermediate-2 and high-risk categories and select intermediate-1 risk patients, alloSCT should be offered. Patients who are not eligible for alloSCT and are intolerant of, have a suboptimal response, or lose their response to JAK inhibitors should be offered enrollment in clinical trials. Ruxolitinib and fedratinib have been effective in reducing splenomegaly, in improving symptoms and QOL, and, in the case of ruxolitinib, prolonging survival in patients with MF. JAK inhibitors have not been shown to eradicate the mutant clone, and patients lose their response to therapy over time. Results from ongoing trials of new targeted agents and rational combinations are eagerly awaited.

CHRONIC EOSINOPHILIC DISORDERS: HYPEREOSINOPHILIC SYNDROME/CHRONIC EOSINOPHILIC LEUKEMIA

Chronic eosinophilic disorders (further referred to as hypereosinophilic syndromes/chronic eosinophilic leukemia [HES/CEL]) are a heterogeneous group of rare disorders characterized by chronic eosinophil overproduction (an absolute eosinophil count [AEC] in peripheral blood >1.5 × 10^9/L) and eosinophilic tissue infiltration with possible end-organ damage. Although the largest portion of these disorders represent primary BM diseases classified as myeloid/lymphoid neoplasms with eosinophilia (MLN-Eo), clinical presentation is mostly driven by the presence of eosinophils irrespective of the underlying cause. HES/CEL can be clinically subdivided into six variants: 1. myeloproliferative, 2. lymphoproliferative, 3. overlap, 4. associated, 5. familial, and 6. Idiopathic.[208] The first 2 categories represent primary MLN-Eo diagnoses. The classification, as revised by the 2016 WHO criteria, is shown in Table 6–1. Hypereosinophilia >1.5

$\times 10^9$/L for more than 6 months, absence of obvious reactive and clonal causes, and evidence of end-organ damage define HES. Idiopathic hypereosinophilia is the preferred diagnosis when end-organ damage is absent. Patients found to have clonal disease (ie, a cytogenetic or molecular abnormality proving the existence of a malignant clone), or peripheral blood blasts 2% or higher, or BM blasts 5% or higher (but both <20%) have chronic eosinophilic leukemia, not otherwise specified (CEL, NOS).[11] Per WHO 2016, the major category of MLN-Eo represents myeloid/lymphoid neoplasm with eosinophilia and rearrangement of *PDGFRα*, *PDGFRβ*, *FGFR1*, and provisional entity of *PCM1-JAK2* (Table 6–1 and Tables 6–13 to 6–18). The identification of the clonal marker, fused *FIP1L1* gene to the *PDGFRα* gene located on 4q12 chromosome in 2003 by Cools et al,[209] led to recognition of other causes of primary eosinophilic disorders driven by constitutively active TKs: genes encoding *PDGFRβ* (chromosome 5q31–q33; >30 gene fusion partners [Table 6–14]),[210,211] fibroblast growth factor receptor 1 (*FGFR1*, chromosome 8p11; ~15 gene fusion partners[212] (Table 6–16); and recently, provisionally added Janus kinase 2 gene, *JAK2* (chromosome 9p24; mostly *PCM1-JAK2* fusion).[11] Some patients, including those with the above classified HES/CEL, may exhibit expansion of cytokine-producing, immunophenotypically aberrant T cells, leading to clonal as well as reactive hypereosinophilia (abnormal overstimulation of eosinophilopoietic growth factors), and might be classified as a lymphoproliferative variant.

HES/CEL are more common in men than women, and patients are usually younger (20–50 years old). The clinical presentation varies; patients might have minimal nonspecific symptoms (such as fatigue, myalgias, low-grade fever), "allergic" symptoms (urticaria, pruritus, angioedema, erythematous papules, cough with pulmonary infiltrates), or serious organ involvement (acute heart failure, mural thrombi, cardiomyopathy, polyneuropathies, optic neuritis).[213] Despite the fact that the skin, lungs, and gastrointestinal tract are the most commonly affected organs, congestive heart failure represents a prototypical illustration of eosinophil-mediated tissue injury.[214]

Diagnosis

The initial step in diagnosis of HES/CEL is to rule out secondary, or reactive, causes of eosinophilia such as infections (especially parasitic), atopy, drug reactions, connective tissue disorders, or vasculitis. Assessment of organ involvement should always be performed as

Table 6–13 Diagnostic Criteria for Chronic Eosinophilic Leukemia, NOS

• Eosinophilia (eosinophil count ≥1.5 × 10^9/L)
• WHO criteria for *BCR-ABL1*–positive chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, primary myelofibrosis, chromic neutrophilic leukemia, chronic myelomonocytic leukemia, and *BCR-ABL1*–negative atypical chronic myeloid leukemia are not met
• No rearrangement of *PDGFRα, PDGFRβ*, or *FGFR1*, and no *PCM1-JAK2, ETV6-JAK2*, or *BCR-JAK2* fusion
• Blast cells constitute <20% of the cells in the peripheral blood and bone marrow, and inv(16)(p13.1q22), t(16;16)(p13.1;q22), t(8;21)(q22;q22.1), and other diagnostic features of acute myeloid leukemia are absent
• There is a clonal cytogenetic or molecular genetic abnormality or blast cells account for ≥2% of cells in the peripheral blood or ≥5% in the bone marrow

mutation are different. Figures 6–11 and 6–12 illustrate the morphologic findings in HES/CEL. The frequency of the *FIP1L1-PDGFRα* rearrangement in patients with hypereosinophilia has been reported between 3% and 88%,[209,215] with the largest series (741 and 376 patients, respectively) showing more realistic percentages of 3%[216] and 11%.[216] Absence of *FIP1L1-PDGFRα* fusion should prompt evaluation for other clonal disorders, including rearrangements of *PDGFRβ* (5q31–q33), *FGFR1* (8p11), and fusion of *PMC1-JAK2*. Additional workup with genetic molecular sequencing, cytogenetic analysis, T-cell immunophenotyping, and T-cell receptor gene rearrangement might reveal other clonal–not otherwise classified abnormalities, further deciphering HES/CEL diagnoses.

A diagnostic and therapeutic algorithm of a patient with suspected primary eosinophilia is summarized in Fig. 6–13.

Treatment

Clinical presentation and its acuity direct initial treatment in patients with HES/CEL. For asymptomatic patients with no organ damage and normal troponin levels, no active therapy is recommended, and these patients should be followed closely. There is no official

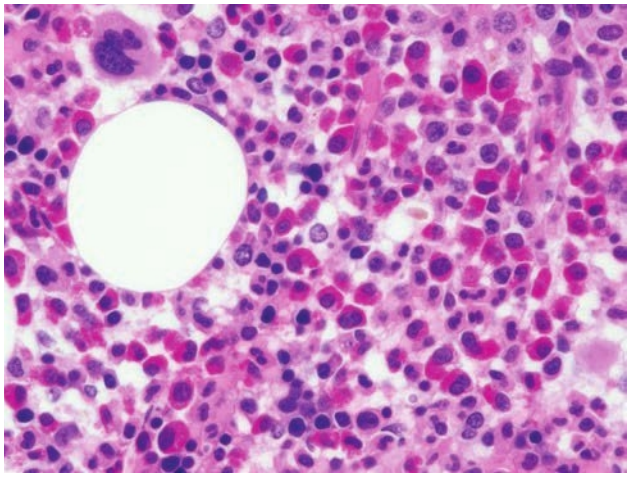

FIGURE 6–11 In CEL/HES, the bone marrow typically shows increased cellularity with striking interstitial infiltration by eosinophils (×400).

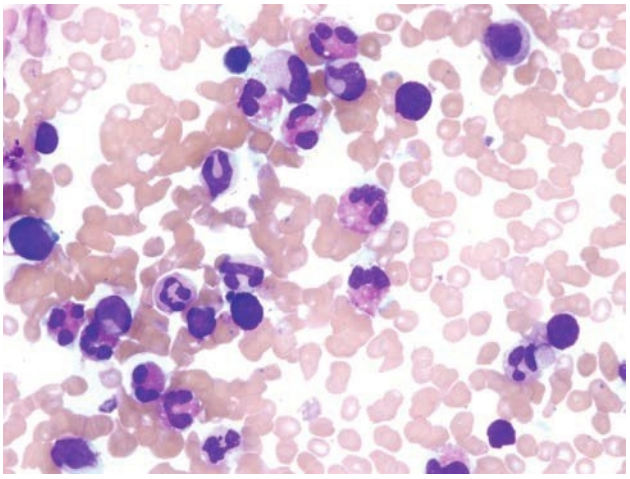

FIGURE 6–12 Markedly increased, morphologically unremarkable eosinophils are typically detected in the bone marrow aspirate smears from patients with CEL/HES (×400).

consensus to recommend therapy solely based on the degree of hypereosinophilia, but AEC 1.5–2 × 10^9/L is generally accepted as a treatment threshold. The exceptions are patients with imatinib-sensitive *PDFGRA/B* rearrangement, who should be treated even in the absence of organ dysfunction to decrease the risk of end-organ damage. For the remaining patients with symptomatic disease or evidence of end-organ damage, therapy for HES generally entails the use of corticosteroids, IFN-α, or cytoreductive agents such as HU, vincristine, or cyclosporine. Glucocorticosteroids (usually prednisone at starting dose of 1 mg/kg/day) are the first line for the treatment of most forms of HES/CEL, and also remain the initial therapy of choice for patients who show life-threatening manifestations. ORR to first-line prednisone is about 70% to 80%,[214] but relapses often occur with cessation of therapy. In patients with possible exposure to *Strongyloides stercoralis,* empiric ivermectin therapy (200 μg/kg orally × 2 days) should be given concomitantly with steroids to prevent potentially fatal steroid-induced hyperinfection syndrome and disseminated disease.[217] Second-line options after steroids include IFN-α, HU, cyclosporin, or low-dose methotrexate. Other agents, such as vincristine, cyclophosphamide, cladribine, or cytarabine, are mostly useful for acute reductions when the total eosinophil count is very high (≥50 × 10^9/L).[214,218–222]

Patients with known imatinib-sensitive mutations, including *FIP1L1-PDGFRα* and *PDGFRβ* involvement (chromosomal translocations of 5q31–q33), should receive imatinib mesylate as a first therapy at a starting dose of 100 mg daily with the possibility to increase to 400 mg daily. Imatinib is also approved as therapy for patients with HES/CEL, whose *FIP1L1-PDGFRα* status is negative or unknown, at a recommended dose of 400 mg daily. The response to imatinib in *FIP1L1-PDGFRα*–negative patients is limited, and it might represent a second-line treatment for refractory patients, unless they have typical clinical presentation (male gender, splenomegaly, elevated tryptase, and typical marrow features) where frontline imatinib shall be considered. Imatinib mesylate, a highly potent tyrosine kinase inhibitor against ABL, PDGFR, and KIT protein kinases, could induce complete hematologic and complete molecular remission in as much as 99% and 95% of patients with *FIP1L1-PDGFRα* and HES, respectively.[211,223,224] Long-term follow-up studies (median duration of imatinib therapy of 6.6 years) showed that these responses are durable in the majority of patients,[225–227] but maintenance therapy is required; otherwise, relapses occur. Of note, in patients with eosinophil-mediated heart damage or even elevated troponin, it is recommended to co-initiate glucocorticoids for the first 10 days of imatinib therapy to avoid sudden heart deterioration.

Patients with *FGFR1* rearrangement usually have a very aggressive disease course with progression to acute leukemia within one to two years.[228] Until recently, high-dose chemotherapy followed by alloSCT represented the only therapeutic option, and SCT still represents the only curative tool. As of this writing,

the oral, small-molecule inhibitor of *FGFR1-3,* pemigatinib (INCB054828), showed excellent efficacy in patients with *FGFR1*-rearranged myeloid/lymphoid neoplasms in interim analysis of the currently ongoing phase 2 FIGHT-203 study (NCT03011372). Among 10 evaluable patients with *FGFR1*-rearranged myeloid/lymphoid neoplasms in whom at least one previous therapy failed, 8 (80%) achieved a major cytogenetic response (including 6 patients with complete cytogenetic response) after therapy with pemigatinib for a median of 6.9 cycles.[229,230]

For patients with HES/CEL refractory to conventional therapies, the use of monoclonal antibody therapy should be considered. So far, antibodies that have been explored include those against interleukin-5 and its receptors, mepolizumab and benralizumab; and the antibody targeting CD52 antigen expressed by eosinophils, alemtuzumab. Initial safety and efficacy of mepolizumab, a humanized antibody against interleukin-5, were shown in a randomized, double-blind, placebo-controlled phase 2 trial in 85 *PDGFRα*-negative patients with HES without life-threatening complications.[231] The primary end point (reduction of the prednisone dose to ≤10 mg/day for ≥8 consecutive weeks) was achieved in 84% of the patients receiving mepolizumab (750 mg monthly intravenously) compared with 43% of the patients in the placebo group ($P < .001$). Long-term safety and efficacy of mepolizumab were confirmed in a long-term extension study in which 78 patients received mepolizumab for a median of 251 weeks (range, 4–302): 69% were still receiving mepolizumab at the end of the study, and 62% of the patients were prednisone-free without other HES treatments for 12 weeks or more.[232] A registrational, placebo controlled, phase 3 study of mepolizumab (300 mg subcutaneously monthly) to prevent flares of HES (NCT02836496) has been recently published.[233] Eligible patients with uncontrolled HES (2 or more flares of symptoms or increased eosinophils in the previous 12 months) were randomized 1:1 to mepolizumab (n = 54) vs placebo (n = 54) for 32 weeks. The primary outcome, reduction of HES flares, was significantly lower with mepolizumab: the proportion of patients experiencing 1 or more flares was 28% with mepolizumab vs 56% with placebo, $P = 0.002$). Rate of adverse events was comparable in both arms (89% vs 87% with mepolizumab vs placebo, respectively), with the most common adverse events on mepolizumab being upper respiratory track infections and extremities pain.[233] Based on these findings, FDA has approved mepolizumab for the therapy of primary HES in patients older than 12 years who had HES for 6 months or older in September 2020. It is possible that efficacy of mepolizumab in patients with steroid-refractory HES/CEL will be lower than when it is used as a steroid-sparing agent. In a trial evaluating compassionate use of mepolizumab at multiple centers, CR was 43% versus 83% in steroid-refractory versus -sensitive disease.[234] Mepolizumab is currently available on a compassionate-use basis for patients with life-threatening HES/CEL in whom other therapies failed.

Monoclonal antibody against interleukin-5 receptor, benralizumab, which is currently approved for adults with severe eosinophilic asthma, has been evaluated in a double-blind, placebo-controlled, randomized phase 2 study in 20 patients with *PDFRA*-negative HES.[235] The primary end point was a reduction of 50% or higher AEC by week 12, and it was met in 9 of 10 patients who received benralizumab vs 3 of 10 patients receiving placebo ($P = .02$). Clinical and hematologic responses with benralizumab were sustained for 48 weeks in 14 of 19 patients (74%) during the open-label phase, with a median duration of 84 weeks. Adverse events, mostly headache and elevated lactate dehydrogenase, did not limit therapy. Patients with lymphoid variant HES and those with *JAK2* mutation lacked any response to benralizumab.

Alemtuzumab is another monoclonal antibody that is used off label in patients with HES/CEL. Among 11 patients with HES/CEL (9 previously treated) prescribed alemtuzumab,[236] 10 achieved CHR (reduction of the AEC and the percentage of eosinophils in peripheral blood to normal values) and 9 had complete symptoms resolution after a median of two weeks. The median duration of CHR was short-lived (3 months), and 7 of the 10 patients with CHR experienced relapse. In a long-term follow-up study of 12 patients (9 from original report),[237] 10 achieved CHR and elimination of disease symptoms after a median of one week; this was sustained for a median duration of 66 weeks. Five patients with CHR receiving maintenance alemtuzumab for a median duration of 20 weeks (range, 1–266) had a significantly longer time to disease progression than those who were not given maintenance therapy ($P = .01$). Eleven patients eventually experienced relapse (only one was on maintenance therapy). Five of six patients achieved a second CHR for a median duration of 123 weeks after re-challenge with alemtuzumab. Alemtuzumab side effects, mostly prolonged myelosuppression and the necessity for maintenance therapy, limit its use in clinical practice.

Another agent explored in patients with *PDGFRα*-negative HES (n = 10) was a small-molecule, orally bioavailable aminobenzothiazole, dexpramipexole (150 mg orally twice daily), as a glucocorticoid-sparing agent.[238] The two primary end points were: the proportion of 50 or more patients with a decrease in the minimum effective glucocorticoid dose (MED) to maintain AEC lower than 1000/μL and control symptoms, and the MED after 12 weeks of treatment as a percentage of the MED at the start of therapy. Of 10 patients, four

Table 6–19 Diagnostic Criteria for Chronic Neutrophilic Leukemia

1. Peripheral blood white blood cell count ≥25 × 10^9/L – Segmented neutrophils plus banded neutrophils constitute ≥80% of the white blood cells – Neutrophil precursors (promyelocytes, myelocytes, metamyelocytes) constitute <10% of the white blood cells – Myeloblasts rarely observed – Monocyte count <1 × 10^9/L – No dysgranulopoiesis
2. Hypercellular bone marrow – Neutrophil granulocytes increased in percentage and number – Neutrophil maturation appears normal – Myeloblasts constitute <5% of the nucleated cells
3. Not meeting WHO criteria for *BCR-ABL1*–positive chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, or primary myelofibrosis
4. No rearrangement of *PDGFRα*, *PDGFRβ*, or *FGFR1*, and no *PCM1-JAK2* fusion
5. *CSF3R*^{T618I} or another activating *CSF3R* mutation **OR** Persistent neutrophilia (≥3 months), splenomegaly, and no identifiable cause of reactive neutrophilia including absence of a plasma cell neoplasm or, if a plasma cell neoplasm is present, demonstration of clonality of myeloid cells by cytogenetic or molecular studies

achieved 50% or higher reduction in MED, and the median ratio of MEDs at 12 versus 0 weeks was 66% (significantly reduced, $P = .03$). All adverse events were self-limited and did not lead to therapy discontinuation. In responders, BM biopsy samples showed selective absence of mature eosinophils. Dexpramipexole appears to be a promising steroid-sparing agent in patients with HES, and evaluation of its efficacy in a phase 3 clinical trial is planned.

CHRONIC NEUTROPHILIC LEUKEMIA

Chronic neutrophilic leukemia (CNL) is an extremely rare neoplasm and was first included as a distinct entity in the 2001 WHO classification system. Diagnostic criteria in 2016 reflected recent changes in the genomic landscape of CNL, endorsing strong association of the colony-stimulating factor 3 receptor (*CSF3R*) mutation with CNL (Table 6–19). The presence of activating *CSF3R* mutation (most frequently T618I) now comprises one of the five diagnostic criteria of CNL. The disease is characterized by the chronic overproduction of mature neutrophils (>80% segmented neutrophils and bands out of WBCs ≥25 × 10^9/L) and an increased number of granulocytes in the BM.

In 2013, the discovery of disease-defining oncogenic mutations in the *CSF3R* revolutionized our understanding of the pathogenesis of CNL and provided a biomarker for diagnosis as well as a potential therapeutic target.[239] Deep sequencing of coding regions of 1862 genes in patients with CNL (n = 9) and atypical CML (aCML) (n = 20) identified mutations in the *CSF3R* gene in 8 of 9 patients with CNL. Two mutational variants were identified: most were point mutations on the membrane proximal region (T618I or T615A); others were nonsense mutations leading to a premature truncation of the cytoplasmic tail of *CSF3R*. The proportion of patients with CNL/aCML harboring only membrane proximal region mutation versus compounding mutations of both was 75% and 25%, respectively. Under normal conditions, *CSF3R*, which is activated by binding its ligand granulocyte colony-stimulating factor, promotes the differentiation of granulocyte progenitor cells into neutrophils. Mutations in the membrane proximal region lead to constitutive activation of the JAK-STAT pathway, whereas truncation mutations result in ligand hypersensitivity and activation of the downstream SRC kinase pathway. Other pathways involved in neutrophilic differentiation, proliferation, and survival include nonreceptor tyrosine kinase SYK, Ras/Raf/MAP kinases, and PI3K/Akt.[240] This study revealed two major dysregulated signaling pathways in CNL and represents a proof of concept for the use of targeted therapies: JAK inhibitor ruxolitinib for membrane proximal region mutations (via JAK-STAT pathway), and tyrosine kinase inhibitor dasatinib for truncating mutations (via SRC pathway).

Studies in mice support the leukemogenic role of *CSF3R* mutations in CNL; deletion of CSFR3 in mice leads to neutropenia, and mice transplanted with *CSF3R*^{T618I}-positive hematopoietic cells develop a CNL-like phenotype, with mature granulocytosis, marrow hypercellularity, and infiltration of the spleen and liver with mature granulocytes.[241]

In another study, the coding region of *CSF3R* was sequenced in patients with clinically suspected CNL (n = 35) or aCML (n = 19), as well as 170 cases of CMML and PMF.[242] The diagnoses were reevaluated using

WHO criteria. Twelve cases of CNL were confirmed, 5 were associated with a monoclonal gammopathy-associated CNL, and 9 were confirmed as aCML. Of the 13 patients found to have the *CSF3R* mutation, 12 had WHO-defined CNL, and one had unconfirmed CNL. All mutations were found in the membrane proximal region, with T618I being the most common (10 patients). None of the cases of monoclonal gammopathy–associated CNL had *CSF3R* mutations, suggesting that patients with evidence of a plasma cell dyscrasia should not be classified as having CNL.

Clinical Features

The median age at diagnosis is around 66 years. The clinical presentation of CNL is heterogeneous, but the majority of patients are asymptomatic at diagnosis, or have nonspecific constitutional symptoms, such as fatigue, palpable splenomegaly, weight loss, easy bruising, bone pain, and night sweats. The median survival in CNL is about 24 months.[242,243] Intracranial hemorrhage is the most common cause of death, followed by leukemic transformation,[243] eventually occurring in a substantial proportion of the patients. There are no prognostic scores to predict survival of patients with CNL, but presence of *ASXL1* or *SETBP1* mutations as well as thrombocytopenia may be associated with shorter survival or blast phase.[242,244]

Diagnosis

Most patients are asymptomatic at presentation and are diagnosed after finding leukocytosis on routine blood testing. Most patients have mild anemia, and platelet counts are usually normal or slightly low. Diagnosis requires exclusion of a number of potential causes of neutrophilia, such as infections and occult malignancy, as well as other myeloid neoplasms (Table 6–19). Until the discovery of *CSF3R* mutation, the absence of *BCR-ABL1* and rearrangement of *PDGFRα*, *PDGFRβ*, and *FGFR1* were key diagnostic criteria. The presence of mostly mature neutrophils, and the notable absence of circulating blasts, monocytes, basophilia, and eosinophilia are important features of CNL that distinguish it from other myeloproliferative disorders (especially from CML). BM is hypercellular (>90% cellularity) as a result of granulocytic hyperplasia, with no dysplastic features. Unlike other MPNs, megakaryocytic hyperplasia or clusters of large atypical megakaryocytes are not seen. Most patients have normal cytogenetics.

Treatment

There is no standard treatment for CNL. HU has historically been the most frequently used agent and could control leukocytosis and splenomegaly in about 75% of the patients, with a median duration of about 12 months.[243] Second-line agents evaluated in these patients include IFN-α, cladribine, or thalidomide, with limited success in decreasing leukocytosis, but they do not possess any ability to modify the natural disease course.[243] Splenic radiation and splenectomy have been used, but splenectomy has been associated with further increases in neutrophil counts.[243] Induction chemotherapy followed by SCT has been used to treat patients in the blast phase, offering possible long-term remission in selected cases.[243,245] After *CSF3R*-mutated cells were shown to be sensitive to the JAK1/2 inhibitor ruxolitinib, this agent was evaluated in a few patients with CNL and some were encouraging, although transient responses, including hematologic, symptomatic, and molecular were observed.[246–248] The role of ruxolitinib in patients with CNL is currently under evaluation in a phase 2 study (NCT02092324). Preliminary results in 21 patients with CNL reported clinical response (defined as at least 50% improvement in counts and spleen size) in 65% of patients. Median time on study was 15.3 months with 86% of patients receiving > 6 cycles.[249]

MAST CELL DISEASE/SYSTEMIC MASTOCYTOSIS

Mast cell disease is a heterogeneous group of disorders characterized by clonal expansion of mast cells (MCs) and their excessive accumulation in various organs such as the skin, BM, gastrointestinal tract, lymph nodes, liver, and spleen. Its clinical course can vary from minimal symptoms to diffuse systemic involvement. In the revised 2016 WHO classification, mastocytosis was removed as one of the subtypes of MPN and listed as a separate major disease entity,[11] further divided into: cutaneous mastocytosis, systemic mastocytosis (SM) with subvariants of indolent SM (ISM), smoldering SM (SSM), aggressive SM (ASM), SM with an associated hematologic neoplasm (SM-AHN), and MC leukemia (MCL) (Table 6–20 through Table 6–22). SM requires the presence of one major (multifocal, dense infiltrates of ≥15 MC) and one minor or at least three minor (presence of atypical MCs/presence of KIT^{D618V} mutation/aberrant expression of CD25 with or without CD2 on MC or persistently elevated tryptase >20 μg/mL) diagnostic criteria (Table 6–22). The presence or absence of B and C findings defines SM subtype: (1) indolent SM with no B/C findings, (2) smoldering SM with B findings (higher disease burden but no organ damage), and (3) aggressive SM with C findings (organ damage by MC infiltration) as shown in Table 6–23. MCL is defined by the presence of ≥20% neoplastic MC

Table 6–20 Classification of Mastocytosis Variants

The complete diagnosis of these variants requires information regarding B (burden of disease) and C (cyto-reduction-requiring) (Table 6–21), all of which may not be available at the time of initial tissue diagnosis.
Cutaneous Mastocytosis
Urticaria pigmentosa/maculopapular cutaneous mastocytosis Diffuse cutaneous mastocytosis Mastocytoma of skin
Systemic Mastocytosis
Indolent systemic mastocytosis[a] (including the bone marrow mastocytosis subtype) Smoldering systemic mastocytosis[a] Systemic mastocytosis with an associated hematologic neoplasm[a] Aggressive systemic mastocytosis[a] Mast cell leukemia
Mast Cell Sarcoma

[a]This variant is equivalent to the previously described entity "systemic mastocytosis with an associated clonal hematologic non–mast cell lineage disease," and the terms can be used synonymously.

Table 6–21 Diagnostic Criteria for Cutaneous and Systemic Mastocytosis

Cutaneous Mastocytosis
Skin lesions, demonstrating the typical findings of urticaria pigmentosa/maculopapular cutaneous mastocytosis, diffuse cutaneous mastocytosis, or solitary mastocytoma, and typical histologic infiltrates of mast cells in a multifocal or diffuse pattern in an adequate skin biopsy[a] In addition, features/criteria sufficient to establish the diagnosis of systemic mastocytosis must be absent. There are three variants of cutaneous mastocytosis (see Table 6–20).
Systemic Mastocytosis
The diagnosis of systemic mastocytosis can be made when the major criterion and at least 1 minor criterion are present, or when ≥3 minor criteria are present.
Major Criterion
Multifocal dense infiltrates of mast cells (≥ 15 mast cells in aggregates) detected in sections of bone marrow and/or other extracutaneous organ(s).
Minor Criteria
In biopsy sections of bone marrow or other extracutaneous organs: • >25% of the mast cells in the infiltrate are spindle shaped or have atypical morphology **OR** • >25% of all mast cells in bone marrow aspirate smears are immature or atypical • Detection of an activating point mutation at codon 816 of *KIT* in the bone marrow, blood, or another extracutaneous organ • Mast cells in bone marrow, blood, or another extracutaneous organ express CD25, with or without CD2, in addition to normal mast cell markers[b] • Serum total tryptase is persistently >20 ng/mL, unless there is an associated myeloid neoplasm, in which case this parameter is not valid

[a]This criterion applies to both the dense focal and the diffuse mast cell infiltrates in the biopsy.
[b]CD25 is the more sensitive marker, by both flow cytometry and immunohistochemistry.

in the BM, and mostly presents as an acute leukemia with C findings/organ damage. Interestingly, the aleukemic variant with fewer than 10% circulating MCs is more common. Advanced SM (AdvSM) is a combined term for ASM, SM-AHN, and MCL and indicates subtypes with frequent organ damage and reduced OS.

Clinical Features

Symptoms of mastocytosis reflect MC mediators release or MC organ infiltration. Vasoactive mediators (histamine, leukotrienes, prostaglandins) released from MCs can lead to itching, flushing, lightheadedness, syncope, palpitations, diarrhea, heartburn, fatigue, and headache and can be exacerbated by infections,

Table 6–22 Diagnostic Criteria for the Variants of Systemic Mastocytosis

Indolent Systemic Mastocytosis
Meets the general criteria for systemic mastocytosis No C findings[a] No evidence of an associated hematologic neoplasm Low mast cell burden Skin lesions are almost invariably present
Bone Marrow Mastocytosis
As above (indolent systemic mastocytosis), but with bone marrow involvement and no skin lesions
Smoldering Systemic Mastocytosis
Meets the general criteria for systemic mastocytosis ≥2 B findings; no C findings[a] No evidence of an associated hematologic neoplasm High mast cell burden Does not meet the criteria for mast cell leukemia
Systemic Mastocytosis With an Associated Hematologic Neoplasm
Meets the general criteria for systemic mastocytosis Meets the criteria for an associated hematologic neoplasm (ie, a myelodysplastic syndrome, myeloproliferative neoplasm, acute myeloid leukemia, lymphoma, or another hematologic neoplasm classified as a distinct entity in the WHO classification)
Aggressive Systemic Mastocytosis
Meets the general criteria for systemic mastocytosis ≥1 C finding[a] Does not meet the criteria for mast cell leukemia Skin lesions are usually absent
Mast Cell Leukemia
Meets the general criteria for systemic mastocytosis Bone marrow biopsy shows diffuse infiltration (usually dense) by atypical, immature mast cells Bone marrow aspirate smears show ≥20% mast cells In classic cases, mast cells account for ≥10% of the peripheral blood white blood cells, but the aleukemic variant (in which mast cells account for <10%) is more common Skin lesions are usually absent

[a]B and C findings indicate organ involvement without and with organ dysfunction, respectively; these findings are listed in Table 6–23.

Table 6–23 B (Burden of Disease) and C (Cytoreduction-Requiring) Findings in Symmetric Mastocytosis, Which Indicate Organ Involvement Without and With Organ Dysfunction, Respectively

B findings
• High mast cell burden (shown on bone marrow biopsy): >30% infiltration of cellularity by mast cells (focal, dense, aggregates) and serum total tryptase >200 ng/mL • Signs of dysplasia or myeloproliferation in non–mast cell lineage(s), but criteria are not met for definitive diagnosis of an associated hematologic neoplasm, with normal or only slightly abnormal blood counts • Hepatomegaly without impairment of liver function, palpable splenomegaly without hypersplenism, and/or lymphadenopathy or palpation or imaging
C findings
• Bone marrow dysfunction caused by neoplastic mast cell infiltration, manifested by cytopenia: absolute neutrophil count $<1.0 \times 10^9$/L, hemoglobin level <10 g/dL, and/or platelet count $<100 \times 10^9$/L • Palpable hepatomegaly with impairment of liver function, ascites, and/or portal hypertension • Skeletal involvement, with large osteolytic lesions with or without pathologic fractures (pathologic fractures caused by osteoporosis do not qualify as a C finding) • Palpable splenomegaly with hypersplenism • Malabsorption with weight loss caused by gastrointestinal mast cell infiltrates

alcohol, exercise, and medications. Common sites of organ infiltration include the skin and gastrointestinal tract. Urticaria pigmentosa is the most common skin manifestation, characterized by reddish-brown macules and papules. Scratching of affected skin characteristically leads to development of urticaria and erythema (Darier sign). Gastrointestinal involvement can present as chronic diarrhea, steatorrhea, malabsorption, nausea, vomiting, and ascites. Cardiovascular symptoms include dizziness, palpitations, and anaphylaxis with hypotension and syncopal events. Anemia is the most common hematologic abnormality caused by BM infiltration, and peripheral eosinophilia is seen in around 20% of the patients. Bone and muscle pain and bone fractures can also occur.

Diagnosis

Diagnosis relies primarily on the identification of neoplastic MCs in various organs (see Table 6–11). Bone marrow examination is imperative for diagnosis of SM, because most patients would have underlying BM involvement. Figures 6–14 and 6–15 illustrate a case of SM detected in the BM. Neoplastic MCs are characteristically spindle shaped and present in multifocal aggregates (≥15 MCs in aggregates) and, unlike normal MCs, neoplastic MCs express the surface marker CD25, with or without CD2. Serum tryptase and urinary histamine are generally increased. One of the most reliable indicators of progressive SM is a steadily increasing serum level of tryptase. Using a sensitive polymerase chain reaction–based assay, a point mutation, resulting in the substitution of valine for aspartate at codon 816 (D816V) in the TK domain of the KIT receptor (*KIT*^{D816V} mutation), is noted in more than 90% of patients with SM.[250] KIT is a TK receptor encoded by the *c-KIT* gene located on chromosome 4q12 in humans, and *KIT*^{D816V} is located in exon 17. Binding of stem cell factor to KIT leads to receptor dimerization and phosphorylation of the downstream signaling molecules,[251] playing an important role in normal hematopoiesis. Furitsu et al first showed that KIT was constitutively activated and expressed in the absence of stem cell factor in a MC cell line derived from a patient with MC leukemia.[252]

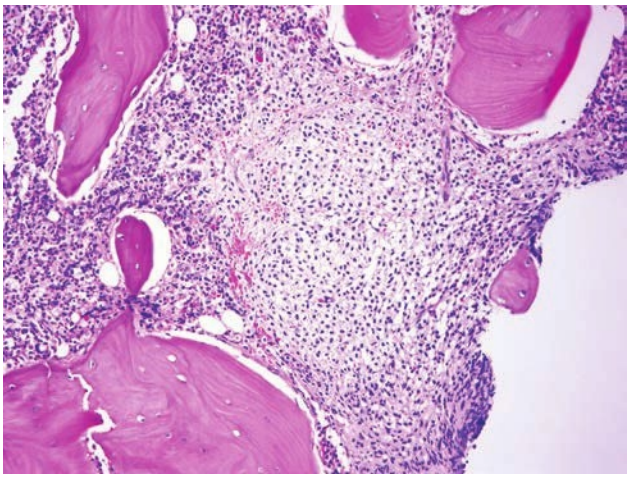

FIGURE 6–14 Bone marrow biopsy from a patient with SM demonstrates total focal replacement of the normal cellular elements by mast cells (×100). Immunohistochemical staining performed on this specimen demonstrated that the neoplastic mast cells aberrantly expressed CD2 and CD25.

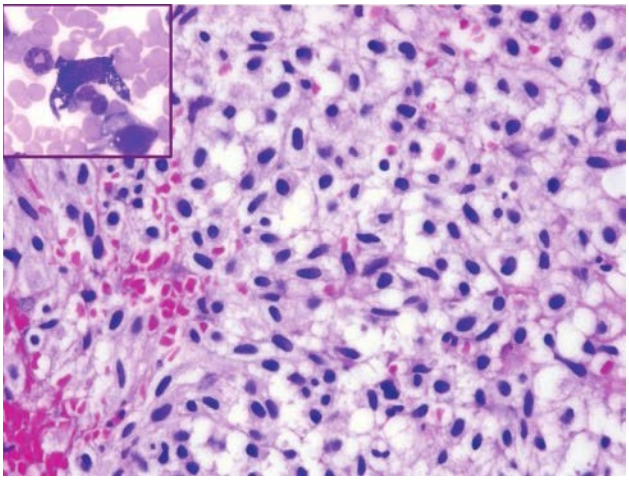

FIGURE 6–15 In SM, in the bone marrow biopsy, mast cells tend to have abundant, colorless cytoplasm and contain elongated-to-oval nuclei (×400). In the bone marrow aspirate smear, the mast cells increase in number and size and attain a spindle shape (inset; original magnification ×400).

Molecular analysis not only led to the discovery of *KIT*^{D816V} as a major oncogenic driver of MC differentiation, proliferation, and survival, but also enhanced our prognostic abilities for this disease. A few prognostic scores were developed and identified the negative prognostic impact of increased age (>60 years), markers of advanced disease (eg, anemia, thrombocytopenia, leukocytosis, high tryptase levels, splenomegaly, BM blasts >5%), poor risk karyotype (eg, monosomy 7 or complex), and additional molecular mutations, especially the presence and number of non-*KIT* mutations: *SRSF2/ASXL1/RUNX1* (S/A/R), or *EZH2, CBL, DNMT3A*.[253–261] The mutation-adjusted risk score for AdvSM (MARS) (N = 383) identified three risk groups with distinct OS (not reached, median 3.9, and 1.9 years, respectively) based on the presence of age older than 60 years, hemoglobin lower than 10 g/dL, platelets <100 × 10^9/L, and one or two S/A/R mutations.[254] The International Prognostic Scoring System for Mastocytosis (IPSM) (N = 1639) stratified patients with AdvSM as well as ISM into subgroups with different

outcomes based on the following risk factors: (1) ISM: age 60 years or older, alkaline phosphatase 100 U/L or more; and (2) AdvSM: age 60 years or older, tryptase level 125 ng/mL or higher, leukocyte count ≥16 × 10^9/L, hemoglobin 11 g/dL or lower, platelets ≤100 × 10^9/L, and absence of skin involvement.[253]

Although ISM has no impact on life expectancy, patients with AdvSM have significantly shortened OS, estimated at about 4 years for ASM, 2 years for SM-AHD, and less than 6 months for patients with MCL.[262,263]

Excellent guidance for diagnosis, symptom management, prognostic evaluation, and therapy of SM is provided in the recent NCCN guidelines for systemic mastocytosis.[264]

Treatment

Treatment of the most common form of noncutaneous SM, ISM, is focused exclusively on symptom relief, whereas reduction of MC burden and prevention of organ damage are the goals in treating AdvSM. All patients should avoid factors that can trigger MC degranulation, such as emotional stress, cold exposure, alcohol use, strenuous exercise, and the use of nonsteroidal antiinflammatory drugs. Symptomatic treatments include the use of oral antihistamines and MC stabilizers. Both sedating and nonsedating H1 antihistamines can be used to alleviate pruritus and itching. Cetirizine has been shown to be equivalent to hydroxyzine in relieving pruritus in patients with chronic urticaria, with the advantage that it does not cause sedation and thus is usually initiated first.[265] Higher doses of sedating antihistamines could be used for patients with severe symptoms. Because both H1 and H2 receptors are present in the skin (85% cutaneous histamine receptors are H1 and 15% are H2), the addition of an H2 blocker should be considered for patients who do not respond to H1 antihistamines alone.[265] Cromolyn sodium is beneficial in patients with gastrointestinal symptoms (eg, diarrhea, vomiting, abdominal pain).[266] Short courses of prednisone can be considered for patients with severe symptoms, especially malabsorption and ascites. Aspirin can cause MC degranulation but may help with flushing. Therefore, patients should be given H1 and H2 antihistamine therapy before starting aspirin therapy.[266] Patients with a history of anaphylaxis or cardiovascular collapse should carry an epinephrine pen. Omalizumab (a humanized murine monoclonal antibody that inhibits immunoglobulin E binding to MCs and basophils) is effective in patients with SM and syncopal episodes and skin manifestations.[267] Patients with osteoporosis might be treated with bisphosphonates or the anti-RANKL monoclonal antibody, denosumab.

Cytoreductive therapies (IFN-α and cladribine) are used for severe disease symptoms and in the case of organ damage. IFN-α plays an especially important role in pregnant patients or in patients with slowly progressive disease. In a multicenter trial in 20 patients with SM, IFN-α-2b led to a partial or minor response in 13 patients.[268] The combination of IFN-α-2b with prednisone has also been studied. Cladribine was the most frequently evaluated chemotherapeutic agent in AdvSM, especially in patients requiring rapid debulking of disease, and can induce overall RR in as much as 72% of patients.[269,270] Stem cell transplantation should be considered in patients with AdvSM and acute MCL at remission.[271]

Mutation in *KIT*^{D816V} is an attractive target because of its high frequency in patients with SM. It confers primary resistance against the tyrosine kinase inhibitor imatinib, which is approved by the FDA for patients with AdvSM without the *KIT*^{D816V} mutation or unknown *KIT* mutation status (at 400 mg daily) and for AdvSM associated with eosinophilia (starting dose 100 mg daily with dose escalation to 400 mg daily as needed). An important subgroup of patients with SM and imatinib responsiveness is the subset with the *FIP1L1-PDGFRα* mutation. In a study by Pardanani et al, 56% of the patients with SM and eosinophilia had the *FIP1L1-PDGFRα* fusion oncogene,[272] and all responded to imatinib (100 mg daily).

Midostaurin, an oral multikinase inhibitor including *KIT*,^{D816V} was approved by the FDA in April 2017 for patients with AdvSM irrespective of *KIT* mutational status. In an open-label study of 116 patients with AdvSM (≥1 measurable C finding), 100 mg of midostaurin orally twice daily resulted in an overall RR of 60% (45% with a major response, eg, complete resolution of ≥1 C finding).[273] Responses were similar across all subtypes (75% for ASM, 58% SM-AHD, 50% for MCL), regardless of *KIT* mutation or number of previous therapies. Symptoms and QOL were significantly improved with midostaurin. The median OS and PFS were the longest in patients with ASM (not reached and 29 months, respectively) than in patients with SM-AHN (21 and 11 months, respectively) and MCL (9 and 11 months, respectively). Additionally, 40% (8/20) and 100% (4/4) patients achieved RBCs and platelets transfusion independence. Therapy with midostaurin was associated with a high incidence of adverse events. The most common AEs included nausea (79% all grades), vomiting (66%), and diarrhea (54%); grade ≥3 AEs occurred in fewer than 10% of patients, but prophylactic antiemetics were recommended before each dose. Grade ≥3 anemia, thrombocytopenia, and neutropenia (new or worsening) occurred in 41%, 29%, and 24% of patients, respectively, and were more common in patients with preexisting cytopenias. Long-term follow-up (median

duration of 10 years) confirmed a similar spectrum of side effects without a new unexpected toxicity, and durable activity with the ORR of 69% (50% major response), 50% or higher reduction in MC burden and serum tryptase in 68% and 46% of the patients, respectively. OS for ASM, SM-SHN, and MCL patients was not reached, 40 months, and 18.5 months, respectively.[274] The negative impact of *ASXL1/SRSF2/RUNX1* mutations and the lack of 25% or more reduction in the KIT^{D816V} allele burden during therapy with midostaurin was shown on ORR, treatment duration, and OS.[275]

Another effective agent in SM is the highly selective TKI inhibitor, avapritinib (BLU-285), with an approximately tenfold higher potency for KIT^{D816V} inhibition than midostaurin, which has just received FDA approval in June 2021 for aggressive SM with platelets > 50×10e9/L at a dose of 200 mg daily. The approval was based on results from phase 1 (EXPLORER, NCT02561988) and phase 2 (PATHFINDER, NCT03580655) trails showing an objective response rate of 57% in all 53 evaluable patients in both trials with a median duration of response of 38.3 months (95% CI, 19-NE).[276,278] A phase 1 clinical trial of avapritinib in AdvSM with at least 1 C finding (EXPLORER trial) began in 2016. Preliminary data were reported on 52 patients treated in the initial escalation phase (32 patients), exploring 7 doses ranging from 30 mg to 400 mg once daily, and in the expansion phase (20 patients) on 300 mg daily. Six patients (12%) did not carry *KIT* mutation. Overall RR was noticed in 83% of patients, including 50% or higher BM MC reduction in 33% (undetectable BM MCs in 58%), reduction of serum tryptase to less than 20 µg/L in 66%, and complete resolution of splenomegaly in 47% of the patients. Decrease in 50% or more of BM KIT^{D861V} allele burden was noticed in 88% of the patients. Treatment-related grade 3 or 4 AEs were noticed in 28 (54%) patients. The most common AEs, most of which were mild, were periorbital edema (62%), fatigue (31%), and nausea (33%). Concerning AEs included ascites (10%), pleural effusion (10%), and cognitive impairment, eg, confusion and short-term memory effects (19%). Grade ≥3 anemia and thrombocytopenia occurred in 15% and 17% of the patients, respectively.[277] Updated results on 80 patients (48 evaluable for response) showed 77% overall RR; with 50% or higher BM MC reduction, 50% or higher reduction of serum tryptase, and 35% or higher reduction in spleen size by imaging were seen in 93%, 99%, and 80% of patients, respectively. Median time to initial response was two cycles, and responses deepened over time. Median OS was not reached for any subtype of AdvSM. Nonhematologic AEs were observed at similar rates over a long time, with grade ≥3 anemia and thrombocytopenia at 29% and 26%, respectively. Importantly, these responses were noticed in patients regardless of previous exposure to midostaurin (ORR of 60% and 85% with and without previous midostaurin, respectively).[278] Phase 2 study PATHFINDER enrolled 62 patients with advSM at the 200 mg daily dose. 81% of patients had SM-AHN, 13% had MCL and 6% had ASM. Interim results in 32 evaluable patients showed overall response of 75% with a median time to response of 2 months. Median OS was not reached at the time of the analysis. The most common adverse events included peripheral (50%) and periorbital (35%) edema and thrombocytopenia (32%). Treatment discontinuation due to treatment related AE was in 5% of patients.

Avapritinib is also being evaluated in symptomatic patients with ISM and SSM in a randomized, placebo-controlled registration trial, PIONEER, and part 1, the dose-finding phase (25 mg, 50 mg, and 100 mg daily), has already completed enrollment. Preliminary data were reported on 39 patients (10 patients in each avapritinib dose cohort and 9 patients in the placebo cohort). Across all avapritinib dose cohorts, mean percent reductions in serum tryptase occurred rapidly during cycle 1, with 48%, 67%, and 62% reduction on 25 mg, 50 mg, and 100 mg of avapritinib per day at 12 weeks. The placebo cohort showed no change in serum tryptase at 12 weeks (0.39%). All tested dose levels of avapritinib were well tolerated, with 5 patients (16.7%) having grade 3 AEs (including one cognitive effect on 100 mg). The recommended phase 2 dose for the next phase was 25 mg daily.[279] Updated data showed a statistically significant mean decline in symptoms (30% vs 3%), improved QOL, and reduction of MC burden, serum tryptase level, and *KIT* D816V allele burden at 16 weeks in patients treated with avapritinib versus those who received placebo.[280]

Masitinib, an inhibitor of pathways involved in MC pathogenesis (eg, KIT, FLN, and LYN), was evaluated in patients with indolent or smoldering SM in a phase 3 randomized, placebo-controlled trial (N = 135, 1:1 randomization). The response rate measured by improvement of symptoms (pruritus, flushes, depression, asthenia) was 18.7% taking masitinib versus 7.4% taking placebo. Most AEs were mild and included diarrhea, rash, or asthenia.[281] Masitinib has not yet been tested clinically in patients with AdvSM.

MD ANDERSON PRACTICE TIPS

- **Polycythemia Vera:** Risk stratify patients by age and thrombosis history. The goal is to keep the hematocrit (Hct) under 45% at all times. Monitor leukocyte counts and symptoms and watch for signs of resistance to or intolerance of hydroxyurea (HU). Aspirin is generally recommended. Interferons (IFNs) are a reasonable alternative to HU for first-line therapy, particularly in very young patients. Ruxolitinib is the cytoreductive drug of choice after failure of HU.
- **Essential Thrombocythemia:** Risk stratify patients by the revised IPSET model and consider observation for "very-low-risk" patients. Low-, intermediate-, and high-risk patients should receive aspirin unless it is contraindicated by acquired von Willebrand disease or extreme thrombocytosis (>1.5 million platelets/μL). Some patients may benefit from twice-daily administration of aspirin. Hydroxyurea is generally the drug of choice when cytoreductive therapy is indicated; IFNs are acceptable as well and may be preferred in very young patients.
- **Myelofibrosis:** Pre-PMF is managed similarly to ET but carries an inferior prognosis. A number of models exist for risk stratification of overt PMF; one that incorporates both clinical and genomic risk factors, eg, MIPSS70/MIPSS70 plus v2.0 is recommended for use in transplantation-age patients. Use the MYSEC-PM for patients with post-V/ET MF. In general, consider allogeneic stem cell transplantation in patients whose predicted life expectancy is less than 5 years. Ruxolitinib is the mainstay of therapy and confers a survival benefit in patients with intermediate-2/high-risk disease. Fedratinib is a reasonable choice after failure of ruxolitinib. Patients with anemia as their main or only disease manifestation may not need JAK inhibition and could be better served by anemia-directed therapies.
- **Chronic Eosinophilic Disorders/Hypereosinophilic Syndromes:** Rule out secondary causes and evaluate for organ damage. Pay particular attention to possible heart involvement and use steroids up to 1 mg/kg with any life-threatening manifestation. Consider using empiric therapy for *Strongyloides*, especially when using steroids. Evaluate for clonality and identify *PDGRA/B* rearrangements because these are sensitive to imatinib. Responses are high, but lifelong maintenance may be necessary. For all other patients, use steroids as first-line treatment but try to find a steroid-sparing agent for a long-term benefit. Consider clinical trials with novel agents for patients with *FGFR1* rearrangement and utilize stem cell transplantation.
- **Chronic Neutrophilic Leukemia:** Rule out secondary causes and confirm the presence of *CSF3R* mutation. There are no prognostic models for survival, but patients with advanced clinical features and multiple molecular abnormalities have inferior outcomes. Disease often progresses to acute leukemia. Use cytoreduction to control counts, such as HU or IFN. Consider clinical trials (ruxolitinib) when possible. Chemotherapy and stem cell transplantation is reserved for aggressive course and blast phase.
- **Systemic Mastocytosis:** It is important to distinguish between cutaneous mastocytosis and systemic mastocytosis (SM) by performing a BM evaluation. Test for KIT^{D816V} mutation and measure tryptase. Once SM is confirmed, patients need to be evaluated for the presence of B and C findings, indicating indolent versus aggressive SM. Treat symptoms and advise patients to avoid triggers. Aggressive SM has limited life expectancy, and patients experience various organ involvements. Monitor for the presence of advanced features/molecular mutations that suggest inferior outcome. Use of kinase inhibitors, midostaurin, or avapritinib in clinical trials, is recommended. Chemotherapy, such as a cladribine-based regimen, has a role in aggressive mast cell leukemia and refractory disease. Stem cell transplantation shall be considered in all patients with aggressive disease.

ACKNOWLEDGEMENT

The authors thank Helen Chifotides, PhD, for excellent scientific editing of the chapter.

KEY CONCEPTS

- Patients with early-stage follicular lymphoma (FL) can experience prolonged remissions with radiation therapy, particularly in the presence of stage I disease and lesions smaller than 3 cm; as such, surveillance should be reserved only to patients who are not candidates for radiation.
- High tumor burden in patients with FL is defined by the presence of one or more Groupe d'Etude des Lymphomes Folliculaires (GELF) criteria; these include: significant lymphadenopathies (one >7 cm or three each >3 cm), splenomegaly, impending organ compromise, pleural effusion, elevated circulating lymphoma cells, and cytopenia. Among patients with advanced-stage FL, those with high tumor burden should be considered for active treatment; in the presence of low tumor burden, observation or single-agent rituximab are potential management strategies.
- Both chemoimmunotherapy and immunotherapy (with lenalidomide) are potential treatment options for patients with advanced-stage, high tumor burden FL; pretreatment positron emission tomography–computed tomography (PET-CT) scan may identify patients who would benefit from an anthracycline-based regimen.
- PET-CT scan performed at the end of chemoimmunotherapy is considered prognostic. Response to frontline therapy may inform pursuit of maintenance therapy given retrospective data suggesting the largest impact of maintenance rituximab observed among those achieving a partial response to frontline chemoimmunotherapy.
- Patients with FL who progress within 24 months from the initiation of frontline chemoimmunotherapy may have a shorter overall survival; these patients should be evaluated for clinical trials with novel agents or cellular therapy

INTRODUCTION

Follicular lymphoma (FL) is a neoplasm composed of centrocytes and centroblasts that are derived from the germinal center of lymphoid follicles.[1] Most cases of FL have a diffuse pattern but these neoplasms rarely have an entirely diffuse pattern. Being derived from germinal center B cells, these neoplasms commonly express CD10, Bcl-6, HGAL, and LMO2 and carry $t^{14;18}$(q32;q21).

Importantly, knowledge of FL has increasing led to the recognition of variants of FL (e.g. in situ follicular neoplasia) as well as distinct types of FL, the latter including primary cutaneous follicle center cell lymphoma, pediatric-type follicular lymphoma, and follicular lymphoma with *IRF4* rearrangement.

In this chapter we focus on the common form of FL that represents about 80-85% of all cases of FL.

EPIDEMIOLOGY

FL, the second most commonly occurring lymphoma in the United States, represents 22% of all B-cell non-Hodgkin lymphomas (NHLs)[2] and 80% of all indolent B-cell lymphomas. FL occurs almost exclusively in adults, with an equal frequency in men and women. The incidence rates are highest among Caucasians, and median age at diagnosis is approximately 63 years.[3] In the United States, from 2012-2016, the number of new cases of FL was 2.7 per 100,000 men and women per year after age-adjustment. The number of deaths was 0.5 per 100,000 men and women per year.[4] Risk of FL increased in persons who have a first-degree relative with NHL or who worked as a spray painter and among women with Sjögren syndrome.[3] About 2% to 3% of patients with FL

per year undergo transformation to aggressive B-cell lymphoma, usually diffuse large B-cell lymphoma (DLBCL), with a life-time risk of 11%. However not all cases are typically biopsy-proven, diagnosis of transformation being sometimes based on clinical, laboratory and radiological features, and this number may need minor adjustment.[5] Survival for patients with FL is improving, with a median survival of 8 to 10 years in the pre-rituximab era[6-8]; while in the more modern era, the median survival of FL patients has been reported to be greater than 18 years, with a 5-year overall survival (OS) of 88.4% in the United States between 2009 and 2015.[4,9]

CLINICAL FEATURES

Patients with FL most often present with asymptomatic lymphadenopathy. Constitutional symptoms such as fever, drenching night sweats, and significant weight loss occur in approximately 15% of patients. Patients may have symptoms related to lymph node enlargement, especially when there are bulky masses. Other symptoms can include fatigue and, occasionally, end-organ consequences, such as obstructive uropathy or bone marrow compromise. Central nervous system (CNS) disease is rare. Urgent situations, such as superior vena cava syndrome or spinal cord compression, are rare, in part related to the usual slow pace of growth of lymphadenopathy in FL. Spontaneous regression of lymphadenopathy can occur in FL patients. Such regressions, however, are usually partial and are typically short-lived. The potential of FL to wax and wane provides one of several clues that suggest that host immune surveillance can play an important role in the disease course. Consequently, FL has been a prime focus for immunotherapy approaches.

Approximately 80% to 90% of patients with FL present with advanced-stage disease (stage III or IV) with generalized lymphadenopathy. The bone marrow is involved in approximately 50% of patients. Clinical features suspicious for transformation to DLBCL include rapidly progressive lymphadenopathy, systemic (B) symptoms, localized pain, and a rise in serum lactate dehydrogenase (LDH) level. While elevated β2-microglobulin may be secondary to renal insufficiency and does not typically raise concern for transformation, in the rituximab era it has shown to play a prognostic role, and has been incorporated in novel prognostic models (see below).

HISTOLOGIC, IMMUNOPHENOTYPIC, AND MOLECULAR FEATURES

In lymph nodes, the normal architecture is partially or completely replaced by FL, which typically forms follicles, but rarely can have a diffuse pattern. FL is composed of centrocytes (small-cleaved cells) and centroblasts (large-noncleaved cells). The method currently recommended in the World Health Organization (WHO) classification for grading FL is based on counting centroblasts.[6,10] In grade 1 FL, centroblasts are rare, less than 5 per ×400 microscopic field. Grade 2 FL contains 5 or more but less than 15 centroblasts per ×400 microscopic field. Grade 3 FL Has more than 15 centroblasts per ×400 microscopic field are present. Importantly, this system was proposed initially when most microscopes had a smaller field of view. With newer microscopes that have a larger filed of view these counts need to be adjusted. The WHO classification states that there is no prognostic benefit derived from distinguishing grade 1 from grade 2 cases and designates these tumors as FL grade 1-2. In contrast, grade 3 cases of FL are subdivided into A and B categories. In grade 3A FL, more than 15 centroblasts per ×400 microscopic field are present. In grade 3B cases, sheets of centroblasts are present with rare or absent centrocytes.[6] Recent data suggest that FL grade 3B has many features in common with DLBCL, although some features of indolent FL are also present.[11]

Histologic concordance is not uncommon in patients with FL. In the 1970s when staging laparotomy was performed for FL patients, discordance of grade between anatomic sites was observed in 20-30% of patients.[12] Currently, histologic discordance between the bone marrow and lymph node may be observed most often. Typically the bone marrow shows low-grade FL and the lymph node may show grade 3 FL or even DLBCL.[13]

Follicular lymphoma is a neoplasm of mature B-cell lineage. Most grade 1 and 2 tumors express surface immunoglobulin (Ig), but a subset of FLs, mostly grade 3, may be Ig negative. All FLs express pan B-cell markers and typically express Ig and B-cell antigens at high density ("bright" immunofluorescence by flow cytometry). These neoplasms also express the germinal center-associated markers CD10, Bcl-6, *HGAL*, and *LMO2* and are negative for T-cell antigens. Bcl-2 is expressed in 80% to 90% of FLs but can be negative, most often in grade 3 neoplasms.[6] Because Bcl-2 is negative in reactive germinal centers, this marker is helpful in making a differential diagnosis (Fig. 7–1).

With conventional cytogenetic analysis, approximately 75% of FL cases grow in culture and can be successfully karyotyped. The cytogenetic hallmark of FL is $t^{14;18}$(q32;q21), which is identified in 80% to 90% of cases. A small subset of FLs lack the t,$^{14;18}$ suggesting that a minor pathway of follicular lymphomagenesis may exist that is independent of $t^{14;18}$. This appears to apply particularly to grade 3B nodal FL, FLs arising in extranodal sites (such as skin), and rare FLs that occur in children, which commonly lack the $t^{14;18}$.

As a result of the $t^{14;18}$, *BCL2* on chromosome 18q21 is translocated adjacent to the joining region of (*IGH*) on chromosome 14q32. *BCL2* is dysregulated by being placed under the influence of *IGH* regulatory elements

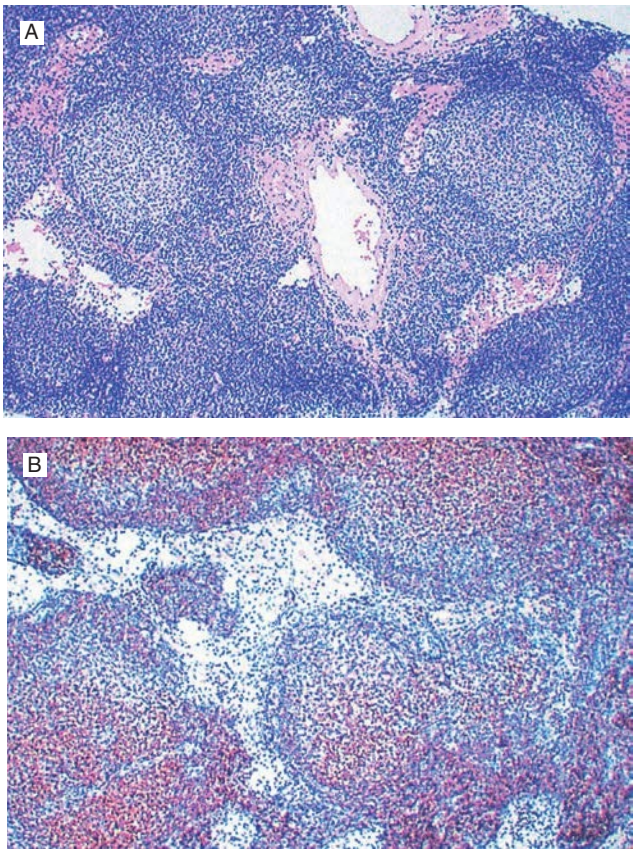

FIGURE 7–1 Follicular lymphoma, grade 1. A. In this needle biopsy specimen, neoplastic follicles partially replace architecture. B. The neoplastic cells are Bcl-2 positive, supporting lymphoma (A, hematoxylin-eosin, ×100; B, Bcl-2 immunostain ×100).

(enhancer region). Insights about the role of the *BCL2* in FL were a gateway to the identification of a large family of proapoptotic and antiapoptotic genes, which play a role in a wide variety of hematopoietic and solid neoplasms.[14–16]

The breakpoints on chromosome 18 are primarily clustered at two sites: the major and minor breakpoint cluster regions, involved in 50% to 60% and 10% to 20% of cases, respectively.[17] Other breakpoint clusters also are described; for example, the intermediate cluster region (ICR). The ICR is involved in approximately 5% of cases; there may be geographic variations in the frequencies of $t^{14;18}$ breakpoints.[18]

The Bcl-2 protein is a 25-kDa molecule that is overexpressed in FL and protects cells from programmed cell death (apoptosis).[14,15,19] Inhibition of apoptosis prolongs cell life, resulting in an expanded compartment of B cells, thereby providing more opportunity for additional molecular defects, which presumably are involved in histologic transformation. The presence of the $t^{14;18}$ alone appears to be insufficient for neoplastic transformation. The $t^{14;18}$ has been identified in rare cells in the tonsils and lymph nodes of normal individuals without clinical evidence of lymphoma.[20] In this regard, recent data show that alternative antiapoptotic proteins, such as Bcl-w (encoded by *BCL2L2*), may also play a crucial role in the pathogenesis of FL.[21]

Other cytogenetic abnormalities have been reported in FL. Of these, trisomy 7 and 18, abnormalities of 3q27-28 and 6q23-26, and 17p deletions are most frequent. Abnormalities of 3q27-28 involve *BCL6* and most often occur in the form of translocations. Secondary cytogenetic and molecular genetic abnormalities also have been extensively studied, including in the context of transformation of FL to DLBCL.[22–24]

The second most common genomic aberration observed in FL is represented by inactivating mutations of *KMT2D* (*MLL2*), found in about 80% of FL cases. These mutations interfere with the ability of KMT2D/MLL2 to activate gene transcription through H3K4 methylation. Although less frequent, mutations of other histone modifiers are also observed, including *CREBBP, EZH2*, *MEF2B*, and *EP300*, suggesting that overall epigenetic dysregulation combined with dysregulated apoptosis may be responsible for the transformation of germinal center B cells into FL cells.[25–28]

In addition, disruption of the epigenome can also alter the tumor immune microenvironment: mutations in CREBBP, for example, are associated with a signature of decreased antigen presentation characterized by reduced transcript and protein abundance of MHC class II on tumor B cells, because of its role in promoting class II transactivator–dependent transcriptional activation of these genes.[29]

The importance of the immunologic microenvironment in the clinical behavior of FL has been an area of intensive study; reduced intratumoral infiltration by host immune cells is associated with a more aggressive clinical course.[30] Gene expression profiling methods have shown molecular signatures attributable to subsets of T cells and macrophages in FLs, the former associated with a milder and the latter with more aggressive clinical features.[31–34] In light of these findings, multiple attempts are ongoing, aimed at characterizing the phenotype of tumor-associated macrophages with a more pronounced protumoral function, using markers such as CD163 and CD172 (or SIRPα).[35–38]

IN SITU FOLLICULAR NEOPLASIA

This lesion, previously known as "follicular lymphoma in situ," is thought to be a preneoplastic stage of FL.[39] Most often, in situ follicular neoplasia (ISFN) is an incidental finding that occurs in lymph nodes excised for a variety of reasons (eg, axillary lymph nodes in a patient with breast carcinoma). The overall frequency of ISFN is low, approximately 2%.

Morphologically, ISFN is difficult to recognize in routine tissue sections stained with hematoxylin-eosin. The lymph node architecture is normal, with widely scattered follicles that are of normal size and inconspicuous. The germinal centers have a sharp peripheral margin and are monotonous, composed almost exclusively of centrocytes, a morphologic clue to the diagnosis of ISFN.[40] Immunohistochemical analysis is essential for the recognition of ISFN. The germinal center cells are strongly positive for Bcl-2 and CD10.[40,41] Typically, Bcl-2 expression by the ISFN cells is brighter than the expression level by mantle zone cells surrounding the germinal center. The cells of ISFN also express pan B-cell antigens and other germinal center B-cell markers, such as *BCL6*, *HGAL*, and *LMO2*.

Cytogenetic and molecular studies have shown that the cells of ISFN carry $t^{14;18}$(q32;q21) and monoclonal *IGH* and Ig light chain gene rearrangements. Array comparative genomic hybridization and other methods performed on ISFN lesions have shown that the cells of ISFN carry $t^{14;18}$ but have relatively few secondary genetic abnormalities, in contrast with fully developed FL.[42] *EZH2* mutations have been detected in ISFN, suggesting this is another early lesion in FL pathogenesis.

Evidence of overt lymphoma at another anatomic site also is present in a small subset of patients with ISFN.[40] In addition, some patients with ISFN subsequently have development of a histologically discordant type of lymphoma. These cases suggest that ISFN could be a marker of genetic instability or a marker of genetic predisposition to lymphoma. Lymphomas most often reported in association with ISFN include classical Hodgkin lymphoma, splenic marginal zone lymphoma, and small lymphocytic lymphoma/chronic lymphocytic lymphoma.[41]

In aggregate, the data suggest that ISFN is a neoplastic process representing an early step in FL pathogenesis that is unlikely to affect patient survival if it is an isolated finding. However, because a subset of some patients with ISFN also have or may develop overt lymphoma at other anatomic sites, staging studies are indicated. If ISFN is the only disease discovered, overtreatment is to be avoided.

DIAGNOSTIC WORKUP AND STAGING

Clinical evaluation requires a comprehensive history, including age; sex; presence of B symptoms (fevers, chills, drenching night sweats, unexplained weight loss of >10% of body mass over 6 months, pruritus); fatigue; and a history of malignancy. Physical examination should include identification and measurement of all accessible lymph node sites, including epitrochlear and occipital lymph nodes, and assessment of the abdomen for splenomegaly or hepatomegaly.

The diagnosis is best established by an excisional lymph node biopsy to provide adequate tissue for assessment of lymph node architecture. The most easily accessible lymph node may not be the most informative or representative one. For example, if a small peripheral lymph node shows grade 1 FL but the patient has a large abdominal mass, a high serum lactate dehydrogenase (LDH) level, elevated standardized uptake value (SUV) on PET scan, and other features suggestive of transformation, then an additional biopsy to exclude higher-grade disease should be considered, because this would influence the selection of appropriate therapy. Core needle biopsies guided by radiographic or imaging techniques may be performed on masses that are not easily accessible. Fine-needle aspiration can be misleading for initial diagnosis; complete classification may not be possible because the limited tissue sample prevents the assessment of architecture, and there is the possibility of sampling error. In the initial staging evaluation, fine-needle aspiration may play a role in documenting and defining sites of involvement.

Once the diagnosis of FL is established, patients should undergo testing to determine stage, assess prognostic risk factors, and evaluate their general health. A complete blood cell count may show anemia or thrombocytopenia, which can result from bone marrow involvement or occasionally from hypersplenism or autoimmune problems. Leukemic involvement can occur in 10% of patients. Serum LDH and β_2-microglobulin (B2M) levels may be elevated and are of prognostic significance. Bilateral bone marrow biopsies with unilateral aspiration are recommended for the staging workup because of the patchy nature of involvement. In FL, the bone marrow characteristically shows a paratrabecular pattern of involvement (Fig. 7–2). Because the lymphoma cells are associated with stroma and are not easily aspirated, bone marrow aspirate smears assessed by routine light microscopy may not be informative. Flow cytometry and molecular assessment (eg, polymerase chain reaction [PCR]) of aspirate material can increase the sensitivity of bone marrow assessment, but in the absence of morphologic abnormalities, positive PCR or flow findings are traditionally not taken as evidence to warrant assignment of stage IV.[43] For example, it is well established that patients at Ann Arbor stage I or II can have cells with the $t^{14;18}$ detected in the peripheral blood or bone marrow by PCR.

Imaging studies should include neck and chest CT for delineation of lymphadenopathy. Abdominal and pelvic CT scans are essential for assessing lymphadenopathy as well as organomegaly. PET using

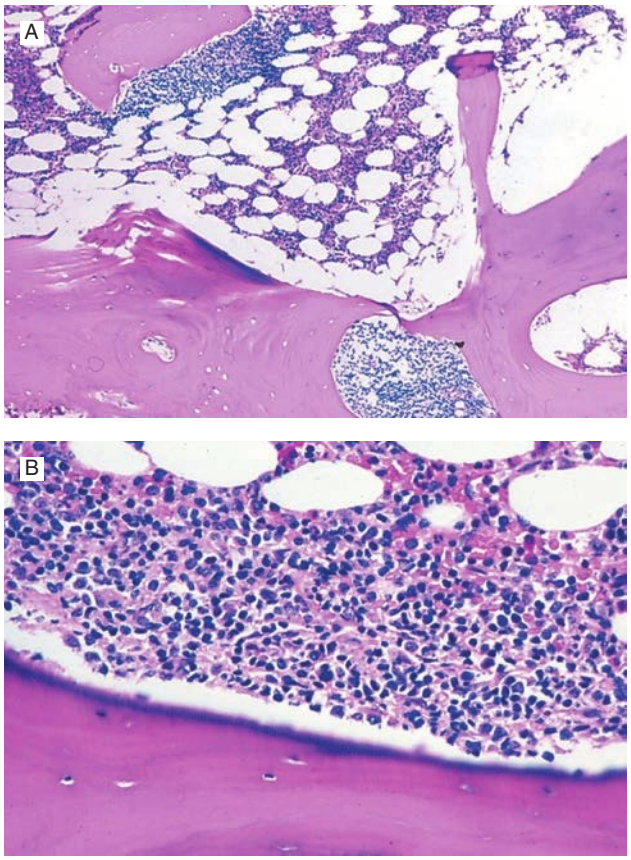

FIGURE 7–2 Follicular lymphoma involving bone marrow. A. The neoplasm is infiltrating the bone marrow with a paratrabecular pattern. B. Neoplastic small-cleaved cells adjacent to bone are seen in this field (A, B, hematoxylin-eosin; A, ×100; B, ×400).

fluorine-18 fluorodeoxyglucose (FDG) combined with CT scan (PET-CT) is a useful tool for assessing patients with FDG-avid lymphomas. Compared with CT scans, PET-CT can improve the accuracy of staging for nodal and extranodal sites and leads to a change in stage in 10% to 30% of patients, more often upstaging these patients.[44] In addition, PET-CT can help identify areas at risk for transformation, as each unit increase in SUV is associated with a 1.25-times increased risk of transformation.[45,46] Recent data show that, even in absence of histologic evidence of transformation, baseline elevated SUV and total metabolic tumor volume may be a surrogate marker for more aggressive biologic features and may help guide treatment selection.[47–50] Improving staging accuracy is important to ensuring patients are appropriately treated. Although most lymphomas are FDG avid, there is great variability in FDG uptake.[46,50,51] Imaging by PET can be less reliable in indolent lymphomas. Therefore, adoption of PET scanning for staging patients with indolent lymphoma has not been embraced to the same extent that it has been for DLBCL and Hodgkin lymphoma. Recent consensus guidelines recommend the use of PET-CT for staging in clinical practice, and clinical trials for patients with FL, and may be used to select the best site to perform biopsy.

PROGNOSTIC FACTORS

The prognostic importance of distinguishing grade 1 or 2 FL from the more aggressive grade 3 FL is well accepted. However, most investigators have not found a clear difference in long-term survival between patients with grades 1 and 2 FL, although older literature suggested that FL grade 2 (nodular mixed-cell lymphoma, in older nomenclature) was more prone to early progression than grade 1 if therapy was deferred.[52] Higher degrees of nodularity have been associated in some reports with improved outcome. An increased proliferation rate is associated with a poorer prognosis, although Ki-67 is not yet acknowledged as an independent prognostic or predictive factor.[53,54]

Variables shown to correlate with survival in patients with FL include tumor burden, host factors, and response to therapy. Tumor burden is estimated according to GELF criteria, by assessing presence of B symptoms, number and size of nodal disease, splenomegaly, compression syndrome, presence of pleural or peritoneal effusions, leukocytosis, and cytopenias.

The International Prognostic Index (IPI) was devised for aggressive lymphomas and consists of five variables, increased risk being associated with: (1) age older than 60 years, (2) Eastern Cooperative Oncology Group performance status 3–4, (3) Ann Arbor stage III–IV, (4) more than one extranodal involvement, and (5) elevated serum LDH level.[55] The IPI is also a useful predictor of survival in patients with indolent B-cell lymphomas. One important limitation of this system is that only about 10% of the patients fall into the high-risk group, and most of these patients have poor performance status and would be poor candidates for aggressive therapy.

Partly for that reason, a Follicular Lymphoma International Prognostic Index (FLIPI) was developed. Initially, an eight-parameter model was proposed, including age 60 years of age or older, male gender, Ann Arbor stages III and IV, at least 5 nodal sites, bone marrow involvement, serum LDH level greater than normal, hemoglobin level lower than 12 g/dL, and lymphocytes at least 1000/mL. However, a simplified version of this model was found to be comparably predictive, using the five parameters of age, Ann Arbor stage, serum LDH, hemoglobin level, and number of nodal sites.[56] This prognostic model separates patients into three prognostic groups: good risk, with 0 to 1 factors; intermediate risk, with 2 factors; and poor risk, with 3 or more factors. The overall five-year survival rate was

90% for the good-risk group, 78% for the intermediate-risk group, and 53% for the poor-risk group.[56] The validity of the FLIPI model has been demonstrated in rituximab-treated patients.[57] A FLIPI-2 model was developed through the prospective collection of prognostic data, producing a five-factor model that incorporates age (>60 years adverse), hemoglobin level (<12 g/dL adverse), serum B2M level (adverse if above normal range), bone marrow (adverse if involved), and size of lymphadenopathy (>6 cm adverse), which has not been validated.[58]

There are more similarities than differences in these models. For instance, the importance of serum B2M was shown in the univariate analyses of both the IPI and FLIPI datasets, but the B2M data were collected prospectively only in the FLIPI-2 report. The importance of sampling the bone marrow, as shown in the FLIPI-2 report, deserves particular emphasis, because practice patterns indicate that the important data offered are often not collected. Easily applied models such as the IPI, FLIPI, or FLIPI-2 can provide a framework for selecting the timing or intensity of therapy, and can facilitate the interpretation of clinical trials, by providing a tool to assess for disparities in patient selection when results of various trials are compared (Table 7–1).

Recently, a model combining the mutational status of seven genes relevant both to FL and the microenvironment (*EZH2, ARID1A, MEF2B, EP300, FOX01, CREBBP, and CARD11*) with the FLIPI has been produced, and termed *m7-FLIPI*. Although not extensively used, it has been shown to be superior to the FLIPI score to identify very high-risk patients.[59]

At the time of relapse, favorable predictors for survival in patients with FL include having achieved a complete response with initial therapy, having had a durable remission of more than 24 months after initial therapy, and being less than 60 years of age. Progression of disease within 24 months from the type of chemoimmunotherapy used as frontline treatment (POD24), in particular, has been shown to be the strongest predictor of long-term outcome in these patients.[60,61]

Table 7–1 Prognostic Models for Lymphoma

B2M			✓

B2M, serum β-2-microglobulin; Hgb, hemoglobin; PS, performance status.

POSTTREATMENT MONITORING

An international working group has recommended end-of-treatment assessment and defined response criteria for NHL. These criteria have been updated recently, with important modifications, including incorporation of PET-CT.[44] In FDG-avid FL, PET-CT should be used for response assessment, using the five-point scale (1, no uptake above background; 2, uptake ≤mediastinum; 3, uptake >mediastinum but ≤liver; 4, uptake moderately >liver; 5, uptake markedly higher than liver and/or new lesions). The criteria based on PET-CT eliminate the complete response unconfirmed criteria and improve the prognostic value of a partial response (PR). A complete metabolic response using PET-CT (5-point scale scores of 1–3), even with a persistent mass, is considered a complete remission (CR). With CT-based assessment, a complete radiologic response is determined by nodal masses regressing to 1.5 cm or less in the longest diameter and no extralymphatic sites of disease. In FL, multiple studies have shown the association between posttreatment response assessment by PET-CT scan and risk of relapse, justifying its use in this setting.[62–65]

Bone marrow reevaluation is performed to confirm clinical remission if the bone marrow involvement was initially positive.

Although the monitoring of patients with molecular studies is not currently considered standard practice, detection of the $t^{14;18}$/*IGH-BCL2* by PCR techniques, used to measure circulating tumor cells, has been useful in the monitoring of subclinical disease. "Molecular remission," the disappearance of cells with $t^{14;18}$ detected by PCR, used to be considered a rarity in patients with FL treated with standard therapy. Gribben et al reported that only 1 of 212 (0.5%) patients achieved molecular remission after conventional chemotherapy.[66] With high-dose therapy and stem cell transplantation (SCT), however, molecular remissions could be attained, and patients with molecular remission experienced more durable remissions. Improvements in therapy have changed this. Even before the advent of anti-CD20 monoclonal antibody (MAb) therapy, more potent chemotherapy regimens were capable of inducing molecular remission in more than half of patients. With the availability of rituximab and obinutuzumab, which can largely eradicate B cells

from the blood and bone marrow, it is now common to see molecular remission. Some recent studies also showed that molecular remission correlates with more durable clinical remission,[67–69] but other studies did not.[70] Finally, novel techniques to assess minimal residual disease in FL are now available for clinical research, measuring circulating free DNA, including droplet digital PCR and targeted capture ultradeep next-generation sequencing (The Cancer Personalized Profiling by Deep Sequencing or CAPP-seq).[71] It is important to note, however, that although their application is quickly progressing in the field of aggressive lymphoma, their use in FL is limited, particularly in patients with low tumor burden disease, because of frequently low quantity of measurable circulating DNA.

SURVEILLANCE IMAGING

There are limited data supporting patient benefit from surveillance imaging for patients with FL. As a consequence, there is considerable variation in practice. Zinzani et al performed one of the only prospective studies of surveillance imaging, which included 78 patients with FL in first CR after induction therapy.[72] Patients received PET-CT scans every 6 months for two years, with annual scans thereafter. The relapse rate was 8% to 10%, as shown by scans performed until 36 months, and decreased after that time. Because the purpose of the study was to describe specificity of scans, the impact on management and subsequent outcome was not reported. Gerlinger et al performed surveillance with annual CT scans and bone marrow evaluation in 71 patients with FL in second or subsequent remission after SCT.[73] Although approximately half of relapses were detected on CT scan, few patients required immediate treatment; there was no difference in OS between patients in whom disease relapse was detected by imaging compared with clinical presentation. They concluded that surveillance imaging was futile in this setting. Surveillance CT scans result in radiation exposure, patient anxiety, and significant healthcare costs, and these issues need to be carefully weighed against any potential benefit. The National Comprehensive Cancer Network guidelines suggest "surveillance CT scans up to every 6 months for the first 2 years following completion of therapy, and not more than annually thereafter." In contrast, the European Society for Medical Oncology guidelines are more conservative, suggesting minimal adequate radiologic or ultrasound investigations every 6 months for two years and annually thereafter. Regular CT scans are not mandatory outside clinical trials, and PET-CT should not be used for surveillance.[74]

TREATMENT OF EARLY-STAGE FOLLICULAR LYMPHOMAS

At diagnosis, approximately 15% to 20% of patients with FL have early-stage disease (stages I and II). Retrospective studies have shown that observation is an option for these patients, with disease in 50% of patients not progressing and remaining untreated when actively followed.[75,76] However, this approach is usually reserved for elderly or comorbid patients unable to tolerate treatment, in light of the limited toxicity of available treatment options. Several series have reported long-term disease-free survival rates of approximately 35% to 50% for stage I to II patients treated with involved-field radiotherapy (RT), so it appears that many of these patients are cured, particularly patients with stage I disease and small disease size (<3 cm).[76–82] Studies with extended-field or total lymphoid RT, in an attempt to increase cure rates, have not shown convincing additional benefit. It is important to note that recent studies have shown that outcomes after RT in PET-CT–staged patients could be better than reported in earlier series, particularly in stage I disease (where cure rate can be as high as 74%), and although longer follow-up is needed, the curative potential of RT for truly localized FL may have been underestimated.[83]

The integration of chemotherapy with involved-field RT has shown promising results in some trials. Investigators at MDACC prospectively treated 85 patients with stage I or II FL with 10 cycles of COP-Bleo (cyclophosphamide, vincristine, prednisone, and bleomycin) or CHOP-Bleo (COP-Bleo plus doxorubicin) and involved-field RT "sandwiched" after the third cycle. The disease-free survival at 5 and 10 years was 80% and 72%, respectively—an apparent improvement over results with RT alone.[84] Analysis of the National LymphoCare Study also demonstrated improvement in progression-free survival (PFS) in patients who received systemic therapy in combination with RT.[85] In addition, a recently published randomized trial showed that systemic therapy with R-CVP after RT reduced relapse outside radiation fields and significantly improved PFS in early-stage FL.[86] Given the effects of RT on the tumor microenvironment—and in particular macrophages,[87] crucial for antibody-dependent cellular cytotoxicity—the combination of RT with rituximab is currently being investigated in clinical trials, particularly in patients with residual disease after RT.

In summary, early-stage FL appears to be potentially curable. The role of RT in these patients is well established, and involved-site RT remains the standard treatment (see Table 7–1). Larger extended-field or involved-field RT techniques targeting nodal regions

are no longer recommended; smaller techniques targeting involved nodal disease, termed *involved-site radiation therapy*, should be used.[81] However, when patients are treated with RT alone (without systemic therapy), the target volumes should be slightly more generous to also include nearby lymph nodes that might contain microscopic disease. These smaller fields have been validated in patients with FL treated with definitive RT, with no significant increase in regional relapses.[25,88] Despite the established role of RT and its endorsement by experts, RT appears to be underutilized in standard clinical practice.[85,89] Total lymphoid RT and combined-modality therapy approaches remain controversial and are seldom used.

MANAGEMENT OF ADVANCED-STAGE FOLLICULAR LYMPHOMAS

For decades, the treatment of patients with advanced-stage FL has been built on two pillars that lean in opposite directions. First, there are numerous effective therapeutic options that can induce remission (Table 7–2); second, relapse appears to be inevitable. If and when therapeutic advances lead to more comprehensive control of FL, then there may be a consensus about early intervention, because a smaller tumor burden would presumably be more easily treatable, analogous to the stage I or II situation. Until then, it is still the case that deferral of therapy is a common consideration for many asymptomatic patients with low tumor burden.

When treatment is appropriate, there are a number of considerations in choosing an initial management strategy. With advances in supportive care, we have seen improvement in the tolerability of chemotherapy and SCT. With a better understanding of B-cell lymphomagenesis and the role of the microenvironment, noncytotoxic therapeutic strategies are being incorporated into frontline clinical trials. The range of therapeutic options for patients with advanced-stage FL remains broad (see Table 7–2). The therapeutic goals continue to focus on minimizing toxicity, providing palliation, and attaining durable CR. Consideration of a clinical trial when available is advisable.

Table 7–2 Standard Frontline Strategies for Follicular Lymphoma

Stages I-II	Deferral of therapy (for older and/or infirm patients) Radiation therapy
Stage III-IV Low tumor burden	Deferral of therapy (if no threatening disease) Rituximab
Stages III-IV High tumor burden	Rituximab-CHOP Obinutuzumab-CHOP Rituximab-bendamustine Obinutuzumab-bendamustine Rituximab-lenalidomide Obinutuzumab-lenalidomide

CHOP, cyclophosphamide, adriamycin, vincristine, and prednisone.

Frontline Treatment of Low Tumor Burden FL

For patients with asymptomatic FL with a low tumor burden, deferment of therapy until development of symptoms or tumor burden becomes high has been accepted based on three randomized trials demonstrating survival rates equivalent to those of patients treated with immediate therapy in the prerituximab era.[90–92] With the long-term safety and efficacy of rituximab established, observation has been challenged in the modern era with rituximab monotherapy in patients with low tumor burden. The goal is to delay the first cytotoxic chemotherapy and to have an impact on health-related quality of life.

The findings of a randomized trial of rituximab versus a watch-and-wait approach in asymptomatic, patients with nonbulky FL suggested that patients who received rituximab monotherapy had a delay in progression compared with those with an initial watch-and-wait approach.[93] Those who received rituximab maintenance after rituximab induction also reported improved quality of life, mainly because of a decrease in anxiety. No significant difference in OS was reported.

The Rituximab Extended Schedule or Retreatment Trial was a randomized cooperative group study evaluating two dosing strategies of rituximab monotherapy in patients with untreated grade I or II FL and low tumor burden.[94] There were 289 patients randomly assigned to receive either rituximab maintenance or retreatment after responding to rituximab induction (4 weekly doses). The median time to treatment failure was similar (3.9 vs 4.3 years), quality of life was similar, and significant toxicity was infrequent among both strategies. For patients with FL with a low tumor burden, rituximab monotherapy followed by a retreatment strategy was associated with less rituximab use while providing comparable disease control to that achieved with a maintenance strategy.

For patients with untreated FL of low tumor burden not eligible for a clinical trial or for more intensive therapy, an initial management strategy of rituximab monotherapy was associated with a delay in the need for cytotoxic therapy, was well tolerated, and was perceived by some to enhance their health-related well-being. Hence, the decision between observation and rituximab monotherapy should be made after a

detailed discussion with the patient about the goals of treatment. Because clinical studies have shown that low levels of vitamin D are associated with worse outcomes in patients with B-cell NHL, and in light of its pleotropic antitumoral effect, the combination of vitamin D with rituximab is currently being investigated in a multicenter phase 3 randomized trial in patients with low tumor burden FL.[95]

Frontline Treatment of High Tumor Burden FL

Several trials have convincingly shown that the addition of rituximab to chemotherapy leads to improved outcomes in FL (Table 7–3). Incorporation of rituximab has become standard. Suitable partners for rituximab in induction regimens include cyclophosphamide, vincristine, and prednisone (CVP); cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP); and bendamustine (B). Few randomized studies have been conducted to inform selection of frontline chemoimmunotherapy. Bendamustine-rituximab (BR) has been compared with R-CHOP in two randomized trials: the Study group indolent Lymphomas study in Europe and the BRIGHT study in the United States. In both studies, and with extended follow-up, BR was better tolerated and modestly more effective than R-CHOP.[100,101] Retrospective studies conducted at MDACC, however, show that R-CHOP may be a better frontline option than BR for patients with elevated SUVmax, also in absence of histologic evidence of transformation.[47,48]

A randomized study comparing R-CVP versus R-CHOP versus R-FM (fludarabine and mitoxantrone) reported R-CHOP and R-FM were superior to R-CVP in regard to time to treatment failure and PFS; however, both, particularly R-FM, were associated with a higher rate of adverse events.[102] Therefore, the latter is not currently used in standard practice. To improve the efficacy of chemoimmunotherapy, novel anti-CD20 monoclonal antibodies in combination with chemotherapy have been investigated in patients with high tumor burden FL. In a randomized phase III trial, named the GALLIUM study, obinutuzumab was compared with rituximab in combination with chemotherapy in patients with previously untreated FL; obinutuzumab was associated with a significantly longer PFS, despite a higher incidence of late myelosuppression, particularly when combined with bendamustine.[103]

Although the most common initial management strategy in the United States currently is chemoimmunotherapy, the paradigm is changing.[89] A phase II study conducted at MDACC reported the efficacy and safety of a novel, nongenotoxic strategy of rituximab and lenalidomide in untreated FL with high response rates (overall response rate [ORR] 98%, CR 87%) and manageable toxicity.[104] This study provided the rationale for conducting a large, global phase III, randomized study investigating rituximab chemotherapy (R-CVP, R-CHOP, or BR) versus rituximab-lenalidomide in patients with untreated FL, named the Rituximab Lenalidomide versus Any Chemotherapy (RELEVANCE) study. The primary end points were complete response (confirmed or unconfirmed) at 120 weeks and PFS, though only the former was mature enough and published. Among 1030 randomized patients, rituximab and lenalidomide were not superior to rituximab and chemotherapy, with a CR rate at 120 weeks of 48% and 53%, and a 3-year PFS of 77% versus 78%, respectively.[105] Although the efficacy results were similar, the safety profile differed, with less frequent grade 3 or 4 neutropenia and febrile neutropenia, but high rates of grade 3 or 4 cutaneous reactions in the rituximab and lenalidomide arm. Attempts to improve on this regimen by adding ibrutinib, an oral Bruton tyrosine kinase (BTK) inhibitor, to lenalidomide and rituximab have been limited by toxicity, particularly skin rash.[106,107] Recent data from a phase II study conducted at MDACC show that obinutuzumab in combination with lenalidomide was associated with

Table 7–3 Frontline Rituximab-Plus-Chemotherapy Trials in Indolent Lymphoma

favorable outcomes, with an impressive 2-year PFS of more than 90%, although a direct comparison with the combination of lenalidomide and rituximab is currently missing.[108] In the next few years, chemotherapy-free approaches could potentially become the standard frontline treatment for patients with high tumor burden FL.

MAINTENANCE AND CONSOLIDATION THERAPY

Rituximab maintenance (Table 7–4) has been widely used after frontline chemoimmunotherapy, with the goal of extending the disease-free interval after induction. A randomized study investigated the efficacy of two years of rituximab maintenance after rituximab plus chemotherapy in patients with previously untreated FL, named the (Primary RItuximab and Maintenance) PRIMA study.[62] Rituximab maintenance after chemoimmunotherapy with R-CHOP/R-CVP significantly improved PFS (HR [hazard ratio], 0.55; 95% CI, 0.44–0.68) and was generally well tolerated but had no impact on OS. Retrospective data have recently shown similar findings for patients receiving maintenance rituximab after frontline BR, the greatest benefit reported for patients who had not achieved CR at the end of chemoimmunotherapy.[109] Factors influencing the decision to pursue a maintenance strategy should include consideration of the patient's risk of early relapse, the response to induction therapy, and the financial burden of extended dosing.

A large multicenter, randomized trial of radioimmunotherapy (RIT) consolidation therapy has shown a significant failure-free survival benefit when used after a variety of induction therapy regimens.[110] Notably, the induction therapy included rituximab in only a minority of the patients. Still, the feasibility and impact of such a strategy is noteworthy. Prolongation of disease control was significant in subset analyses of both complete and partial responders to the induction therapy. Patients who attained only partial remission after chemotherapy commonly attained CR after RIT (77%) (Table 7–5).

Other trials have also studied RIT consolidation. A SWOG trial compared CHOP followed by RIT versus R-CHOP in patients with advanced-stage FL.[111] With a follow-up of 4.9 years, there was no significant difference in the two-year PFS (80% vs 76%) or OS (93% vs 97%) rates. With the benefits and safety profile of rituximab as part of induction or as maintenance established, the role of RIT in the modern era is unclear.

Table 7–4 Maintenance Rituximab

		Induction Response		↑ FFS With
	Induction	% CR	% PR	Maintenance[a]
A. Frontline trials	Rituximab	9	58	Yes
	CVP	13	60	Yes
	Various +R	—	—	Yes
B. Frontline retrospective studies	BR	41	18	Yes (for CR patients)

SALVAGE THERAPY

There are many effective therapeutic options for patients with relapsed disease, including chemoimmunotherapy, anti-CD20 monoclonal antibodies, targeted agents, immunomodulatory agents, and cellular therapies (Table 7–6).

Chemoimmunotherapy

Numerous non–cross-resistant chemotherapeutic agents can be effective in patients with indolent lymphomas. Typically, those agents not chosen for a patient's frontline treatment are candidates for salvage use. It is notable that retreatment of previously responsive patients with the same agents is a legitimate option. Long-term follow-up studies have shown that second and later responses can be attained, even with the same agents, but the ensuing clinical remissions become progressively more brief. Some physicians advocate the avoidance of the toxicities of certain agents (eg, doxorubicin or the nucleoside analogs) in the frontline setting; their role in the salvage setting is an important consideration.

Monoclonal Antibodies

The efficacy of single-agent rituximab has been demonstrated reproducibly, although most responses to salvage rituximab show PR rather than CR. Attempts at improving the rate of CRs and enhancing the duration of response are evolving.

Newer anti-CD20 MAbs are being investigated, with modifications that theoretically represent enhancements over rituximab, such as fully humanized MAbs as opposed to a chimeric mouse–human construct; MAbs with enhanced capacity for mediation of complement-dependent cytotoxicity; MAbs with enhanced mediation of antibody-dependent cellular cytotoxicity; and other modifications. In this regard, in a phase III randomized study comparing obinutuzumab (combined with bendamustine) followed by single-agent obinutuzumab maintenance to single-agent bendamustine, a significantly longer PFS was observed (29 vs 14 months) with the addition of obinutuzumab; these results led to its FDA approval for patients with rituximab-refractory relapsed FL.[112]

Monoclonal antibodies that target antigens other than CD20 have been developed, including those used alone and as immunotoxins, the latter link a toxin to an antibody that delivers the toxin to the lymphoma cells, analogous to the delivery of isotopes with RIT. These agents include polatuzumab vedotin (targeting CD79b) and tafasitamab (monoclonal antibody targeting CD19). Polatuzumab has been investigated in combination with rituximab in a randomized phase II study (termed ROMULUS) and in combination with obinutuzumab and lenalidomide in a phase I/II study. Tafasitamab has been studied as a single agent in a phase II study; all studies showed a promising safety and efficacy signal.[113–115]

Targeted Agents

Many therapeutic options under study in the past decade have been developed against specific cell growth regulatory pathways. These agents include those targeting the B-cell receptor pathway, such as BTK inhibitors (eg, ibrutinib) and phosphatidylinositol-3-kinase (PI3K) inhibitors (eg, idelalisib); agents targeting apoptosis, such as BCL2 inhibitors (eg, venetoclax); and agents targeting epigenetic regulators, such as EZH2 inhibitors (eg, tazemetostat).

Single-agent ibrutinib has been investigated as a treatment for patients with relapsed FL in one phase I and in two phase II studies; although it was shown to be safe and well tolerated, the ORR was only 21% to 37.5% and the CR rate was only 11% to 12.5%, thus ibrutinib is not currently approved for this indication.[116–118] Acalabrutinib, a more potent and specific oral BTK inhibitor than ibrutinib, is being currently investigated as a single agent and in combination with rituximab in patients with relapsed FL. Although it has been shown to be safe, only more mature follow-up will shed light on its activity in this setting.[119]

The efficacy of the oral PI3Kδ inhibitor idelalisib has been investigated for the treatment of patients with relapsed FL (previously exposed to both rituximab and an alkylating agent) in a phase II study, showing an ORR of 56%, a CR rate of 6%, and a median PFS of 11 months.[120] Similar results have been observed for the oral PI3Kαγ inhibitor duvelisib and the intravenous

PI3Kαγ inhibitor copanlisib.[121,122] Based on the efficacy of these agents, and in light of dis-immune toxicity, more pronounced in less heavily treated patients, all three agents are currently approved for third-line treatment of patients with relapsed FL. In addition, efforts are ongoing to identify potentially safer PI3K inhibitors, such as umbralisib.[123,124]

Despite BCL2 translocation and overexpression being the hallmark of FL, its inhibition with the oral BCL2 inhibitor venetoclax has not been successful, with an ORR of 38% and a CR rate of 15% in the relapsed setting.[125] Multiple attempts are now ongoing to identify alternative antiapoptotic proteins as targets for future trials.[21]

Finally, given the frequency of mutations in genes involved in epigenetic regulation in FL, targeted inhibitors of this pathway have been investigated. Tazemetostat is a first-in-class, selective, oral EZH2 inhibitor that has demonstrated antitumor activity in patients with relapsed FL, independently from the presence of an EZH2 mutation. In a multicenter, open-label phase I/II study including 90 patients with relapsed FL, 45 with mutated EZH2 and 45 with WT EZH2, ORR was 98% and 71%, respectively, with a median PFS of 14 months and 11 months, respectively.[126,127] Based on these data, a new drug application for accelerated approval has been recently submitted to the FDA.

Immunomodulatory Agents

As previously discussed, immune modulation is an attractive approach for patients with indolent lymphoma. The activity of lenalidomide in combination with rituximab has been investigated as treatment for patients with relapsed FL in a key phase II study, yielding an ORR of 76% and a CR rate of 35%.[128] These results were followed by a randomized phase III study, termed the AUGMENT study, in which the combination of lenalidomide and rituximab was compared with single-agent rituximab. The results showed a significantly prolonged duration of response (39 vs 14 months), leading to its FDA approval for this patient population.[129] Obinutuzumab instead of rituximab has been recently investigated in combination with lenalidomide in patients with relapsed FL in two phase II studies, showing an ORR as high as 98%, and a CR rate as high as 72%, representing a viable therapeutic option in clinical practice for these patients.[130]

Enhancement of the endogenous antitumor response by targeting the microenvironment may be achieved with immune checkpoint inhibitors, such as anti-PD1 MAbs. The activity of pidilizumab with rituximab has been investigated in 32 patients with relapsed FL and reported an ORR of 66% and CR rate of 52% with no autoimmune or treatment-related grade 3 or 4 adverse events.[131] An alternative, antitumoral activity can also be achieved through enhancement of the macrophage component of the tumor microenvironment. This aim has been achieved through inhibition of CD47, a "do not eat me" signal that FL cells provide to macrophages. In a phase I/II study employing the combination of 5F9, an intravenous anti-CD47 antibody, and rituximab in patients with relapsed FL, there was an ORR of 71% and a CR rate of 43%, supporting the development of novel ongoing experimental combinations for these patients.[132]

Cellular Therapy

Stem cell transplantation approaches can be arduous but deserve strong consideration in patients with recurrent high-risk FL. Autologous SCT strategies result in substantially more durable remissions than conventional-dose salvage therapy, particularly for patients with POD24.[133,134] Allogeneic SCT is a strategy that is contingent on availability of a donor, and is a complex undertaking that includes substantial risks of treatment-related mortality. Nonetheless, allogeneic SCT not only can result in long-term remission but can potentially lead to cure, presumably through its graft-versus-lymphoma effect. Data suggest that nonmyeloablative allogeneic SCT is associated with less toxicity than conventional myeloablative allogeneic SCT, and augmentation of the conditioning regimen, including incorporation of bendamustine, has resulted in reduced myelosuppression and graft-versus-host disease.[135] With improved tolerance of SCT and the potential for cure, this remains a management strategy for eligible patients, and can be preferred to autologous SCT, particularly in patients with bone marrow involvement. It is important, however, to remember that nonrelapse mortality is significantly higher for allogeneic compared with autologous SCT, and for matched unrelated donors compared with matched-sibling donors.[136] Chimeric antigen receptor (CAR) T-cell therapy may represent a more effective and safer alternative to SCT: two phase II studies investigating its use for patients with relapsed FL have completed accrual, and results are eagerly awaited. Early promising results have been reported for the bispecific antibody mosunetuzumab, bringing together CD3+ T cells to CD20+ FL cells, and triggering antitumoral activity similar to what is observed with the use of chimeric antigen receptor T-cell therapy.[137]

Palliative Treatment

Palliative treatment for patients with FL can include involved-site RT to sites of problematic or painful disease (eg, for obstructive uropathy). In this setting, it is important to consider the use of lower RT doses (eg, 4 Gy), because prior studies have confirmed

high response rates even with low-dose RT.[138] This approach also minimizes treatment-related toxicity. Among chemotherapy options, one historically mild option is chlorambucil. Observation without therapy is also an option, even at the time of initial diagnosis, in patients with active but no threatening or symptomatic disease. The approach of deferral of therapy is common, but it should be done thoughtfully and with monitoring. Older patients are often selected for a "watch-and-wait" strategy, but this option should be weighed against the observation that older patients with FL have a tenfold increased risk of dying within one year compared with age-matched controls.[58]

Finally, consideration of a clinical trial in the setting of relapsed or refractory FL is strongly recommended given the vast trial options available and evolving management strategies, particularly for patients with POD24.

CONCLUSIONS

To date, most advanced-stage indolent B-cell lymphomas, including FL, remain incurable. Novel approaches to therapy continue to be explored, including next-generation MAbs, pathway inhibitors, and immune modulators. These approaches to therapy and novel combinations will likely play an increasingly important role in the management of patients with indolent FL. Allogeneic transplantation in indolent FL continues to be an area of heightened interest, especially with the development of more effective and better tolerated cellular therapies. As emerging therapies become integrated with the best of conventional therapies, it is optimistic that a curative approach for more patients with indolent FL is achievable. Equally promising is widespread use of well-tolerated therapy that is associated with durable disease control, resulting in chronic management. Also worthwhile of clinical exploration is identifying the most effective sequencing of therapy over an individual's disease course. With so many unanswered questions and emerging novel strategies, consideration of clinical trials for FL is strongly recommended to facilitate the translation of important scientific breakthroughs.

MD ANDERSON PRACTICE TIPS

- Although the Follicular Lymphoma International Prognostic Index (FLIPI) score has prognostic value and can help guide frequency of surveillance and stratification strategies for clinical trials, it has no predictive value and should not be used to determine initiation of treatment or treatment selection.
- There is currently no universal agreement about the optimal treatment of patients with FL grade 3A; an elevated Ki-67 (>40%) may help identify those in need of anthracycline-based approaches.
- The selection of bendamustine and rituximab compared with lenalidomide and rituximab as frontline treatment for patients with advanced-stage FL and high tumor burden should be driven by patient comorbid health conditions and preferences (chemotherapy vs immunotherapy; 6 months vs 18 months of treatment; insurance coverage).
- In young patients without significant comorbid health conditions, obinutuzumab should be considered over rituximab in combination with frontline chemoimmunotherapy, given improved survival in the GALLIUM study.
- Elevated SUV on PET-CT scan may identify patients with FL who would benefit from an anthracycline-based regimen.
- Outcomes among patients with FL experiencing disease progression within 24 months of frontline chemoimmunotherapy remain suboptimal, and experimental approaches are preferred in these patients.

8 Marginal Zone and Other Small Cell Lymphomas

Melody Becnel
Felipe Samaniego

KEY CONCEPTS

- Marginal zone lymphoma (MZL) is an indolent B-cell non-Hodgkin lymphoma composed of three subtypes: extranodal (mucosal-associated lymphoid tissue [MALT] lymphoma), splenic, and nodal.
- MALT lymphoma, the most common subtype, is composed of gastric and nongastric MALT and is often associated with infectious organisms such as *Helicobacter pylori*.
- Nongastric MALT is often associated with inflammatory conditions such as Sjögren syndrome and Hashimoto thyroiditis.
- Translocations well characterized in MALT lymphomas include t(11;18), t(14;18), t(1;14), and t(3;14). No unique recurrent chromosomal abnormalities are noted in nodal MZL. *MYD88* L265P mutations (as seen in Waldenström macroglobulinemia) have been identified in 10% to 20% of cases of splenic MZL.
- WHO classification restricts small lymphocytic lymphoma (SLL) to tumors involving lymph nodes with the same B-cell immunophenotype as CLL without leukemic involvement and considers SLL to be the nodal or tissue counterpart of chronic lymphocytic leukemia (CLL).
- Abnormalities of the *p53* or *MYC* genes correlate with increased risk of histologic transformation (Richter syndrome) and poorer prognosis in CLL/SLL.

MARGINAL ZONE LYMPHOMA

Marginal zone lymphoma (MZL) is the second most common B-cell–indolent non-Hodgkin Lymphoma (NHL; <10% of NHL cases in adults). MZL generally presents at a median age of 60 years old, and women have a slightly increased propensity toward MZL developing compared with men.[1,2] There are three subtypes of MZL: extranodal MZL of mucosa-associated lymphoid tissue (MALT lymphoma), which represents 7% to 8% of all NHLs; nodal marginal zone lymphoma, which represents approximately 2% of all NHLs; and splenic B-cell marginal zone lymphoma (SMZL), representing less than 1% of all NHLs.[3,4] Splenic MZL can be associated with circulating lymphocytes with villous cytoplasmic projections. The entity previously described as splenic lymphoma with villous lymphocytes is, in most cases, SMZL.

Extranodal Marginal Zone B-Cell Lymphoma

Clinical Features

Patients with MALT lymphoma present with extranodal disease that is often localized (stage I-E or II-E). There may be a history of infection or autoimmune disease, which are conditions that lead to chronic B-cell receptor activation.[5] Peripheral lymph node involvement is uncommon in patients with MALT lymphoma. The most common site of involvement is the stomach, but numerous other extranodal locations can be involved, including lung, skin, orbit, salivary glands, other parts of the gastrointestinal tract, thyroid gland, and other rare sites.[2] Dissemination occurs in up to 30% of cases, most often in patients with nongastric MALT lymphoma, and dissemination generally occurs to other extranodal sites. In patients with nongastric

MALT lymphomas, subclinical gastric involvement is not uncommon. The bone marrow is involved in only 10% to 20% of patients.

The stomach is the best-studied site of involvement. Patients often present with signs and symptoms suggestive of peptic ulcer disease, such as epigastric pain and dyspepsia. Anemia, weight loss, and gastrointestinal bleeding can be seen in patients with more advanced disease. *Helicobacter pylori* is present in the gastric mucosa of many patients with MALT lymphoma. Antibiotic elimination of *H pylori* has resulted in regression of MALT lymphoma in more than half of treated patients.[6,7] Thus, *H pylori* is thought to be essential to lymphomagenesis in gastric MALT lymphoma.

In nongastric MALT lymphomas, symptoms are related to the anatomic site involved. Disseminated disease is generally more common in these patients than in patients with gastric MALT lymphoma. Despite the higher frequency of stage IV disease, the five-year survival rate is 90% when treated with a variety of therapies.[2,5]

Histologic Features

Four findings are present in most MALT lymphomas: a population of neoplastic small lymphoid (centrocyte-like) cells that may have monocytoid features, occasional large lymphoid cells (blasts), lymphoepithelial lesions, and reactive lymphoid follicles (Figs. 8–1 through 8–3).[4]

The neoplastic small lymphoid cells exhibit a range of cytologic appearances. In some cases, the cells resemble small lymphocytes with or without plasmacytoid differentiation. In other cases, the neoplasm appears biphasic: one component is a population of small lymphoid cells, and the other is a population of cells with extensive plasmacytoid differentiation, resembling mature plasma cells (see Fig. 8–3). In some cases, the cells have markedly irregular nuclear contours and resemble small cleaved cells. All of these cell types may have abundant pale cytoplasm, imparting a

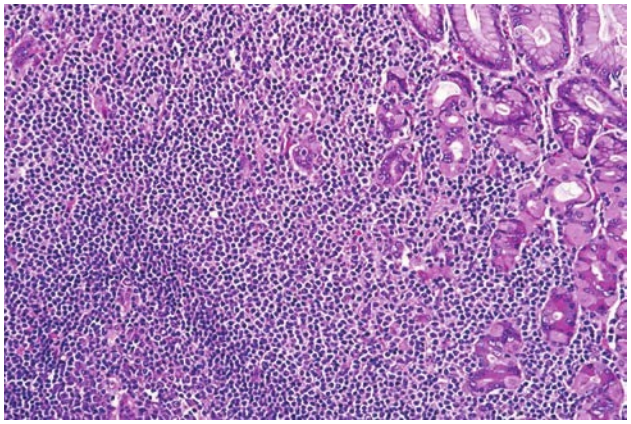

FIGURE 8–1 **Extranodal marginal zone B-cell lymphoma of MALT (MALT lymphoma) involving the stomach. The neoplasm partially replaces gastric mucosa and infiltrates epithelium. A reactive follicle is present at the bottom left of the field.**

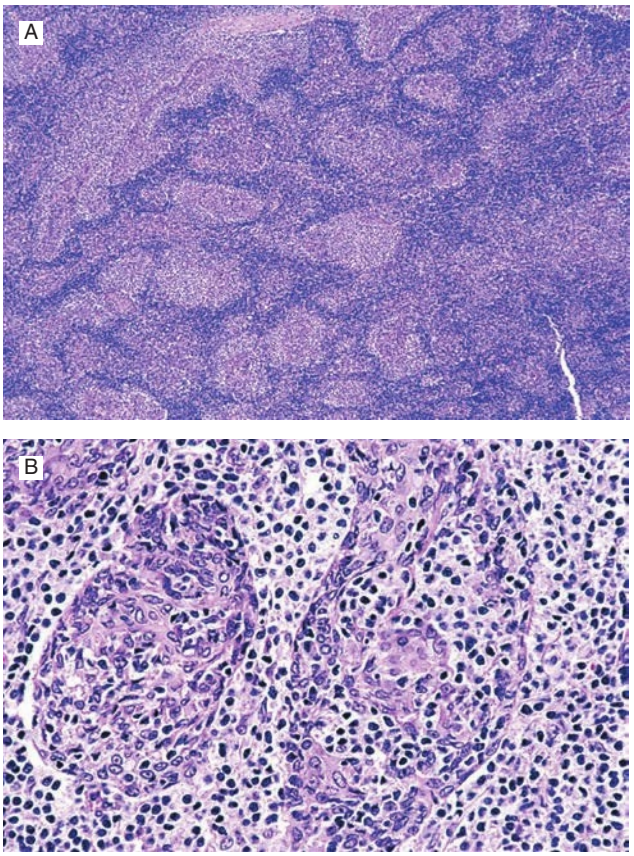

FIGURE 8–2 **A MALT lymphoma of a salivary gland. A. The neoplastic cells have a pale (monocytoid) low-power appearance and surround ducts. B. Lymphoepithelial lesions are prominent in this case (A, B, hematoxylin and eosin; A, ×20; B, ×400).**

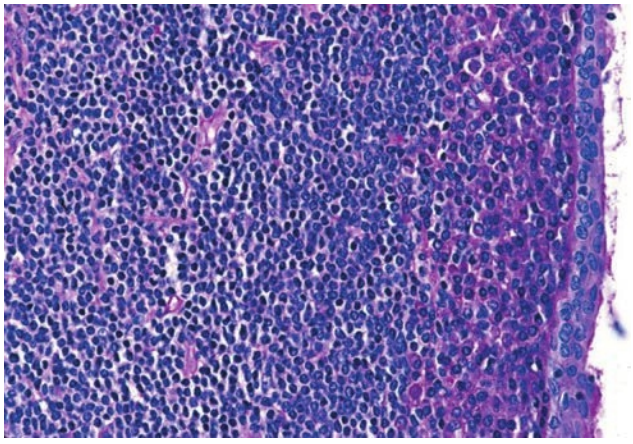

FIGURE 8–3 **A MALT lymphoma of the conjunctiva. In this field, the neoplasm has a biphasic pattern, with the subepithelial portion exhibiting extensive plasmacytoid differentiation (periodic acid–Schiff, ×400).**

Table 8–1 Translocations and Gene Abnormalities in MALT

Translocation	Tissues Involved	Genes Involved
t(11;18)	15%–40% of MALT, most commonly present in lung and stomach MALT	*BIRC3*, *MALT1* to form a fusion gene
t(14;18)	In 15%–20% of MALT; seen in nongastrointestinal MALT lymphoma	Juxtaposes *IGH* and *MALT1*, causing overexpression of *MALT1*
t(1;14)	In 1%–2% of MALT; seen in lung and stomach	Juxtaposes *BCL10* and *IGH*, truncating *BCL10* and causing loss of proapoptotic function
t(3;14)	Most commonly present in MALT of skin, thyroid, and ocular adnexal site	Juxtaposes *FOXP1* and *IGH*, causing overexpression of *FOXP1*

monocytoid appearance. In most MALT lymphomas, occasional large lymphoid cells (blasts) are also present. However, when large cells are numerous and form confluent sheets, the neoplasm has evolved to diffuse large B-cell lymphoma.[4]

The small neoplastic cells have a marked tendency to infiltrate epithelium, forming so-called lymphoepithelial lesions (see Fig. 8–2). In well-formed lesions, aggregates of neoplastic cells are found within the epithelium. Reactive lymphoid follicles are also usually present in MALT lymphomas, generally surrounded by neoplastic small lymphoid cells. Neoplastic cells can also accumulate in these follicles (termed *colonization*), imparting a vaguely nodular appearance at low-power magnification.[4]

Anatomic site–specific histologic findings are also observed in MALT lymphomas, involving chronic antigenic stimulation caused by the presence of either an infectious organism or autoimmune disease. For example, normal lymphoid tissue is not usually present in the stomach. However, some forms of MALT are acquired in response to *H pylori* infection. *Chlamydia psittaci, Borrelia burgdorferi*, and *Campylobacter jejuni* are other infectious agents that have been associated with orbital, skin, and small intestinal MALT lymphomas, respectively, although the data linking *B burgdorferi* to skin lymphomas do not appear to be strong. Like the stomach, normal lymphoid tissue is also poorly developed in the lung. However, two inflammatory diseases are frequently associated with lung MALT lymphoma: Sjögren syndrome and lymphoid interstitial pneumonia. Similarly, MALT lymphomas of the salivary gland are usually associated with Sjögren syndrome, and Hashimoto thyroiditis usually precedes MALT lymphoma of the thyroid gland.[8,9]

Immunophenotypic, Cytogenetic, and Molecular Features

The MALT lymphomas express monotypic immunoglobulin (Ig) light chain, pan–B-cell antigens, and Bcl-2. These tumors typically do not express IgD, CD10, CD21, CD23, Bcl-6, cyclin D1, or T-cell antigens, including CD5. Four chromosomal translocations are well characterized in MALT lymphomas: t(11;18), t(14;18), t(1;14), and t(3;14). The frequency of these translocations varies by anatomic site of the lymphoma, and each translocation results in dysregulation of specific genes (see Table 8–1).[8,10] Vinatzer et al identified additional chromosomal translocations or partner genes in MALT lymphomas, including t(1;14)/*IGH-CNN3*, t(5;14)/*IGH-ODZ2*, t(3;14)/*IGH-BCL6*, t(9;14)/*IGH-JMJD2C*, and t(6;7)(q25;q11).[8] The translocations alter signaling associated with proliferation or inhibit apoptosis. Activation of NF-κB may be a final common pathway in MALT lymphomas. API2-MALT1 is known to activate NF-κB. Similarly, overexpression of MALT1 or BCL10, by binding with each other, can form a complex in the cell and act to activate NF-κB.[11]

Workup and Management

The diagnosis of gastric MALT lymphoma and presence of *H pylori* is established by endoscopy, with multiple biopsies obtained from abnormal and normal mucosa.[6] Endoscopic ultrasound and computed tomography scans may also be helpful in determining the depth of the lesion and for staging. Early-stage disease can be successfully treated initially with antibiotic therapy, with complete regression in 35% to 100% of patients with a low rate of recurrence.[6,11] Therefore, the recommended therapy for stage I or II disease is a standard regimen of antibiotic therapy for *H pylori* with follow-up endoscopy two to three months later to document *H pylori* eradication. If patients remain *H pylori*–positive, a second-line anti-*Helicobacter* regimen is administered until the patient tests negative for *H pylori*. The time between *H pylori* eradication and complete remission of gastric MALT lymphoma varies and can take longer than one year. More extensive disease, as documented by endoscopic ultrasound demonstrating lymphoma involvement beyond the mucosa and in regional nodes, is less likely to respond

to antibiotic therapy.[6,12] Lack of response has been correlated with the presence of the t(11;18) translocation.[9]

Surgery, radiotherapy (RT), chemotherapy, and anti-CD20 monoclonal antibody therapy have been used for both gastric and nongastric types of MALT lymphomas and other MZLs. The treatment of choice is dependent on the site and stage of disease and the patient's clinical presentation. Surgery and RT are prime therapeutic approaches for localized MALT lymphoma, including gastric MALT lymphoma that does not respond adequately to antibiotic therapy and *H pylori*–negative disease.[12] Chemotherapy and monoclonal antibody therapy are also options for advanced-stage MZL. Conconi et al studied rituximab in patients with MALT lymphoma and found significant clinical activity in both untreated and relapsed patients.[13] By extrapolation from small lymphocytic lymphoma/chronic lymphocytic leukemia (SLL/CLL) data, combinations that include nucleoside analogues have been explored.[14] In recent years, nonchemotherapy treatment approaches have been explored, such as the use of the ibrutinib, a Bruton tyrosine kinase inhibitor that was FDA approved in 2017 for the treatment of MZL, and the immunomodulatory agent lenalidomide in combination with rituximab, which was FDA approved in 2019.[15–17] In addition, other targeted agents such as PI3 kinase inhibitors such as umbralisib (FDA granted breakthrough therapy designation.) and copanlisib have been explored.[18] The best systemic treatment option is not clear, but therapy for relapsed or extensive disease should be approached in the same manner as relapsed follicular lymphoma (refer to Chapter 7, Indolent Follicular Lymphomas).[9,12]

Nodal Marginal Zone Lymphoma

Clinical Features and Management

Patients with nodal MZL typically present with peripheral or para-aortic lymphadenopathy and bone marrow involvement. The five-year overall and failure-free survival rates are lower for patients with nodal MZL compared with patients with MALT lymphoma (56% vs 81% and 28% vs 65%, respectively). The majority of effective treatment regimens and outcomes of patients with nodal MZL are similar to that of patients with advanced follicular lymphoma (FL).

Histologic, Immunophenotypic, and Molecular Features

Nodal MZLs have a propensity to involve the marginal zones of a lymph node. In most cases, however, the neoplasm also expands into the perifollicular compartments with sparing of germinal centers, or it may completely replace lymph node architecture. The

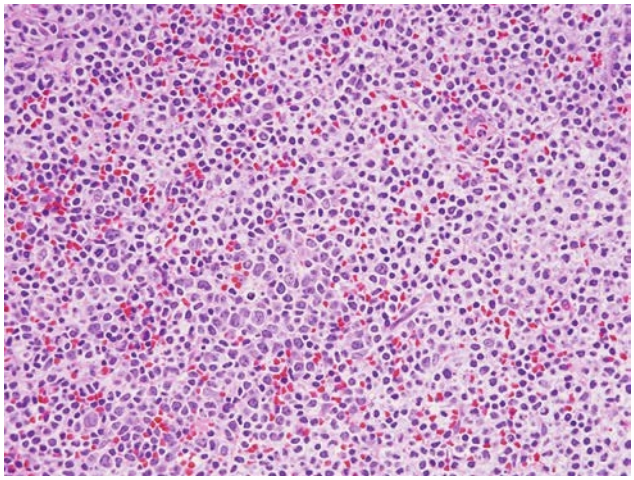

FIGURE 8–4 Nodal marginal zone lymphoma. In this field, the neoplastic cells have abundant pale cytoplasm and surround a reactive germinal center composed of large cells (center of field) (hematoxylin and eosin, ×400).

cytologic features of nodal MZL are the most distinctive aspect of this neoplasm. The tumor cell cytoplasm is relatively abundant and pale, with well-delineated cell borders (Fig. 8–4). The tumor cell nuclei are small, chromatin is relatively clumped, and mitotic figures are infrequent. Rare large cells are also present.[5]

Nodal MZLs are mature B-cell neoplasms that express monotypic Ig, pan–B-cell antigens, and Bcl-2. These tumors do not express CD10, CD21, CD23, BCL6, cyclin D1, or T-cell antigens, including CD5. Conventional cytogenetics and fluorescence in situ hybridization (FISH) studies have identified a variety of abnormalities, most often trisomy.[3] However, there are no unique recurrent chromosomal abnormalities in nodal MZL. The t(11;18), t(14;18), and t(1;14) have not been identified in nodal MZL5.

Splenic Marginal Zone Lymphoma

Clinical Features and Management

Patients with SMZL usually present with splenomegaly, cytopenias, and circulating malignant lymphocytes. They commonly have modest abdominal lymphadenopathy and bone marrow involvement. Monoclonal gammopathy, usually of IgM type, can be observed in 10% to 20% of patients. Peripheral lymphadenopathy and B-type symptoms are uncommon. The clinical course is indolent, with the five-year overall survival rate ranging from 65% to 78%.[19]

Approximately one third of patients with SMZL will never require therapy. Splenectomy is indicated in patients with symptomatic splenomegaly or cytopenias secondary to hypersplenism. If splenectomy is contraindicated, low-dose splenic irradiation may

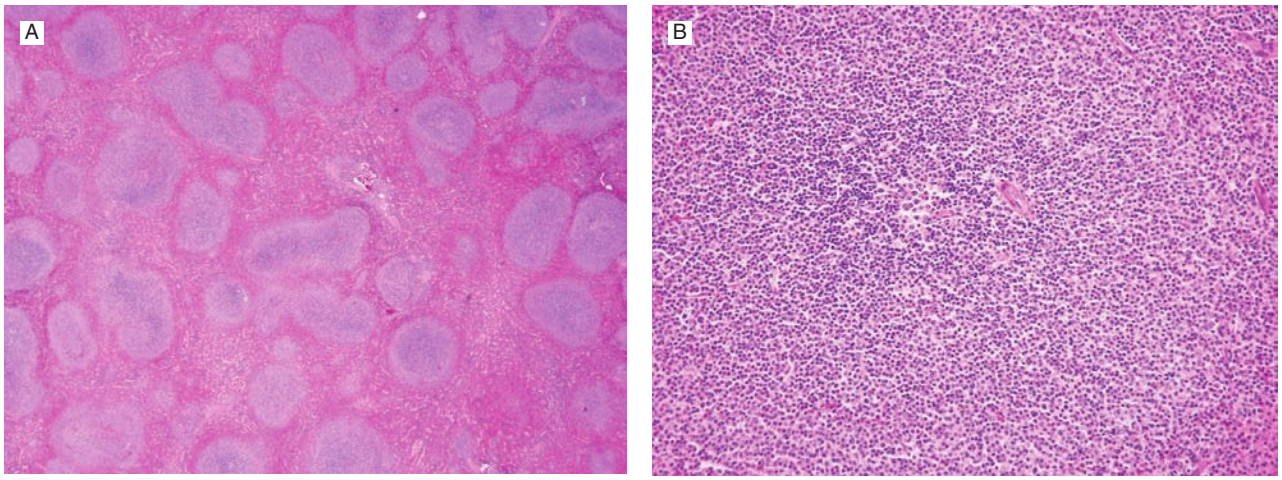

FIGURE 8–5 **Splenic marginal zone lymphoma. A. At low power, the white pulp of the spleen is markedly expanded by lymphoma, which has a biphasic pattern. B. One white pulp nodule at higher magnification (A, B, hematoxylin and eosin; A, ×20; B, ×200).**

be an alternative. Alkylating agents have been used, but responses are usually partial and not durable. Patients treated with fludarabine demonstrate a higher response rate and longer lasting remission than those treated with alkylating agents. Rituximab has significant activity in SMZL. In addition, in SMZL associated with hepatitis C, treatment of the underlying infection may be sufficient treatment for the lymphoma as well.[19]

Histologic, Immunophenotypic, and Molecular Features

In SMZL, the white pulp is expanded by a neoplasm that initially replaces the marginal and mantle zones and then eventually replaces the white pulp (Fig. 8–5). Lesser red pulp involvement is also usually present. At high-power magnification, the neoplastic cells are small lymphocytes with abundant pale (monocytoid) cytoplasm. The neoplastic cells may exhibit plasmacytoid differentiation. Occasional large lymphoid cells are present. In a peripheral blood smear, the neoplastic cells can have villous cytoplasmic projections.[19]

Splenic MZL is a mature B-cell neoplasm that expresses monotypic immunoglobulin, pan–B-cell antigens, and Bcl-2. A subset of cases is positive for IgD or CD5 (dim intensity detected by flow cytometry). These neoplasms are negative for CD10, Bcl6, cyclin D1, and T-cell antigens (other than CD5).

Conventional cytogenetics and FISH analysis have identified a variety of abnormalities, most often trisomy of chromosomes 3 and 7. Deletion of 7q is present in approximately 50% of cases. A recent study using array-based comparative genomic hybridization has demonstrated the presence of del(7q36.2) involving the sonic hedgehog (*SHH*) gene and del(7q31.32) involving the protection of telomere 1 (*POT1*) genes in SMZL.[20] *MYD88* L265P mutations have been identified in 10% to 20% of cases of SMZL and correlate with IgM gammopathy.[21]

SMALL LYMPHOCYTIC LYMPHOMA/ CHRONIC LYMPHOCYTIC LEUKEMIA

Small lymphocytic lymphoma represents approximately 7% of all NHLs.[3,4] The WHO classification restricts SLL to tumors involving lymph nodes with the same B-cell immunophenotype as CLL without leukemic involvement and considers SLL to be the nodal or tissue counterpart of CLL.[4] Cases of SLL and CLL combined represent about 12% of all B-cell NHLs.

Clinical Features and Management

Patients with SLL often present with asymptomatic lymphadenopathy. B symptoms are uncommon and are observed in less than 10% of patients. Splenomegaly is common. Bone marrow is often involved, affecting approximately 70% of patients.[3,4] Although the traditional staging systems for SLL and CLL differ, these systems share common features, and the prognosis of patients with SLL is similar to that of patients with CLL.

Management strategies for patients with FL and CLL are often applicable to patients with SLL, but there are some caveats (refer to Chapter 3, Chronic Lymphocytic Leukemia and Associated Disorders, and Chapter 7, Indolent Follicular Lymphomas). For instance, because CD20 is usually expressed at low levels in SLL/CLL, anti-CD20 antibody therapy for SLL may be better modeled on the results of studies in CLL

rather than the results of studies in patients with FL. Nonchemotherapy drug therapy consisting of venetoclax and obinutuzumab is FDA approved for SLL, with an overall response rate of 85%.

Histologic, Immunophenotypic, and Molecular Features

The lymph node architecture is diffuse and usually totally effaced by SLL/CLL4. The neoplastic cells are predominantly small, round lymphocytes. Vague pale areas composed of lymphocytes, prolymphocytes, and paraimmunoblasts, known as proliferation centers (or pseudofollicles), are usually present and are diagnostic of this neoplasm. In 5% to 10% of SLL/CLL cases, residual reactive lymphoid follicles are present, surrounded by neoplasm; this represents the so-called interfollicular pattern of SLL/CLL. In this morphologic variant, proliferation centers can surround benign follicles, mimicking nodal MZL.

The SLL/CLL cells express monotypic immunoglobulin light chain, IgM, usually IgD, pan–B-cell antigens, and Bcl-2. CD23 is usually positive in 90% to 95% of cases, and CD22, CD79B, and FMC7 are negative in most cases. The density of Ig and CD20 antigen expression on the surface of SLL/CLL cells is characteristically low ("dim" immunofluorescence by flow cytometry). These neoplasms almost invariably express the CD5 antigen, a pan–T-cell antigen that is not expressed on normal B cells. Other T-cell antigens are not expressed4. CD38 and ZAP70 are expressed in a subset of cases, and expression correlates with unmutated Ig genes and poorer prognosis.[22] The neoplastic cells are negative for CD10 and Bcl-64.

Conventional cytogenetic analysis has shown chromosomal abnormalities in 50% to 60% of SLL/CLL cases. This low frequency is partly attributable to poor cell growth in culture. Translocations involving the Ig genes are rare in SLL/CLL. The t(14;19)(q32;q13) translocation involving the *BCL3* gene at 19q13 is most common but is present in less than 5% of SLL/CLL cases. The t(14;19) translocation is associated with atypical morphologic or immunophenotypic features and a poorer prognosis.[23]

FISH analysis has shown a higher frequency of abnormalities in SLL/CLL because this technique can assess interphase as well as metaphase nuclei and does not require cell growth in culture. At our center, SLL/CLL cases are routinely assessed by FISH with a panel of probes, including those specific for 6q, 11q (ATM), trisomy 12, 13q14, and 17p (p53). Deletion of the 13q14 locus is the most common abnormality in SLL/CLL. Trisomy 12 is detected in approximately 15% to 20% of cases and appears to be a secondary event, because it is usually found in only a subset of the neoplastic cells.[24] Both del (11q) has been correlated with poorer prognosis. Abnormalities of the *p53* or *MYC* genes correlate with increased risk of histologic transformation (Richter syndrome) and poorer prognosis.

MD ANDERSON PRACTICE TIPS

- Many patients with MZL and SLL present asymptomatically. There are currently no data to suggest that the early initiation of treatment leads to improved overall survival; therefore, a close observation approach is indicated in many patients as is the case with other low-grade lymphomas.
- Patients with gastric MALT often present with symptoms of gastroesophageal reflux disease and abdominal pain. In addition to endoscopic evaluation, *H pylori* testing and advanced imaging is important to determine the extent of disease.
- Localized *H pylori*–positive gastric MALT is treated with triple or quadruple antibiotics targeting *H pylori*. Treatment should be continued until the patient is negative for *H pylori*. More extensive disease and patients with translocation t(11;18) may not respond to antibiotics alone and may need systemic treatment extrapolated from studies of FL.
- Nodal MZL should be treated in the same manner as FL.
- Splenic MZL that is associated with hepatitis C should be first managed by treating the hepatitis C. Rituximab is the treatment of choice in most cases of splenic MZL; splenectomy can be considered in specific circumstances such as symptomatic splenomegaly and refractory cytopenias cause by splenic sequestration.
- In SLL, abnormalities of the *p53* or *MYC* genes correlate with increased risk of histologic transformation (Richter syndrome) and poorer prognosis.

9 Aggressive B-Cell Lymphomas

Raphael Steiner

L. Jeffrey Medeiros

KEY CONCEPTS

- Evaluation of pretreatment prognostic factors of diffuse large B-cell lymphoma (DLBCL) includes scores such as the International Prognostic Index (IPI); cell-of-origin (germinal center B-cell subtype [GCB] and activated B-cell [ABC] subtype); genetic profiling (such as fluorescence in situ hybridization studies [FISH] for *MYC* rearrangement, if *MYC* rearrangement is detected, additional FISH studies for *BCL2* and *BCL6* rearrangements should be performed); and immunophenotypic studies (such as *MYC, BCL2*, and *BCL6 expression)*.
- The baseline workup of aggressive B-cell lymphoma should not omit testing for hepatitis B and HIV, echocardiogram, or multigated acquisition scan (if planned therapy with anthracycline), and fertility counseling for eligible patients.
- Besides a clinical trial, the standard-of-care frontline therapy of DLBCL not otherwise specified is still rituximab cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP). However, many studies are ongoing to outperform this combination.
- The treatment plan of aggressive B-cell lymphoma should evaluate the potential need for central nervous system (CNS) prophylaxis for patients presenting with the following risk factors: elevated CNS-IPI (age >60 years, Eastern Cooperative Oncology Group [ECOG] Performance Status ≥2, extranodal disease >1 site, stage III/IV, elevated lactate dehydrogenase, kidney/adrenal involvement); extranodal disease with testicular, uterine, breast, epidural, skin involvement); aggressive B-cell lymphoma subtypes (Burkitt lymphoma, double/triple-hit lymphoma/high-grade B-cell lymphoma, double-expressor lymphomas, HIV-associated lymphoma, DLBCL with ABC subtype, intravascular DLBCL, CD5+ DLBCL, IgM-secreting DLBCL).
- The baseline workup of a suspected primary CNS lymphoma should include magnetic resonance imaging (MRI) of the brain and biopsy of the lesion, search for additional disease sites, such as testicular ultrasound for men >60 years old, full ophthalmologic examination including slit-lamp eye examination, spine MRI, positron emission tomography/computed tomography (PET/CT) scan, and bone marrow biopsy.
- The optimal frontline therapy of Burkitt lymphoma has yet to be defined in a prospective randomized trial, but R-CHOP is not an adequate therapy. If a patient cannot be enrolled in a clinical trial, aggressive combination chemotherapy such as R-Hyper-CVAD/MA, R-CODOX-M/IVAC, or DA-EPOCH-R with adequate CNS prophylaxis is recommended.

It is clinically useful to divide B-cell non-Hodgkin lymphomas (NHLs) into indolent and aggressive groups based on their clinical behavior.[1] Patients with indolent NHLs typically have a survival of many years, even if the NHL is untreated, but paradoxically, the NHLs are usually incurable. Patients with aggressive NHL have a survival time measured in weeks to months if untreated yet the NHLs are usually chemosensitive and frequently curable. In this chapter, we focus on the clinical characteristics, pathology, and treatment of aggressive B-cell NHLs.

EPIDEMIOLOGY

Globally, lymphoma incidence rates have declined slightly (0.3% per year) since 2001 in females and since 2004 in males in the US. Earlier, lymphoma incidence

rates increased steadily during the 1970s and 1980s, leveled off in the 1990s, and began a slight decline by the end of that decade. This drop, independent of HIV infection may in part reflect International Classification of Diseases coding changes in 2001, when the World Health Organization (WHO) classification system was first published.[2]

Among mature lymphoid neoplasms, the fastest increase over the 12-year period from 2001 through 2012 was for plasma cell neoplasms. The trend in increasing body size may partly explain this increase, because obesity was steadily increasing over this time period and is a risk factor for plasma cell neoplasms.[2] In 2020, the American Cancer Society estimated that 77,240 individuals would be diagnosed with NHL in the United States during the year, and 19,940 patients would succumb to disease.

Diffuse large B-cell lymphoma (DLBCL), the most common NHL subtype, has an aggressive behavior and is more common in Whites than African Americans in the United States; however, 5-year survival outcomes are worse in African Americans.[3,4]

ETIOLOGY

Most cases of aggressive B-cell NHL do not have a well-defined etiology. Recent work has shown that the lifetime risk for many cancers correlates with the total number of divisions of normal self-renewing cells.[5] The implications of these findings suggest that many cancers may not be caused by hereditable genetic aberrancies, environmental exposures, infectious etiologies, or other known causes, but instead are attributable to a combination of factors that may include chance. For the NHLs that appear to have currently identifiable drivers, there are five groups of drivers: immune suppression (both acquired and primary), infectious agents, toxic exposure, lifestyle, and familial factors (Table 9–1). Moreover, risk factors may be different for children and adults.[2]

Most cases of DLBCL not otherwise specified arise de novo (referred as primary) but can also represent a transformation of an indolent/less aggressive lymphoma, such as chronic lymphocytic leukemia/small lymphocytic lymphoma, follicular lymphoma, marginal zone lymphoma or nodular lymphocyte-predominant Hodgkin lymphoma.[6]

Immunosuppression

The strongest association with aggressive B-cell NHLs is immune suppression, both primary and acquired.[7] Examples of primary immunodeficiency include inherited immune disorders, such as Wiskott-Aldrich syndrome, severe combined immune deficiency, common variable immune deficiency, and ataxia-telangiectasia.[8] These diseases and other inherited disorders are associated with an increased lifetime risk of developing NHL, with aggressive B-cell NHL being most common.

Patients who are immunosuppressed for therapeutic reasons—for example, after organ transplantation—are also at increased risk of NHL, especially if the disease is treated with cyclosporine, azathioprine, prednisone, or monoclonal antibodies for the removal of T cells.[9] A loose association can be drawn between the level of immune suppression and lymphoma risk. Transplant patients treated with the highest doses of immunosuppressive agents, such as heart transplant recipients, are at greater risk of lymphomas developing. These lesions are also more likely to be aggressive and are often extranodal forms. Individuals treated with pharmacologic immune suppression for autoimmune disorders—such as systemic lupus erythematosus, Sjögren syndrome, or rheumatoid arthritis—are also at increased risk for NHL, including the tumor necrosis factor antagonists.[10] A subset of these NHLs is histologically aggressive and associated with Epstein-Barr virus (EBV) infections. These

Table 9–1 Risk Factors Associated With Aggressive Non-Hodgkin Lymphomas

Inherited and acquired immune deficiency
– Wiskott-Aldrich syndrome
– Ataxia-telangiectasia
– Chédiak-Higashi syndrome
– X-linked immunoproliferative disorder
– Severe combined immunodeficiency
– Common variable immune deficiency
– Iatrogenic immune suppression
– Solid organ or bone marrow transplant
Toxic exposures
– Prior chemotherapy
– Phenoxyherbicides
– Dioxin
– Radiation or radiation therapy
Infectious exposures
– Epstein-Barr virus
– Hepatitis C virus
– Human T-cell leukemia/lymphoma virus
– Human herpesvirus type 8 (HHV-8)
– HIV
Lifestyle
– Higher young-adult body mass index
Autoimmune disorders
– Sjögren syndrome
– Celiac sprue
– Systemic lupus erythematosus
– Rheumatoid arthritis

lesions may regress after withdrawal of the immunosuppressive agent, speaking to a complex interaction between the immune system and an immune clonal population.[11]

Infectious Exposure

Infectious agents associated with development of aggressive B-cell NHLs include HIV, EBV, human herpesvirus type 8, and human T-cell lymphotropic virus type 1.[12] The greatest factor involved in the worldwide increase in NHLs, although lessened with the advent of highly active antiretroviral therapy, is HIV infection. The risk of NHL is increased by up to 300% in untreated HIV-infected patients, rising in proportion to the duration of the HIV infection. Although the risk of NHL in HIV-infected patients appears to be decreased by highly active antiretroviral therapy, the relative risk of NHL in these patients remains much higher than that for those not infected with HIV. Aggressive B-cell NHLs can occur in HIV-infected patients at any stage of infection, but the risk increases as CD4 counts drop to $<100 \times 10^3/\mu L$. In addition, Burkitt lymphoma (BL), DLBCL arising in the CNS, and DLBCL–immunoblastic variant are considered as AIDS-defining illnesses.[13–15] Further information can be found in the Chapter 52 on acquired immunodeficiency syndrome–related cancers.

EBV also plays a role in lymphomagenesis, in part because of chronic antigenic stimulation.[16] EBV is virtually always associated with certain types of NHL, such as endemic BL and extranodal T-cell/natural killer (NK)-cell lymphoma of nasal type, with many other NHL types occasionally positive for EBV. Many patients with HIV-related lymphomas are coinfected by EBV, including HIV-associated primary CNS lymphoma, which is infected in essentially 100% of cases.[17]

Hepatitis C virus has been associated with different types of B-cell NHL, notably marginal zone lymphomas, lymphoplasmacytic lymphoma, and DLBCL.[18,19]

Human herpesvirus type 8 (HHV8) is associated with primary effusion lymphoma (PEL), which tends to occur in HIV-infected patients, but also occurs less often in endemic geographic regions (eg, sub-Saharan Africa). Human T-cell lymphotropic virus type 1 is integrated into the genome of the neoplastic cells of adult T-cell lymphoma/leukemia.

Toxic Exposure

Environmental and occupational exposures to toxins are associated with an increased risk of NHL. Herbicides have been implicated.[20] Occupations held by individuals reported to be at increased risk for NHL include farming, metalworking, forestry, aircraft maintenance, woodworking, and dry cleaning. One of the common exposures in these industries is the use of organic solvents.[21]

Lifestyle and Family History

Higher body mass index in young adults has been described as a risk factor for DLBCL.[19] Family history of NHL is also a potential risk factor for some types of NHL. Individuals who have relatives with NHL may be at a slightly higher risk of acquiring NHL, but data are inconclusive and mechanisms are unclear.[22]

CLINICAL PRESENTATION

The clinical presentation of patients with aggressive B-cell NHL varies substantially based on histologic type and anatomic site of disease. The likelihood of B symptoms, including fever greater than 38 °C, night sweats, or weight loss more than 10% of body weight in the preceding 6 months, increases with NHL aggressiveness.[23] Approximately 13% to 53% of patients present with these B symptoms, often with fatigue, malaise, and pruritus, although these are less common initially.[24]

Most patients present with painless lymphadenopathy, which is often first treated with antibiotics for presumed infection and then eventually lymph nodes are biopsied when lymphadenopathy fails to regress. The most common scenario involves a diagnosis based on examination of peripheral lymph nodes, which may be detectable before internal lymph nodes become enlarged and cause symptoms. Peripheral lymph nodes are not usually painful, unless they enlarge rapidly or are massive. Symptoms vary with the anatomic site of internal lymphadenopathy. Patients with mediastinal lymphadenopathy frequently experience cough, chest pain, and, less commonly, superior vena cava syndrome. Patients with large nodal masses in the abdomen or retroperitoneum frequently experience pain, abdominal fullness, or early satiety. Retroperitoneal lymphadenopathy can cause back pain and discomfort.

Extranodal disease is common in patients with aggressive NHL. The most common extranodal sites are the gastrointestinal (GI) tract, tonsils, and skin, although the frequency of involvement of these sites varies across reports. Disease in the GI tract can manifest as nonspecific symptoms, including gastric obstruction, blood loss with subsequent anemia, or diarrhea. Other extranodal sites include liver, lungs, testes, breasts, ovaries, bones, CNS, and spleen; however, aggressive extranodal NHL may involve nearly any organ system.[23]

CLINICOPATHOLOGIC CHARACTERISTICS

The current WHO classification of lymphoid neoplasms has refined the diagnostic criteria for some entities, detailed the expanding genetic/molecular landscape of numerous lymphoid neoplasms and their clinical correlates, and refers to investigations leading to more targeted therapeutic strategies. This new classification of large B-cell lymphomas is illustrated in Table 9–2.[1,25] Most cases of DLBCL are designated as not otherwise specified (NOS). However, about 20% of cases, are designated as specific variants of DLBCL. These variants, are specified on the basis of distinctive morphologic or immunophenotypic findings or distinctive biological or clinical issues associated with their diagnoses.[26]

Table 9–2 2016 WHO Classification of Large B-Cell Lymphoma

DLBCL, NOS
Morphological variants
Centroblastic
Immunoblastic
Anaplastic
Other rare variants
Molecular subtypes
Germinal center B-cell subtype
Activated B-cell subtype
Other lymphomas of large B-cells
T-cell/histiocyte-rich large B-cell lymphoma
Primary diffuse large B-cell lymphoma of the central nervous system
Primary cutaneous DLBCL, leg type
EBV-positive DLBCL, NOS
DLBCL associated with chronic inflammation
EBV-positive mucocutaneous ulcer
Lymphomatoid granulomatosis
Large B-cell lymphoma with IRF4 rearrangement
Primary mediastinal (thymic) B-cell lymphoma
Intravascular large B-cell lymphomas
ALK-positive large B-cell lymphoma
Plasmablastic lymphoma
HHV8-positive diffuse large B-cell lymphoma
Primary effusion lymphoma
High-grade B-cell lymphoma
High-grade B-cell lymphoma, with MYC and BCL2 and/or BCL6 rearrangements
High-grade B-cell lymphoma, NOS
B-cell lymphoma, unclassifiable
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and
Classic Hodgkin lymphoma

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

Epidemiology

DLBCL–NOS is the most common type of lymphoma and accounts for approximately 25% of all NHLs in the developed world.[2]

DLBCL–NOS occurs mainly in adults, with a median age in the sixth decade of life. Men are affected slightly more often than women.[2]

Clinical Presentation

B-type symptoms or bulky disease occurs in one-third of patients. Nodal presentation is most common, but extranodal sites are involved in approximately 40% of patients (Figs. 9–1 and 9–2), and more than one-third of patients have more than one extranodal site of disease.[27] Slightly more than half of patients have stage III or IV disease. Bone marrow involvement occurs in approximately 10% to 20% of patients.[27] DLBCL uncommonly involves privileged sites, such as the testes and CNS, of which the latter portends a poorer prognosis.

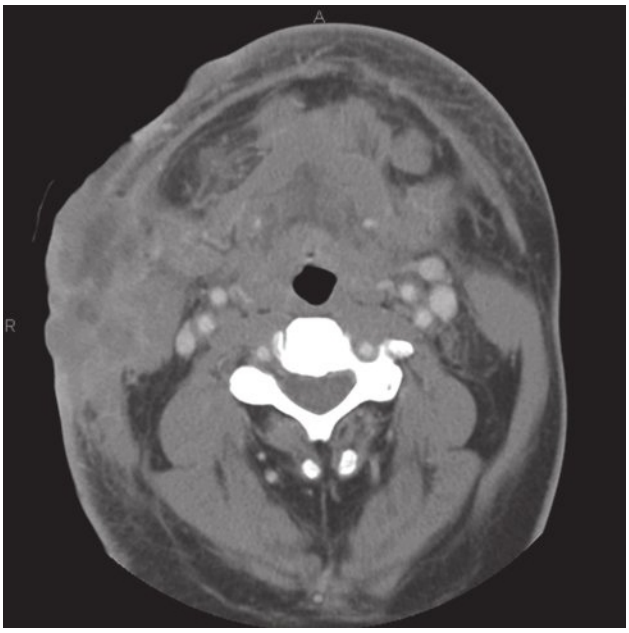

FIGURE 9–1 Computed tomography scan showing diffuse large B-cell lymphoma with extensive lymph node involvement in the neck.

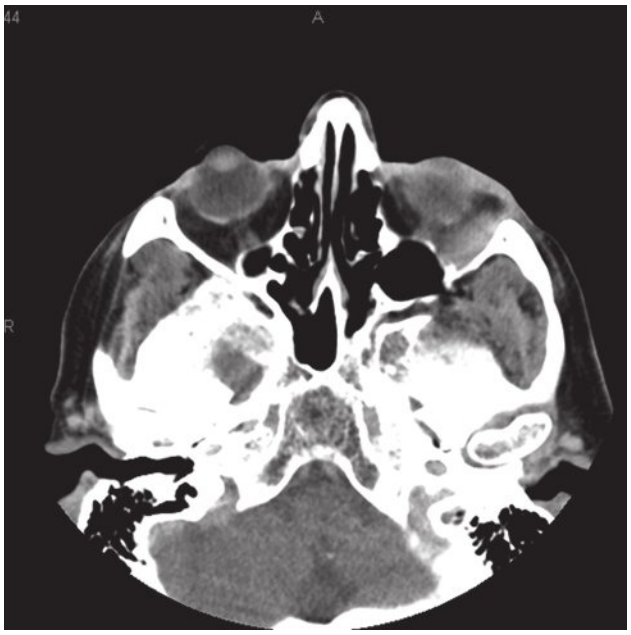

FIGURE 9–2 **Computed tomography scan showing diffuse large B-cell lymphoma as a periorbital mass.**

Interestingly, patients with limited-stage DLBCL tend to present a pattern of continuing relapse after completion of therapy, likely a result of biological differences between limited- and advanced-stage lymphoma.[28]

Microscopic Morphology

DLBCL is defined as a neoplasm with a diffuse growth pattern composed of medium-size or large B cells whose nuclei are the same size as, or larger than, the nuclei of normal macrophages, or more than twice the size of normal lymphocytes.[25]

Morphologic, biologic, and clinical studies have subclassified DLBCLs into subtypes and distinct entities, as illustrated in Table 9–2. However, there remain many cases that may be biologically heterogeneous, for which there are no universally accepted criteria for subdivisions. These cases are classified as DLBCL–NOS (Figs. 9–3 and 9–4).[25]

The most common morphologic variant is the centroblastic variant. Centroblasts are medium to large lymphoid cells with oval to round, vesicular nuclei containing fine chromatin and two to four membrane-bound nucleoli.

The immunoblastic variant (Fig. 9–5) represents about 10% of all cases of DLBCL–NOS and is composed of more than 90% immunoblasts, defined as a large cell with a central round nucleus and a prominent single, centrally located nucleolus. One study demonstrated that DLBCL with immunoblastic variant more often demonstrated *MYC* rearrangement (13 of 39

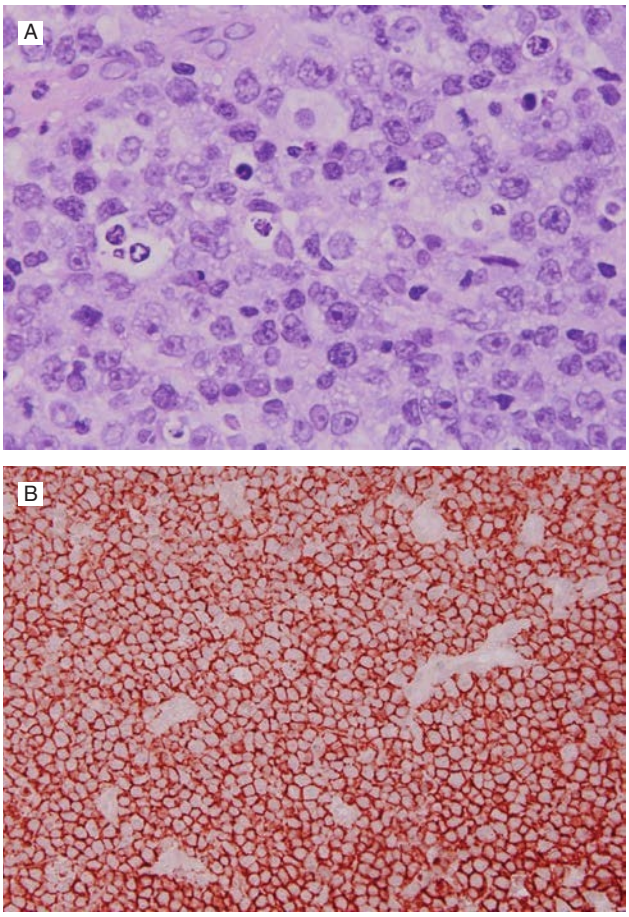

FIGURE 9–3 **Diffuse large B-cell lymphoma. A. The neoplastic cells are large with vesicular chromatin and are arranged in a diffuse pattern. B. The neoplastic cells are positive for CD20. (A, hematoxylin-eosin, ×1000; B, immunohistochemistry, ×400.)**

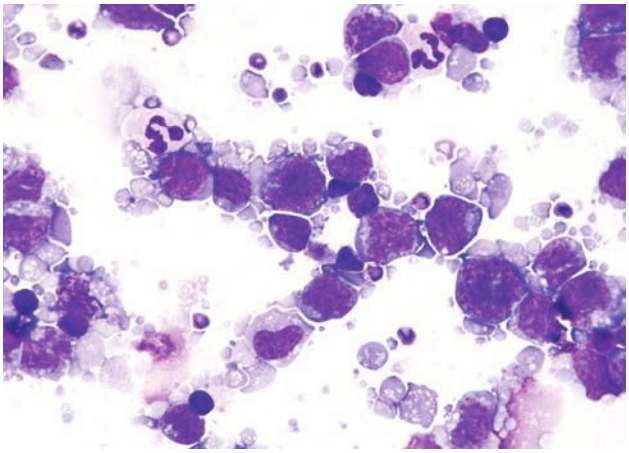

FIGURE 9–4 **Diffuse large B-cell lymphoma. Fine-needle aspiration of cervical lymph node. The neoplastic cells are large (compared with neutrophils in field) with abundant basophilic cytoplasm (Wright-Giemsa, ×1000).**

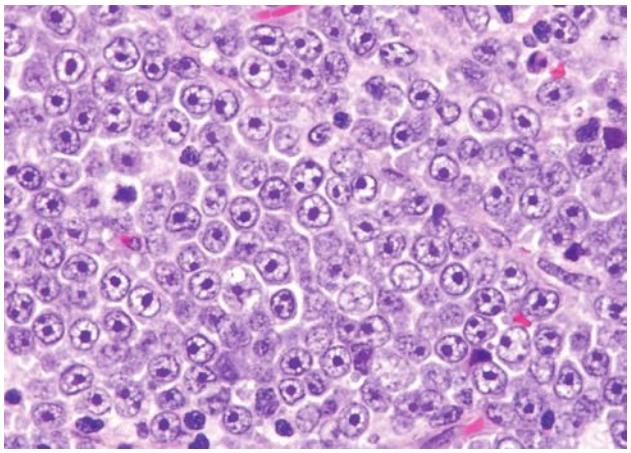

FIGURE 9–5 Diffuse large B-cell lymphoma, immunoblastic variant. The neoplastic cells are large with prominent central nucleoli imparting a "target-like" appearance (hematoxylin-eosin, ×1000).

immunoblastic DLBCLs including 10 with *MYC* rearrangement as a single hit compared with 5 of 68 non-immunoblastic DLBCLs).[29] Some studies have found an adverse impact of immunoblastic morphology.

The anaplastic variant represents 2% to 3% of all cases of DLBCL and is characterized by large to very large cells with bizarre pleomorphic nuclei, which may resemble partially Hodgkin/Reed-Sternberg cells or the neoplastic cells of anaplastic large cell lymphoma. CD30 is often expressed by the neoplastic cells of the anaplastic variant.[25]

There are also rare morphologic variants including cases with myxoid stroma, fibrillary matrix, signet ring morphology, spindle-cell morphology, and microvillous morphology (by electron microscopy). Because of the rarity of those variants, their clinical significance is unclear, but occasionally these unusual morphologic features might create diagnostic challenges.

Immunophenotype

Immunophenotypic studies have shown that DLBCLs are of mature B-cell lineage. Approximately two-thirds of cases express monotypic immunoglobulin (Ig). These tumors express pan–B-cell markers such as CD19, CD20, CD22, CD79a, and PAX5, although occasionally the neoplasm might demonstrate an aberrant loss of one of the pan–B-cell markers. About 60% to 70% of DLBCL–NOS cases express BCL2, and a 40% to 60% subset is positive for CD10 and BCL6. The Ki-67 proliferation index is high, usually more than 40% and may be even as high as more than 90% in some cases. p53 is expressed in more than 50% of cells in 20% to 60% of cases.[25] Immunohistochemistry also can be used to determine cell of origin (COO; see below).

MYC, BCL2, and Double-Expressor Lymphoma

Immunohistochemistry is also commonly used to detect MYC expression in DLBCL cases. MYC is detected in 30% to 50% of cases of DLBCL using a 40% cutoff (which is most commonly used in the literature). MYC expression correlates loosely with the presence of *MYC* rearrangement. Concomitant expression of BCL2 (50% cutoff) and MYC occurs in 20% to 35% of cases of DLBCL, and this is known as a double-expressor phenotype or "double-expressor lymphoma." The incidence of double protein expression is estimated to be 19% to 34%.[30] Most of these tumors do not carry *MYC/BCL2* chromosomal alterations. In most studies, the double-expressor lymphomas are more frequently of the ABC subtype and have a worse outcome than other DLBCL–NOS, but they offer a better outcome than aggressive B-cell lymphoma with rearrangements of *MYC* and *BCL2* and/or *BCL6*. Overall, double expression of MYC and BCL2 proteins without gene aberrations is be considered a prognostic indicator in DLBCL–NOS, but is not considered a separate category.[1,31–34]

Genetic Profile

Common somatic mutations in DLBCL are inactivating mutations of *TP53* and genes involved in immunosurveillance (*B2M*, *CD58*), alterations in epigenetic regulators (*CREBBP/EP300*, *KMT2D/C* [*MLL2/3*], *MEF 2B*), and oncogenic activation of *BCL6*.[1]

DLBCLs are heterogeneous at the molecular level. A subset of cases carries the t(14;18)(q32;q21) involving *BCL2*, as shown by conventional cytogenetic or molecular studies.[35,36] Another subset of DLBCLs has translocations or other abnormalities involving *BCL6* at chromosome 3q27. *BCL6* is rearranged in approximately 20% to 40% of DLBCLs, more often in tumors arising at extranodal sites.[37] *MYC* translocation occurs in 10% to 15% of DLBCL cases.

Cell of Origin

The WHO classification recommends determining the COO in all cases of DLBCL. The best approach is to use gene expression profiling (GEP) methods, which requires fresh tissue to extract RNA. A number of studies using this approach was published about 20 years ago, but the most popular system classified cases into germinal center B-cell (GCB), activated B-cell (ABC), and an unclassified group, the latter representing about 15% of all cases. This COO classification not only defined subgroups with distinct biology and pathogenesis, but in many studies (but not all) identified groups of patients with different outcomes after therapy.[38]

Although the COO classification was an important first step, more recent studies have shown the limitations of this system, which is not sufficiently precise. Studies by Schmitz and colleagues and Chapuy et al. showed four and five groups, respectively and a recent study by Conley et al showed six groups, with one divided into two subgroups: MCD, N1, A53, BN2, EZB MYC+, and EZB MYC–. Analysis of genetic pathways suggested that MCD and BN2 DLBCLs rely on "chronic active" B-cell receptor signaling that will be amenable to therapeutic targeted inhibition.[39,40] Outside a clinical trial, these genetic groups do not have currently therapeutic consequences.

Nevertheless, in our opinion, this system will likely be refined and applied to cases of DLBCL in routine practice, although this approach may take some time to institute. Recent technologies such as Nanostring assays (Nanostring) will likely facilitate this progress.[41]

Because gene expression profiling is not available in many laboratories, immunohistochemistry surrogates are considered acceptable using markers such as CD10, MUM-1, BCL6, GCET1, and FOXP1. The most popular system is the one proposed by Hans and colleagues, which used CD10, MUM-1, and BCL6, and subclassifies DLBCL groups into germinal center B-cell subtype (GCB) and non-GCB, with relatively good concordance with GEP.[42,43]

Other Lymphomas of Large B Cells

T-Cell/Histiocyte-Rich Large B-Cell Lymphoma

T-cell/histiocyte-rich large B-cell lymphoma (THRLBCL) accounts for less than 5% of DLBCL and is a diffuse neoplasm in which most of the cells are reactive T cells and histiocytes. The large, neoplastic B cells represent less than 10% of all cells in the infiltrate (Fig. 9–6). THRLBCL frequently harbors genetic mutations in *JUNB*, *DUSP2*, *SGK1*, *SOC1*,or *CREBBP*.[26] Patients with THRLBCL commonly have a history of nodular lymphocyte-predominant Hodgkin lymphoma, and THRLBCL may represent a transformation event in some patients.[25,44]

Primary Diffuse Large B-Cell Lymphoma of the Central Nervous System

This entity includes DLBCL arising within the brain, spinal cord, leptomeninges, or eye. It notably excludes lymphomas of the dura, intravascular large B-cell lymphoma, and lymphomas with evidence of systemic disease. Primary DLBCL of the central nervous system (PCNSL) accounts for less than 1% of all NHL and 2.4% to 3% of all brain malignancies. Approximately 20% of patients present with or develop intraocular lesions and 80% to 90% of patients with intraocular

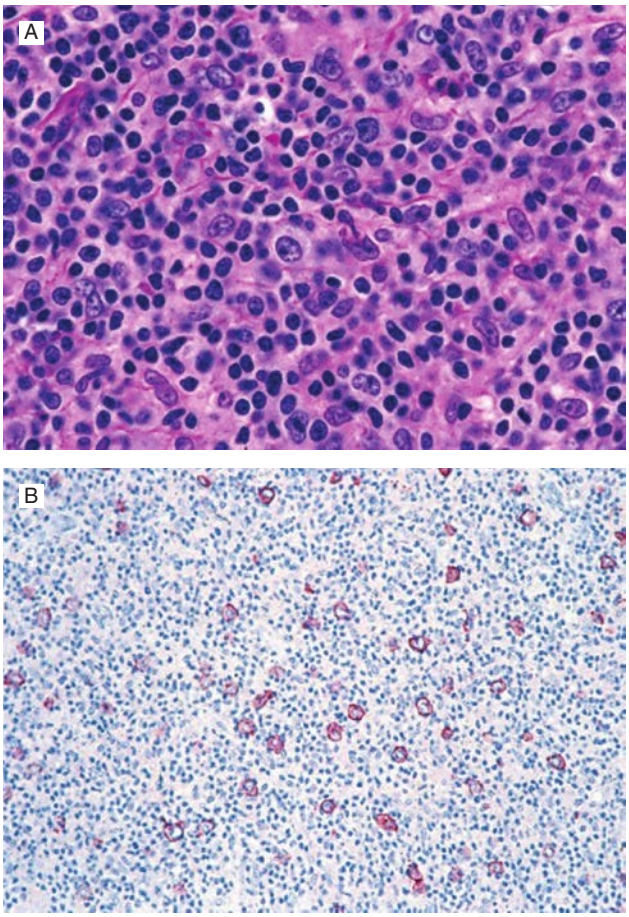

FIGURE 9–6 T-cell/histiocyte-rich large B-cell lymphoma. A. Scattered large neoplastic lymphoid cells in a background of numerous small lymphocytes. B. The large neoplastic cells are positive for CD20, and the small lymphocytes are T cells (immunostain not shown). (A, hematoxylin-eosin, ×630]; B, immunohistochemistry, ×200.)

DLBCL develop contralateral tumors and parenchymal brain lesions. Interestingly, dissemination to extraneural sites is rare.[25]

Patients present focal neurologic deficits in 56% to 70% of cases and other signs and symptoms include mental and behavioral alteration, intracranial pressure symptoms, and seizures.[26]

Although these lymphomas are remarkable for their unique clinical presentation, histologically and at the immunophenotypic level, these neoplasms closely resemble other cases of systemic DLBCL. The neoplasm demonstrates pan–B-cell markers such as CD19, CD20, CD22, CD79a, and PAX5. Most cases are positive for BCL6 and IRF4/MUM1, whereas only a small proportion (<10%) of neoplasms is positive for CD10. The Ki-67 proliferation rate is usually high (>70%), and BCL2 and MYC expression is common (>80%). EBV infection is consistently absent. Central nervous system (CNS) DLBCLs show a high prevalence of *MYD88*

mutations and *CDKN2A* biallelic loss and alteration of the B-cell receptor/toll-like receptor/NF-κB pathways.[45] PCNSL may be considered a post–germinal center disease associated with the ABC-DLBCL type in origin.[46] Approximately one-third of the cases demonstrate translocations involving *BCL6*.

In HIV-positive patients, DLBCL arising in the brain is an AIDS-defining malignancy. These neoplasms differ from cases of PCNSL in which a history of immunodeficiency is not accepted. In HIV-associated DLBCL of the brain, CD4 counts in affected patients are commonly less than 50 cells/μL. The neoplastic cells often have immunoblastic cytologic features and are positive for EBV.[47] However, the incidence of DLBCL in patients living with HIV has declined with widespread adoption of antiretroviral therapy.[48]

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

Primary cutaneous diffuse large B-cell lymphoma, leg type (PCLBCL-LT), as the name suggests, presents as cutaneous lesions without extracutaneous disease. PCLBCL-LT, originally described in the lower extremities, presents in legs in 85% to 90% of patients. However, all skin sites may be affected. PCLBCL-LT accounts for 4% of all primary cutaneous B-cell lymphomas.[25,49] Lesions are often red or blue-red and eventually become diffuse and ulcerated. Histologic sections show diffuse sheets of monotonous neoplastic cells, often with immunoblastic morphology with frequent mitotic figures.[50] The neoplastic cells are positive for CD20, CD79a, BCL2, IRF4/MUM1, FOXP1, and monotypic Ig. Up to 80% of cases are MYC positive and about two-thirds of cases have a double-expressor immunophenotype. Fluorescence in situ hybridization (FISH) studies can show rearrangements of *MYC i*n up to one-third of cases.[26,51]

Epstein-Barr Virus–Positive Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

This nomenclature replaces EBV-positive DLBCL of the elderly because this neoplasm may occur in younger patients. However, this lymphoma occurs usually in individuals older than 50 years, with a peak in the eighth decade of life. This neoplasm accounts for 10% to 15% of DLBCLs among Asian and Latin American patients and less than 5% of Western patients. The increased incidence of this lymphoma in the elderly is believed to be related to physiologic immunosenescence. Histologically, these neoplasms have a diffuse pattern and show a spectrum of features, and two morphologic variants are recognized: polymorphous, with a broad range of B-cell maturation in the reactive background, and monomorphous, which contains mostly large cells.[1,25] Geographical necrosis is common, and the neoplastic cells usually have a non–GCB immunophenotype. The lymphoma cells express B-cell markers such as CD19, CD20, CD22, and CD79. CD30 is expressed in about 40% of cases.[52]

The prognosis of EBV-positive DLBCL tends to be significantly worse in older adult patients than in young-adult patients.[53]

Diffuse Large B-Cell Lymphoma Associated With Chronic Inflammation

The prototype DLBCL associated with chronic inflammation (DLBCL-CI) is known as pyothorax-associated lymphoma. These neoplasms typically develop in patients with a longstanding (often >10 years) history of therapeutically-induced pyothorax as part of treatment for pulmonary tuberculosis. These neoplasms are often large with a poor prognosis. This type of lymphoma occurs worldwide but appears to be more common in Japan and China.[25]

A second group of cases included in the DLBCL-CI are very different. These neoplasms are small, often microscopic in size, and arise at sites of chronic inflammation, such as chronic osteomyelitis, metallic implant insertion, surgical mesh implantation, and chronic skin venous ulcer.[54] Another name proposed for these neoplasms is fibrin-associated lymphoma.

DLBCL-CI (both groups) is composed of large cells with centroblastic, immunoblastic, or, less commonly, anaplastic features.[26] Most cases express CD20 and CD79a; some cases show CD30 expression. Many cases show plasmacytic differentiation; in some cases the plasmacytic differentiation becomes so prominent that the neoplasm shows loss of CD20 and/or CD79a and acquires IRF/MUM1 and CD138. DLBCL-CI are uniformly EBV-positive and are believed to arise from post–germinal center B cells in a hypoxic and perhaps immune protected environment.

Epstein-Barr Virus–Positive Mucocutaneous Ulcer

EBV-positive mucocutaneous ulcer (EMCU) presents with isolated circumscribed ulcerative lesions, typically in patients with age-related or iatrogenic immunosuppression. EMCU is associated with defective host immunosurveillance of EBV infection. The lesions are most common in the oral mucosa but may also occur in the skin or in the GI tract. The lesions contain a polymorphous inflammatory infiltrate mixed with scattered EBV-infected B cells, which frequently include cells resembling Hodgkin/Reed-Sternberg cells morphologically and immunophenotypically (CD30+, CD15+/–).[25,55,56]

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LYG) is an angiocentric and angiodestructive lymphoproliferative disease, composed of EBV-positive CD20+ B cells and reactive T cells. This entity is EBV-driven and can present in a subset of patients with underlying immunodeficiency, such as in Wiskott-Aldrich syndrome, X-linked lymphoproliferative syndrome, and other conditions linked to immunodeficiency.

Patients with LYG typically present with extranodal disease, almost always in the lungs, followed by the CNS, skin, liver, mediastinum, adrenal glands, kidneys, and breasts. Bone marrow and lymph node involvement are rare.[57]

Histologically, LYG is characterized by atypical large B cells in a pleomorphic background of lymphocytes, plasma cells, and histiocytes. Angiocentricity and necrosis are common. Histologic grading of LYG ranges from I to III and is based on the number and density of EBV-positive atypical B cells and degree of coagulative necrosis.[58] The clinical behavior ranges from indolent process to aggressive large B-cell lymphoma.[1,59]

Large B-Cell Lymphoma with *IRF4* Rearrangement

This neoplasm is characterized by strong expression of MUM1/IRF4 and is associated with chromosome *6p25/IRF4* rearrangement. The histologic pattern can be follicular, follicular and diffuse, or entirely diffuse. These neoplasms represent 0.05% of all cases of DLBCL, and affected patients are usually children and younger adults with a median age of 12 years (range, 4–79).

Patients generally present with localized disease involving head and neck lymph nodes or components of Waldeyer ring. These neoplasms are composed of medium or large cells that can exhibit blastoid features, usually without starry-sky pattern. BCL-6 and CD10 are usually positive, supporting a germinal center B-cell immunophenotype.[25,26]

Primary Mediastinal (Thymic) B-Cell Lymphoma

Primary mediastinal (thymic) B-cell lymphoma (PMBL) accounts for 2% to 3% of all NHLs and 6% to 10% of all DLBCL. The median age of diagnosis is 35 to 37 years, and women are affected more than men.[60] Patients present with an often-bulky mediastinal mass, potentially leading to compressive symptoms, including superior vena cava syndrome. The lymphoma cells have round or pleomorphic nuclei and Reed-Sternberg–like cells may be observed occasionally. The lymphoma cells are positive for pan–B-cell antigens, BCL-6 (~95%), MUM-1/IRF-4 (~95%), and MYC (~65%); CD30 is positive in approximately 80% of cases but is usually weak and heterogeneous. PD-L1/PD-L2 is positive in approximately 50% to 75%. CD10 positivity is less common (~25%).

Major pathways involved in the pathogenesis of PMBL include the NF-κB, cell cycle dysregulation, apoptosis, JAK-STAT, and immune evasion pathways. Major genetic alterations involving the NF-κB pathway include amplification of *REL* (~75%) and *BCL11A* (~50%). Gains/amplification of chromosome 9p24.1, the site of *JAK2* as well as *PD-L1* and *PD-L2*, are also common (~70%).[25,26] Decreased expression of HLA molecules, CD58, and other immune recognition molecules on the surface of the lymphoma cells as a result of molecular alterations (eg, mutations, translocations of *CIITA*) are also common.

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma (IVLBCL) is a rare neoplasm that is mostly confined within the lumina of small- to medium-sized blood vessels, particularly capillaries (Fig. 9–7). In general, larger blood arteries and veins are not involved. There are three clinical variants of IVLBCL: classic, hemophagocytic syndrome–associated, and cutaneous. Patients with the classic form (mostly present in Western countries) present nonspecifically with B symptoms and organ-related manifestations, particularly involving the CNS and the skin. The hemophagocytic syndrome–associated form is characterized by pancytopenia, hepatosplenomegaly, multiorgan failure, and bone marrow involvement. An isolated cutaneous variant, identified invariably in Western females, is characterized by restriction of the tumor to the skin and is associated with a better prognosis. The lymphoma cells express pan–B-cell markers and most cases have a complex karyotype, with chromosome 1 commonly involved in 72% of cases.[25,26]

ALK-Positive Large B-Cell Lymphoma

ALK-positive large B-cell lymphoma (ALK+ LBCL) accounts for less than 1% of all cases of DLBCL. These neoplasms are more common in young men (median age, 43 years) and present with nodal and/or extranodal disease. Approximately 60% of patients present with stage III/IV disease. By definition, the neoplastic cells express ALK and have a plasmablastic phenotype, positive for plasma cell–associated markers that are usually positive, including CD138, VS38, IMUM-1/IRF-4, XBP-1, and BLIMP-1. Other pan–B-cell markers (CD20, CD79a, and PAX5) are usually negative or show only focal and weak expression. IPI score and Ann Arbor stage are significant risk factors.[61,62]

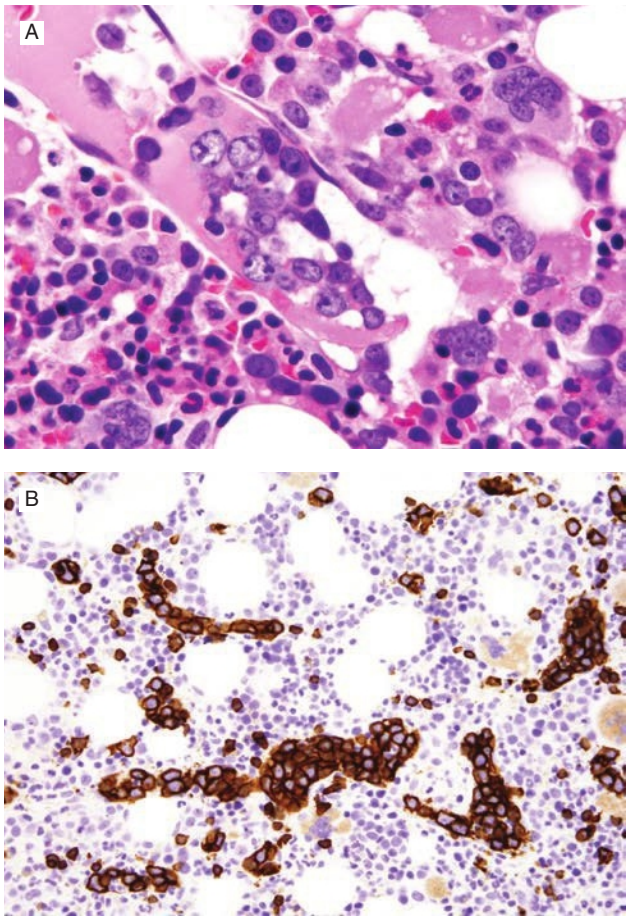

FIGURE 9–7 Intravascular large B-cell lymphoma involving bone marrow. A. Large neoplastic cells are present with a small blood vessel. B. The anti-CD20 antibody highlights numerous large neoplastic cells within many blood vessels. (A, hematoxylin-eosin, ×1000; B, immunohistochemistry, ×400.)

Plasmablastic Lymphoma

Plasmablastic lymphoma (PBL) represents less than 1% of all cases of DLBCL and occurs commonly in the setting of immunodeficiency. PBL commonly presents in patients with HIV infection and represents approximately 3% of HIV-related lymphomas. PBL can also occur in patients after allogeneic transplant and in patients with other forms of immunodeficiency, including physiologic immunosenescence. The most frequent sites of involvement include the oral/nasal cavity and the GI tract.

PBL is composed of immunoblast- or plasmablast-like cells with variable degrees of plasmacytic differentiation. The neoplastic cells are usually positive for plasma cell markers such as CD38, CD138, IRF/MUM1, BLIMP1, and cytoplasmic Ig, and negative for CD45 (LCA) and most pan–B-cell markers. Many cases show expression of CD30 and Epithelial Membrane Antigen (EMA). CD79a is positive in 40% to 50% of cases. The Ki-67 proliferation rate is usually over 90%. In situ hybridization for EBV-encoded RNA (EBER) is positive in about 70% of cases.[25,26]

HHV8-Positive Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

HHV8+ DLBCL–NOS is an extremely aggressive and rare disease. Approximately 50% of patients are HIV+. Notably, patients with HIV+ HHV8+ multicentric Castleman disease are at 15 times higher risk of developing HHV8+ DLBCL. However, most often, HHV8+ DLBCL–NOS arises in association with HHV8+ multicentric Castleman disease, but very rarely neoplasms present de novo without known Castleman disease. Lymphadenopathy occurs in about 80% of patients and disseminated disease, hepatomegaly, and splenomegaly may occur. Moreover, coexistent Kaposi sarcoma may occur. Patients have an aggressive clinical course and often a poor prognosis. HHV8+ DLBCL is composed of sheets of plasmablasts that disrupt normal architecture, sometimes with a background of multicentric Castleman disease. In addition to HHV8, the lymphoma cells are positive for cytoplasmic IgM and lambda. HHV8 virus induces B-cell receptor revision to lambda, with CD20, CD38, CD45, or CD79a positive in subsets of cases. Unlike PEL, HHV8+ DLBCL–NOS are EBV-negative.[25,26]

Primary Effusion Lymphoma

PEL is a human herpesvirus 8 (HHV8)-driven malignancy that involves the pleural, pericardial, or peritoneal cavities without usually forming a mass. Extracavitary PEL refers to a solid neoplasm that has characteristics similar to conventional PEL.

In the United States, most PEL patients are HIV-positive adult men; few are HIV-negative patients, notably in the posttransplant or physiologic immunosenescence setting. Patients with conventional PEL present with symptoms associated with an effusion. The GI tract and lymph nodes are most frequently involved by extracavitary PEL.

PEL cells are pleomorphic, resembling immunoblasts, plasmablasts, or anaplastic cells with Hodgkin/Reed-Sternberg–like features. Moreover, PEL cells usually lack pan–B-cell markers such as CD19, CD20, and CD79a, but are positive for HHV8, MUM-1/IRF-4 (up to 100%), CD38 (up to 100%), CD45 (>80%), CD138 (35%–75%), and CD30 (>50%). These neoplasms have an ABC/non-GCB immunophenotype. Interestingly, extracavitary PEL more often expresses CD20 or CD79a.[25,26]

Table 9–3 Diagnostic Table for the Differential Diagnosis of High-Grade B-Cell Lymphomas

		B-Lymphoblastic Leukemia/Lymphoma	HGBL, NOS	DLBCL	HGBL DHL/THL	BL
Morphology	**Blastoid**	Yes	Yes		Yes	
	DLBCL			Yes	Yes	
	DLBCL/BL		Yes		Yes	Yes
	BL					Yes
IHC	**TdT**	Positive	Negative			
	CD10	Positive				Positive
	BCL6	Negative				Positive
	CCND1	Negative	Negative			
	BCL2					Negative
	Ki-67					~100%
FISH	**No DH**		Yes	Yes		
	SH MYC-IG					Yes
	DH/TH	Yes			Yes	

BL, Burkitt lymphoma; CCND1, c-terminal Cyclin D1; DH(L), double-hit (lymphoma); DLBCL, diffuse large B-cell lymphoma; IHC, immunohistochemistry; FISH, fluorescence in situ hybridization; HGBL, NOS, high-grade B-cell lymphoma, not otherwise specified; SH MYC-IG, single-hit with IG/MYC fusion but no translocation involving BCL2, BCL6, or CCND1; TdT, Terminal deoxynucleotidyl transferase; TH(L), triple-hit (lymphoma).
Data from Swerdlow SH, Campo E, Harris NL, et al: *WHO Classification of Tumors of Haematopoietic and Lymphoid Tissues*, 4th ed. IARC, *Lyon*; 2017 and Swerdlow SH, Campo E, Pileri SA, et al: The 2016 revision of the World Health Organization classification of lymphoid neoplasms, *Blood* 2016 May 19;127(20):2375-2390.

High-Grade B-Cell Lymphoma

High-grade B-cell lymphoma (HGBL) is a subset of very aggressive tumors with features intermediate between DLBCL and BL, or with a blastoid appearance, as illustrated in Table 9–3.

High-Grade B-Cell Lymphoma, With *MYC* and *BCL2* and/or *BCL6* Rearrangements

HGBL with *MYC* and *BCL2* and/or *BCL6* rearrangements, also called "double-hit lymphoma" and "triple-hit lymphoma" (DHL and THL), are aggressive lymphomas that account for around 7% to 10% of DLBCL.

Similar to DLBCL, these lymphomas present mostly in the sixth to seventh decade of life. More than half of patients present with Ann Arbor stage IV and more than one extranodal site of disease, notably with CNS involvement in up to 45% of cases.

At least half of DHL and THL have the morphology of DLBCL–NOS, and starry-sky macrophages may be present. The number of mitotic figures and apoptotic figures are highly variable, occasionally with a somewhat low (50%–70%) Ki-67 proliferation index. Another subset of DHL and THL shows a morphology with features intermediate between DLBCL and BL. For these cases, starry-sky macrophages are generally present, with many mitotic figures. Other cases of DHL and THL can have a blastoid cytomorphology. Unlike B-cell lymphoblastic leukemia/lymphoma, staining for terminal deoxynucleotidyl transferase is negative and, unlike the blastoid variant of mantle cell lymphoma, cyclin D1 is negative (Table 9–3, Fig. 9–8).

These lymphomas are of mature B-cell lineage with expression of CD19, CD20, CD79a, and PAX5. Rearrangements, usually as a result of translocations, occur in *MYC* (chromosome 8q24), *BCL2* (chromosome 18q21), and/or *BCL6* (chromosome 3q27). These lymphomas are predominantly observed in the GCB subset of DLBCL. Lymphoma with both *MYC* and *BCL6* translocations (*MYC/BCL6*) is likely a different disease biologically compared with DHL with *MYC/BCL2* translocations. Indeed, *MYC/BCL6* lymphoma is much less common and more likely to be of ABC/non-GCB type. Interestingly, *MYC/BCL2* DHL frequently exhibits TP53 mutations, whereas MYC/BCL6-rearranged lymphomas do not. THL has a prognosis comparable with DHL.[30] Most double-hit lymphomas have a double-expressor phenotype, but the reverse is not true.[25]

At MDACC, we routinely perform FISH studies for *MYC* rearrangement on all new cases of DLBCL, irrespective of Ki-67 index. If *MYC* rearrangement is detected, additional FISH studies for *BCL2* and *BCL6* rearrangements are performed. If a lymphoma does not demonstrate *MYC* rearrangement, no additional studies are required.

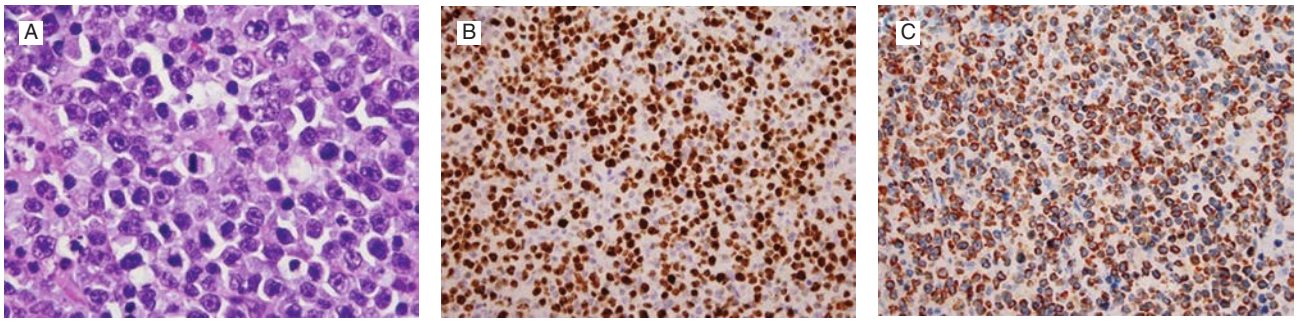

FIGURE 9–8 High-grade B-cell lymphoma, with *MYC* and *BCL2* and/or *BCL6* rearrangements. Similar to Burkitt lymphoma, the neoplastic cells are intermediate-sized and demonstrate brisk mitotic activity, but unlike Burkitt lymphoma, cells have prominent single nucleoli (A). Although the proliferative rate is similar to Burkitt lymphoma (B), the neoplastic cells strongly express BCL2 (C). In this case, fluorescence in situ hybridization detected both translocations t(8;14) and t(14;18), so-called double-hit lymphoma (lymph node; A, hematoxylin-eosin, ×1000; B, Ki-67 (Mib-1), ×400; C, BCL2, ×400).

High-Grade B-Cell Lymphoma, Not Otherwise Specified

HGBL–NOS is a rare and heterogeneous category with cases that appear with blastoid cells and cases that appear intermediate between DLBCL and BL. About 20% to 35% of cases have a MYC rearrangement, but by definition lack *BCL2* and/or *BCL6* rearrangement (Table 9–3). Some cases show increased copy numbers of *BCL2* or, rarely, amplification of 18q21 involving *BCL2*. In addition, some cases demonstrate *BCL2* rearrangement and increased copy numbers of *MYC* gene.[1,25]

B-Cell Lymphoma, Unclassifiable, With Features Intermediate Between DLBCL and Classic Hodgkin Lymphoma

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma (cHL) is also known as grey-zone lymphoma (GZL). These neoplasms are very rare and not precisely defined as of this writing. The median age of patients is around 40 years, with males more commonly affected. Mediastinal GZL (MGZL) is most common, and patients present with a large anterior mediastinal mass. Nonmediastinal GZL (NMGZL) often presents in older patients and tends to be a more advanced-stage disease with higher IPI score.[63]

Morphologically, cases of GZL tend to be tumor cell–rich and can be further divided into two subtypes: cases in which the neoplastic cells morphologically resemble Hodgkin and Reed-Sternberg cells, and cases morphologically resembling DLBCL/PMBL. Cases morphologically resembling cHL usually show CD45 (LCA) positivity and strong expression of pan–B-cell markers such as CD20, CD22, CD79a, PAX5, OCT2, and BOB1. Cases morphologically resembling DLBCL/PMBL may show loss of some pan–B-cell markers or CD45 but demonstrate positivity for CD15 and CD30. Immunophenotype does not appear to differ based on presentation with MGZL versus NMGZL disease.[63]

GZL is a highly heterogeneous disease harboring somatic driver events shared with PMBL and cHL. Chromosomal aberrations in GZLs show gains including amplifications in 2p16.1 (*REL/BCL11A* locus) in 33% of all cases, alterations of the *JAK2/PDL2* locus in 9p24.1 in 55%, rearrangement of the *CIITA* locus at 16p13.13 in 27%, and gains of 8q24 (*MYC*) in 27%.[64,65] These lymphomas are often aggressive and resistant to chemotherapy, and patients have worse outcomes than patients with either cHL or PMBL.[64,66]

Burkitt Lymphoma

There are three variants of BL: endemic (African), sporadic (nonendemic), and immunodeficiency-associated. Endemic BL occurs in equatorial Africa and in Papua, New Guinea, and is associated with EBV infection in 95% to 100% of patients. The peak incidence is at 4 to 7 years and the male-to-female ratio is 2–3:1. Jaw and facial bones lesions are present in about 50% of patients. Mesentery, gonads, and CNS are other common sites of presentation.

Sporadic BL occurs worldwide, accounts for 1% to 2% of lymphomas in the United States and is associated with EBV infection in 25% to 40% of patients. Patients are usually in their third decade of life, but there is also an incidence peak in the elderly. The male-to-female ratio is 2–3:1. Clinical presentation most frequently involves the ileocecal region, and less commonly the bone marrow, ovaries, kidneys, breasts or CNS.

BL can also occur in the clinical setting of immunosuppression, including HIV infection (further information in Chapter 52), post transplant, or congenital immune deficiency. In HIV-infected patients, BL appears often when CD4+ T-cell counts are still in the normal range or low, but not extremely low, and the risk of developing BL persists in spite of highly

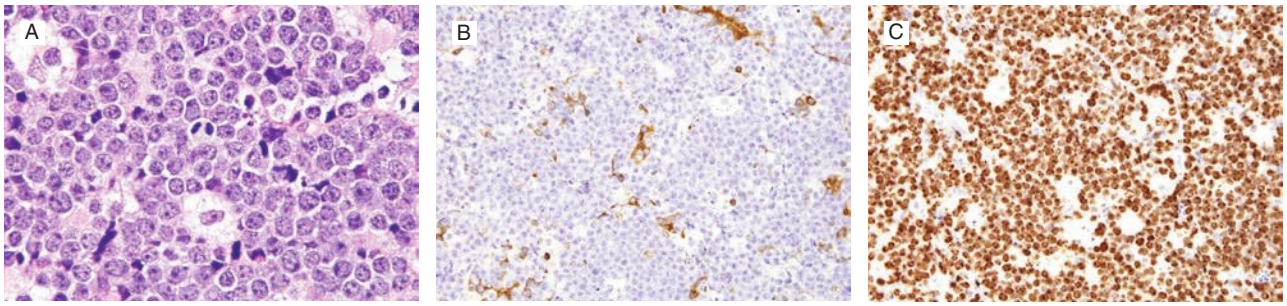

FIGURE 9–9 Burkitt lymphoma. A. The neoplastic cells are intermediate in size, similar to that of benign histiocyte nuclei, with multiple small nucleoli. A "starry-sky" pattern is also seen in this field. B and C. The neoplastic cells are negative for BCL2 (B) and are over 99% positive for Ki-67 (C). (A, hematoxylin-eosin, ×1000; B-C, immunohistochemistry, ×400.)

active antiretroviral therapy. EBV infection occurs in 25% to 40% of cases. A nodal presentation is most common, with occasional bone marrow involvement. CNS dissemination can occur as well.[67] Burkitt leukemia variant tends to involve the CNS at diagnosis or early in the disease course.

In general, all variants of BL show similar morphologic features. At low power, clear tingle-body macrophages in the background of deep-blue lymphoma cells impart a "starry-sky" appearance. The neoplastic cells are typically intermediate in size and relatively homogeneous, with basophilic cytoplasm containing small vacuoles and round nuclei. The neoplastic cells in sporadic cases might be more pleomorphic; the neoplastic cells in immunodeficiency cases can show plasmacytic features. The nuclear chromatin is granular with small nucleoli and recurrent mitoses.

All BL types are of mature B-cell lineage and of GCB origin, expressing surface Ig, pan–B-cell antigens, CD10, and BCL6.[22] Burkitt lymphomas have a very high proliferation rate, approaching 100%, using an antibody specific for Ki-67 (Table 9–3, Fig. **9–9**) and are negative for BCL2. *MYC* translocations are typical of BL; 80% of cases carry the t(8;14)(q24;q32), with the other cases having one of two variant translocations, t(2;8)(p11;q24) or t(8;22) (q24;q11). Common to each of these translocations is involvement of chromosome region 8q24, the site of the *MYC*, which is deregulated. Via these translocations, *MYC* is juxtaposed with the *IGH* or *IGK* or *IGL*. Mutations in the *transcription factor 3* (*TCF3*) or its own negative regulator *ID3* occur in approximately 70% of sporadic and immunodeficiency-related BL and 40% of endemic cases. TCF3 promotes survival and proliferation in lymphoid cells by activating the B-cell receptor/phosphatidylinositol 3-kinase (PI3K) signaling pathways and modulating the expression of cyclin D3, which is also mutated in 30% of BL.[1,25,67]

Burkitt-Like Lymphoma With 11q Aberration

Burkitt-like lymphoma with 11q aberration (BLL-11q) is a lymphoma that closely resembles BL but lacks *MYC* rearrangement and has some other distinctive features. Notably, these neoplasms carry a chromosome 11q alteration characterized by proximal gains and telomeric losses. Compared with BL, BLL-11q have more complex karyotypes, lower levels of MYC expression, a certain degree of cytologic pleomorphism, sometimes a follicular pattern, and frequently a nodal presentation. This malignancy may be closer to HGBCL or DLBCL than to BL.[1,25,68]

STAGING AND INITIAL EVALUATION

General Workup

The Ann Arbor Staging system, developed in 1971 for Hodgkin lymphoma, is used to stage patients with NHL (Table 9–4). Of interest, there does not appear

Table 9–4 Ann Arbor Staging System for Non-Hodgkin Lymphomas[a]

Stage I	Involvement of a single nodal group or extranodal site (I_E)
Stage II	Involvement of two or more nodal groups on the same side of the diaphragm or localized involvement of an extranodal site or organ (II_E) and one or more nodal groups on the same side of the diaphragm
Stage III	Involvement of nodal groups on both sides of the diaphragm, which may be accompanied by localized involvement of an extranodal region or site (III_E) of spleen (III_S) or both (III_{SE})
Stage IV	Diffuse or disseminated involvement of one or more distant extranodal sites

[a]Temperature >38 °C, weight loss more than 10% of body weight in the last 6 months, and night sweats preceding diagnosis are defined as "B" symptoms and designated by the suffix B. Others are designated by the suffix A.

to be any meaningful difference in the outcomes of patients with stage III or IV disease, and thus the purpose of staging is to identify the patients with localized NHL who may benefit from a reduced course of systemic therapy and eventual additional local therapy.[69]

A careful history and physical examination, including findings of systemic symptoms (including B symptoms), is essential. Performance status and comorbid conditions should be assessed. Physical examination should include a complete survey of all external lymph node groups including cervical, supraclavicular, axillary, epitrochlear, inguinal, and popliteal areas. Examination of abdomen for organomegaly is necessary, and in men the testes should be examined. A complete neurologic examination must also be performed. Laboratory evaluation includes a complete blood count with differential diagnosis; lactate dehydrogenase (LDH) level; kidney and liver function tests; albumin, calcium, and uric acid levels; pregnancy testing in women of childbearing age; testing for hepatitis B (especially indicated before rituximab therapy, as the virus may reactivate during or after treatment); hepatitis C; and HIV.[70] Serum protein electrophoresis can be considered in some cases.

Left ventricular function should be assessed by echocardiogram or multigated acquisition scan. Fertility-preserving treatments, such as sperm cryopreservation for males and referral to a fertility specialist for females, should be discussed with eligible patients.[70]

Imaging Studies and Bone Marrow Evaluation for Initial Staging

Based on the recent consensus recommendations for staging and restaging of lymphoma developed by the clinical and imaging working groups of the International Conference on Malignant Lymphomas, fluorodeoxyglucose positron emission tomography/computed tomography (FDG-PET/CT) scan is recommended as standard practice for staging patients with DLBCL. Indeed, PET/CT is more sensitive, especially for extranodal disease, and improves staging accuracy and subsequent response assessment[69] (Figures 9-10 and 9-11). Moreover, several studies showed that high baseline total metabolic tumor volume negatively impacts outcome in DLBCL patients.[71]

Limitations of PET/CT scan for staging of aggressive lymphoma include the fact that uptake of FDG is not specific to tumors and that infection and inflammatory processes are common false-positive findings on PET scans. As a result, an unexpected FDG-avid lesion that will result in a significant change in management should be confirmed by biopsy. The presence of high normal background activity in an organ—for example, in the kidneys or testes—may also make it difficult to identify abnormal FDG sites in that region. Although there is usually high normal metabolic activity within the brain, CNS lymphomas are often positive on FDG-PET scans, showing greater metabolic activity than the adjacent brain. However, additional imaging with magnetic resonance imaging (MRI) is indicated for confirmation.

Focal bone marrow FDG uptake with or without increased diffuse uptake is more sensitive than bone marrow biopsy (BMB) for infiltration in aggressive B-cell lymphoma and is highly specific. Of note, the pattern of uptake within the bone marrow spaces on FDG-PET is important because a diffuse pattern is commonly seen with activation (eg, with underlying anemia or infection, or after chemotherapy or growth factor treatment), and caution should be taken in interpreting this as diffuse bone marrow involvement by tumor. In contrast, focal or nodular uptake within osseous structures is suspicious

However, low-volume involvement (<10%–20%) and discordant lymphoma may be missed by PET/CT imaging, but these positive BMB/negative PET/CT findings are lower than 10% (Figure 9-12). Therefore, BMB is no longer required when a PET/CT scan demonstrates bone or marrow involvement indicating

FIGURE 9–10 **Positron emission tomography scan showing right cervical lymph nodes involved by diffuse large B-cell lymphoma.**

stage IV, but is appropriate in case of negative PET, when its results would change prognosis and treatment, especially when a shortened number of immunochemotherapy cycles is proposed or as workup of unclear cytopenia.[72]

If bone marrow aspiration and biopsy are performed, bilateral iliac crest assessment is preferred because sensitivity of detection is higher than with unilateral biopsy.[73]

Specific Considerations

Assessment of CNS Disease

Examination of the cerebrospinal fluid (CSF) should be strongly considered for patients with risk factors such as: elevated CNS-IPI[74] (age >60 years, Eastern Cooperative Oncology Group [ECOG] Performance Status ≥2, extranodal disease >1 site, stage III/IV, elevated LDH, kidney/adrenal involvement; low risk (0–1 factors), intermediate risk (2–3 factors), and high risk (≥4 factors). In addition, extranodal disease with involvement of testicular, uterine, breast, epidural, and skin is a risk factor for CNS. Moreover, the following aggressive B-cell lymphoma subtypes, such as BL, double-/triple-hit lymphoma/HGBCL, double-expressor lymphomas, HIV-associated lymphoma, non-GCB DLBCL, intravascular DLBCL, CD5+ DLBCL, PCDLBCL-LT, and IgM-secreting DLBCL,[75] present increased risk of CNS involvement.[76,77]

Evaluation of clinical or radiologic suspicion of primary or secondary CNS lymphoma requires lumbar puncture (unless contraindicated), MRI of the brain and biopsy of the lesion (preferably a stereotactic biopsy). It is important to withhold corticosteroids before biopsy, because they can induce rapid tumor shrinkage and prevent an appropriate diagnosis.[25]

Moreover, in case of suspected PCNSL, a vigorous search for additional disease sites, such as testicular ultrasound for men older than 60 years, full ophthalmologic examination including slit-lamp eye examination, spine MRI, PET/CT, and BMB should be done concurrently, because therapy for CNS and systemic disease will need to account directly for both.[78]

FIGURE 9–11 Extranodal lymphoma on FDG-PET/CT. The patient presented with mediastinal lymphoma; this is easily seen on a maximum intensity projection image from FDG-PET/CT. However, an additional focus is present in the right kidney; although not confirmed by biopsy, the renal lesion disappeared after chemotherapy, and the stage was changed from stage I to stage IV.

Involvement of the Gastrointestinal Tract

Lymphomas of the GI tract, especially in the stomach, require endoscopy for diagnosis unless other disease sites can be found to biopsy. It is especially important that multiple biopsies of different areas of the stomach be obtained because sampling error is frequent. There is no utility to gastrectomy or other surgical management for extranodal disease.

Intravascular Large B-Cell Lymphomas

Standard staging workup usually has a high proportion of false-negative results because of a lack of detectable tumor masses. Random skin biopsies of normal-appearing skin and transbronchial lung biopsy can be necessary. Evaluation for CNS disease is recommended because of the high risk of CNS relapse.[25,81]

Laboratory abnormalities are frequent, particularly high serum LDH and soluble IL-2 receptor levels.[26]

PROGNOSTIC FACTORS

Pretreatment

Prognostic factors in patients with aggressive NHL can be broadly grouped into pretreatment (tumor-related) and treatment-related characteristics. Tumor-related

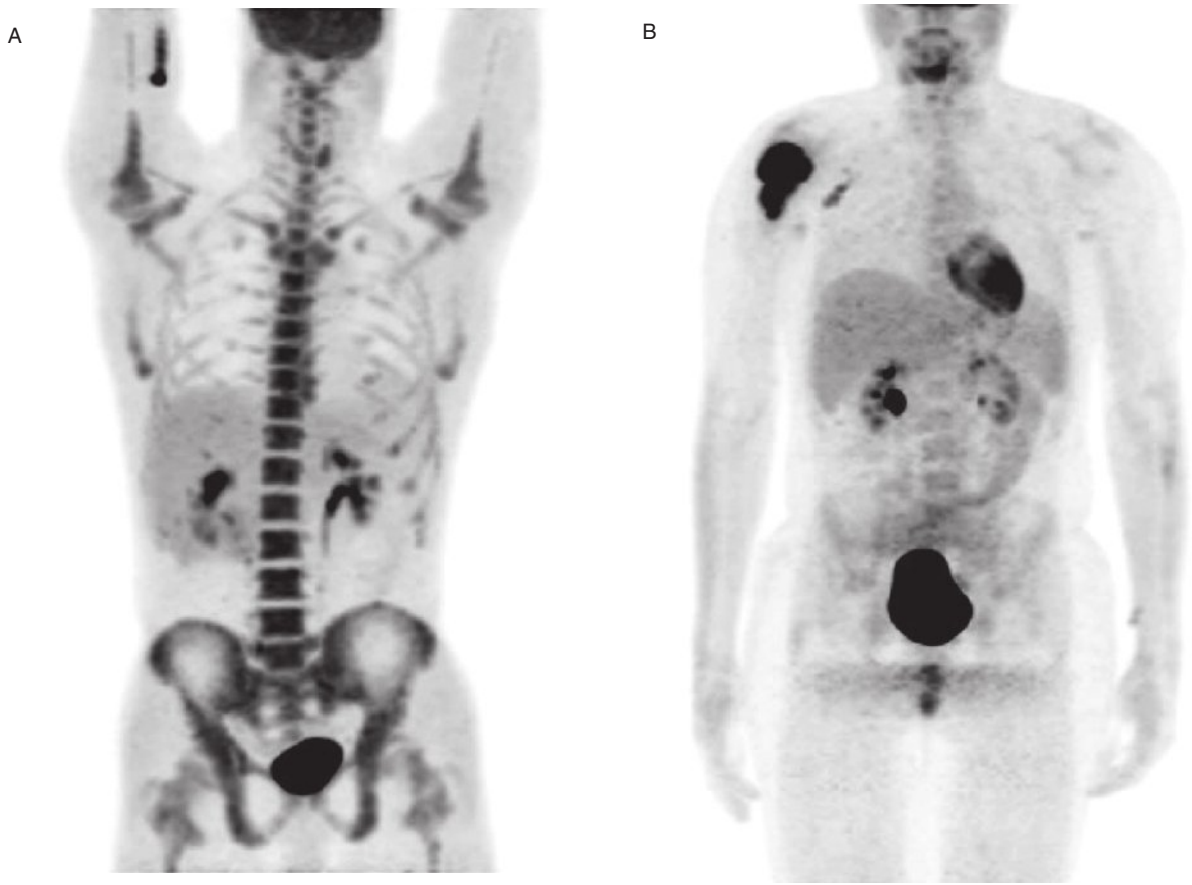

FIGURE 9–12 **Bone and bone marrow uptake on FDG-PET/CT. A. Typical pattern of marrow activation, commonly seen after chemotherapy or with growth factor treatment. This is diffuse but homogenous. In contrast (B), another patient had negative bilateral iliac crest biopsies but had focal activity in a destructive lesion involving the right humerus. Directed biopsy of this site was positive for bone involvement.**

genetic characteristics of importance, as noted earlier, include GCB or non-GCB origin genetic profile and the presence of *MYC* and *BCL2* and/or *BCL6* translocations (double-hit lymphomas).

Other tumor-related characteristics reported to be of prognostic value include a complex karyotype shown by conventional cytogenetics, high proliferation rate (high Ki-67 expression), and BCL2 and/or MYC expression shown by immunohistochemical staining.[1] In addition, a study found that P53 alterations correlated with poorer survival and augmented the negative prognostic effect of MYC rearrangement, expression, or concurrent MYC/BCL2 expression in DLBCL.[80]

High serum LDH level is a measure of anaerobic metabolism and/or cell turnover and tumor bulk and is associated with a lower probability of complete remission and poorer long-term survival in patients with aggressive NHL. Other pretreatment prognostic factors include serum β_2-microglobulin level, stage, number of disease sites, bulky disease, presence of bone marrow involvement, poor performance status, and age.[81] Of these pretreatment factors, age appears to be the most important, with patients over the age of 60 years having lower response rates and higher rates of relapse.[82]

The IPI score remains a widely used prognostic model, despite its not accounting for any tumor-specific biologic features. With rituximab plus chemotherapy–based disease management, the progression-free survival (PFS) and overall survival (OS) rates for DLBCL patients with IPI, age-adjusted IPI, National Comprehensive Cancer Network (NCCN)-IPI and Revised IPI (R-IPI) are shown in Tables 9–5, 9–6, and 9–7.[83,84] Compared with the IPI, the NCCN-IPI better discriminates low- and high-risk subgroups, by refined categorization of age and LDH, and the identification of disease involvement at specific extranodal sites.[84] The NCCN-IPI was shown to better discriminate between patients with poor and favorable OS compared with the IPI/R-IPI.[85] However, even if these data are informative, they are not reliably predictive of outcomes for an individual patient and are not validated in routine practice for choice of therapy. Nearly half of patients will have a poor-risk R-IPI, and of these patients, approximately half will be cured.

Prognostic Factors in Primary Central Nervous System Lymphoma

Age and LDH level are important prognostic factors in patients with HIV-negative primary CNS lymphoma; however, the most important factor is performance status at the time of treatment. Elevated LDH, CSF protein, and tumor mass location(s) are also contributors to prognosis.[86] Many patients can improve their condition by use of corticosteroids and thus be candidates for intensive chemotherapy-based regimens that are potentially curative.

Therapy-Associated Prognostic Factors

An important posttreatment prognostic indicator is tumor response to induction chemotherapy. In patients with aggressive NHL, dramatic response to induction with early complete remission (by the third cycle of therapy) is associated with a superior outcome. FDG-PET has been found to be highly sensitive for the detection of aggressive NHL in posttreatment residual masses, but its ability to detect interim therapy response is controversial.[87] Moskowitz et al found that DLBCL patients with persistent FDG avidity after four cycles of rituximab plus CHOP (R-CHOP) had an 86% false-positive rate (PET/CT positive, biopsy negative for persistent disease).[88] Similar data have been shown by many others, highlighting the need for biopsy confirmation of a positive PET/CT scan before therapeutic decisions.

Patients who fail to achieve at least a good partial response to induction chemotherapy have primary refractory disease and an unfavorable prognosis. Another important indicator of prognosis is duration of remission obtained after induction chemotherapy, because patients with relapses occurring at less than one year have a worse outcome.[89]

APPROACH TO THERAPY

There is a diversity of clinical practice surrounding the preferred treatment approach for patients with aggressive B-cell lymphoma, notably related to its wide pathologies, molecular variations, and clinical behaviors. At MDACC, our preference is that all patients with aggressive B-cell lymphoma be evaluated for a clinical trial at each treatment stage.

Frontline Therapy

Large B-Cell Lymphomas

R-CHOP remains the backbone of therapy for untreated DLBCL. However, the total number of cycles and addition of radiation depends on stage at presentation and tumor bulk. Abundant efforts to improve R-CHOP, including increased dose density with 14-day cycles, the use obinutuzumab in place of rituximab, or intensification of therapy to, for example, dose-adjusted (DA) etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (EPOCH) have been made, but have generally failed to show significant clinical benefits.[90–92] Notably, the phase 3 trial Alliance/CALGB 50303 showed that DA-EPOCH-R was more toxic and did not improve PFS and OS compared with R-CHOP. However, the subgroup analysis showed improvement of PFS for patients with high IPI (3–5) when treated with DA-EPOCH-R.

Treatment Option by Stage

Early-Stage Aggressive Non-Hodgkin B-Cell Lymphoma

Therapy of early (localized) stage I and II includes chemoimmunotherapy with R-CHOP administered alone or combined with radiation therapy (RT; combined modality therapy [CMT]). The choice of chemoimmunotherapy alone versus CMT and number of cycles of systemic therapy are influenced by adverse effects, comorbidities, response to therapy, and personal preference. For instance, for patients in whom RT may cause substantial early toxicity (notably if there is involvement of the oronasopharynx or pelvis) or late toxicity (in young women whose breasts would be in the RT field), treatment with chemoimmunotherapy alone can be favored. Inversely, the lower total dose of doxorubicin of an abbreviated course of chemotherapy associated with CMT may be preferred for a patient with marginal cardiac function.

The following trials studied the optimal therapy of early-stage DLBCL, which has to be tailored according

to adverse features, size of lesion(s) and response to therapy.

The FLYER trial showed that in patients with favorable prognosis (aged 18–60 years, with stage I-II disease, normal serum LDH, ECOG performance status 0–1, and without bulky disease [max tumor diameter <7.5 cm]), four cycles of R-CHOP plus two cycles of rituximab was noninferior to six cycles of R-CHOP (Table 9-8), with relevant reduction of toxic effects. After a median follow-up of 66 months, 3-year PFS was 96% with four cycles of R-CHOP versus 94% with six cycles of R-CHOP.[95]

Moreover, in the SWOG S0014 trial, patients with limited-stage disease and at least one adverse risk factor as defined by the stage-modified IPI (nonbulky stage II disease, age >60 years, WHO performance status of 2, or elevated serum LDH) treated with three cycles of R-CHOP plus one cycle of rituximab followed by 40–46 Gy of involved-field radiation therapy (IFRT) showed 2-year PFS of 93% and 4-year PFS of 88%. This study highlighted a pattern of continuing relapse likely related likely to biologic differences between limited- and advanced-stage lymphoma.[28,94]

In addition, some studies, such as RICOVER-60/RICOVER-noRTh (6 cycles of R-CHOP plus 2 cycles of rituximab followed by IFRT of 36 Gy to sites of initial bulky [≥7.5 cm] disease and extralymphatic involvement) report that adding RT to chemoimmunotherapy may improve outcomes for patients with bulky disease; however, this is not well proven.[95]

Alternatively, the NCTN Study S1001 proposed PET-directed therapy to improve outcomes and decrease toxicities. After three cycles of R-CHOP, patients with nonbulky (<10 cm), stage I/II, untreated DLBCL had an interim PET after cycle 3. Patients with negative PET scan results (Deauville 1–3, interim [i] PET-negative) proceeded with one additional cycle of R-CHOP. Patients with positive PET scan results (Deauville 4–5, iPET-positive) were initiated 36 Gy of IFRT, plus an additional boost to FDG-avid area up to 9 Gy, within 5 weeks of the third cycle of R-CHOP. This was followed by ibritumomab tiuxetan three to six weeks after completing IFRT. NCTN S1001 demonstrated that 89% of patients maintained excellent outcomes after four founds of R-CHOP with PET-directed therapy. Only 11% of patients were iPET-positive and required radiation, but they also had excellent outcomes. Together with the FLYER trial in younger patient, this NCTN trial may establish a new standard approach to limited-stage disease for the majority of patients.[96]

Advanced-Stage Aggressive Non-Hodgkin Lymphoma

For patients with advanced-stage lymphoma, six cycles of immunochemotherapy are the standard of care, as established by different trials. In the MInT study, with patients aged 18–60 years with maximal IPI I in stage II–IV disease, or who had stage I disease with bulk, received six cycles of R-CHOP. Bulky and extranodal sites received additional radiotherapy. After a median

Table 9–8 Most Commonly Used Chemotherapeutic Regimens in Aggressive B-Cell Lymphomas

Regimen	Dose/Route	Days	Interval
Frontline			
R-CHOP			
Cyclophosphamide	750 mg/m² IV	1	21 days
Doxorubicin	50 mg/m² IV	1	
Prednisone	100 mg PO	1–5	
Vincristine	1.4 mg/m² IV	1	
Rituximab	375 mg/m² IV	1

follow-up of 34 months, the 3-year event-free survival (EFS) was 79% and 3-year OS was 93%.[97]

Treatment Options by Cell of Origin

Multiple studies have shown that patients with the ABC disease subtype have significantly poorer outcomes with standard up front similar therapy, compared with GCB disease. For instance, in a study of 344 patients with DLBCL treated with R-CHOP that used the Lymph2Cx assay on the paraffin-embedded tissue to identify COO, the 5-year PFS was 48% versus 73%, and 5-year OS was 56% versus 78%, respectively in ABC disease compared with GCB disease.[38,98]

Efforts to improve up front therapy in ABC-DLBCL have combined biologic agents, including ibrutinib,[99] bortezomib,[100] or lenalidomide[101] with R-CHOP with varying success. These agents were chosen for their synthetic lethality specific to the ABC disease, driven by dysregulation and constitutive activation of B-cell receptor signaling, leading to downstream activation of the NF-κB) pathway and uncontrolled gene transcription and cellular survival and proliferation.[98] Alternatively, the Smart Start trial with rituximab, ibrutinib, and lenalidomide alone and combined with chemotherapy in patients with ABC-DLBCL achieved impressive results with 1-year PFS of 92.5% and 1-year OS of 96.5%. Instead, the more intensive R-ACVBP regimen (rituximab, doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone, followed by consolidation with methotrexate, has demonstrated superiority to R-CHOP, but vindesine is not available in the United States.[102] Nevertheless, frontline R-CHOP is still considered the standard of care regardless of COO type. Patients with non-GCB DLBCL should be referred for trials investigating novel therapies.

CNS Prophylaxis

The incidence of CNS relapse among patients with DLBCL is only around 5% in unselected cohorts.[103] However, in high-risk patients, such as those with adrenal/kidney involvement, estimates as high as 36% have been reported (25% at time of diagnosis, 75% at time of relapse).[104] Patients with CNS relapse may have indications of occult disease at diagnosis. Indeed, CSF diagnostic sensitivity is low. Nevertheless, the overall consequence of CNS relapse is often devastating, and for most patients, the median OS is typically only a few months, highlighting the need to accurately identify at-risk patients, screen for CNS disease, and develop safe and effective treatment/prophylaxis strategies.[76]

There are several approaches for risk stratification, prophylaxis methods, and diagnostic tools related to CNS prophylaxis in patients with aggressive B-cell lymphoma.

The CNS-IPI represents a robust risk model but does not integrate high-risk CNS biomarkers such as rearrangement of MYC and BCL2 (DHL), at-risk extranodal sites such as testicles, or subtypes such as IVDLBCL. A retrospective population-based database of patients with DLBCL treated with R-CHOP demonstrated the following two-year CNS relapse risk estimates: CNS-IPI low risk, 0.8%; intermediate risk, 3.9%; and high risk, 12.0%.[76]

There is no prospective study integrating all the previously described risk factors for CNS disease. However, it can be considered reasonable to give CNS prophylaxis to the following patients: any patient with CNS-IPI score of at least 4, any patient with testicular or breast involvement, any patient with DHL/THL, any patient with HIV-associated aggressive B-cell NHL; BL; intravascular DLBCL; plasmablastic lymphoma; PEL; CNS-IPI score of at least 2 *and* adrenal/kidney/uterine/skin involvement; or double-expressor lymphoma (DEL) and/or ABC/non-GCB. Consider as well CNS prophylaxis for patients with CD5+ DLBCL and IgM-secreting DLBCL.[76,105]

Considering the most recent evidence, systemic CNS prophylaxis with 2 to 4 cycles high-dose methotrexate (HDMTX) 3–3.5 g/m^2 is the preferred option with early integration if feasible, typically on days 10 to 15 of R-CHOP.[106,107] Nephrotoxicity is typically the main limiting factor affecting feasibility of this approach, especially in older patients. Also, hepatotoxicity can rarely occur with HDMTX and is contraindicated in patients with effusions, because this can be a drug reservoir, thus enhancing toxicity. Further, given that HDMTX can also cause neutropenia, growth factor support should be considered if HDMTX is to be integrated with R-CHOP. Given the high frequency of leptomeningeal disease in high-risk CNS-IPI patients, intrathecal (IT) chemotherapy (MTX and/or cytarabine 4–8 doses, at least once per cycle of systemic chemotherapy) may be an alternative if HDMTX is contraindicated or integrated in more intense chemotherapy regimens such as EPOCH-R and R-Hyper-CVAD/MA (cyclophosphamide, vincristine sulfate, doxorubicin, dexamethasone/methotrexate and cytarabine) or as a result of patient preference.[76] There is an unmet need for prospective studies validating prognostic models integrating the diverse clinical, biochemical, molecular, and histologic features of aggressive B-cell lymphomas and new less toxic CNS prophylaxis therapies.

Tumor Lysis Syndrome Prophylaxis

Tumor lysis syndrome (TLS) is a potentially life-threatening oncologic emergency characterized by metabolic abnormalities, which may lead to renal insufficiency and cardiac arrhythmias. Cairo-Bishop

risk classification includes biological evidence of laboratory TLS (≥2 of the following changes within 3 days before or 7 days after cytotoxic therapy: uric acid ≥476 μmol/L or ≥25% increase from baseline, potassium ≥6.0 mmol/L or ≥25% increase from baseline and phosphate ≥2.1 mmol/L or ≥25% increase from baseline, calcium ≤1.75 mmol/L or 25% decrease of baseline); proliferation (particularly BL), bulk, and stage of aggressive B-cell NHL; and renal impairment and/or involvement at the time of TLS diagnosis.[108] The best treatment is prevention, based on disease-specific estimated risk of TLS. Low-risk disease is defined as an approximate risk of less than 1% of developing TLS, and requires intravenous fluids, allopurinol, and daily laboratory tests. Intermediate-risk disease is defined as a risk of approximately 1% to 5% of developing TLS, and requires intravenous fluids, allopurinol or rasburicase, and laboratory tests every 8 to 12 hours. Finally, high-risk disease is defined as a risk of greater than 5% of developing TLS, and requires intravenous fluids, rasburicase, cardiac monitoring, and laboratory tests every 6 to 8 hours.[108,109]

For further information about the prevention and management of TLS, please see Chapter 61, Oncologic Emergencies.

SPECIAL TYPES AND SITUATIONS OF LARGE B-CELL LYMPHOMAS

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

Double-Expressor DLBCL

Despite the inferior outcomes seen with R-CHOP therapy, there are limited data evaluating alternative treatment strategies for DEL. Indeed, several retrospective studies showed potentially improved outcome for patients treated with DA-EPOCH-R.[110,111] However, unplanned subset analyses from several trials, including the CALGB 50303 trial, have not found a difference with more intensive treatment for patients with DEL, although they were not powered to look for differences specifically in this subset.[92]

Interestingly, in a retrospective study, patients with DEL stage I/II treated with R-CHOP–like therapy, with or without radiation, did not show significantly inferior PFS or OS compared with patients with non-DEL.[112]

Further prospective clinical trials are needed to better delineate the optimum treatment approach in this patient population. In the absence of definitive data to guide decision making, both R-CHOP and more intensive induction regimens such as DA-EPOCH-R are reasonable approaches for DEL.[113] Because of the increased risk of CNS disease, evaluation for prophylaxis is recommended.

Testicular Involvement

Patients with testicular involvement in DLBCL have increased risk of CNS and extranodal disease and failure in contralateral testis. To prevent these events, it is standard practice to treat them similarly to that in the study IELSG-10, with six cycles of R-CHOP, CNS prophylaxis, preferably with systemic MTX (alternatively with 4 cycles of IT MTX), and RT to the contralateral testis (30 Gy) for all patients and RT to regional lymph nodes (30 to 36 Gy) for stage II disease.[114] Unilateral orchiectomy is usually performed for diagnostic purposes, but orchiectomy alone or RT alone is not a sufficient treatment, even for stage I disease.

T-Cell/Histiocyte-Rich Large B-Cell Lymphoma

Outside a clinical trial, THRLBCL should be treated similarly to other stage-matched DLBCLs. There is conflicting evidence regarding prognosis. However, some studies report that THRLBCL follows a natural history similar to those of other DLBCLs and responds similarly to therapy.[115] Nevertheless future therapies may target the relationship of the tumor cells with their inflammatory microenvironment.[116]

Primary Diffuse Large B-Cell Lymphoma of the Central Nervous System

The treatment of HIV-negative patients with primary diffuse large B-cell lymphoma of the central nervous system (PCNSL) is limited to drugs that can cross the blood-brain barrier, unlike R-CHOP. The most important drug is HDMTX, in general at doses ≥3.0 g/m^2. However, there is no uniform consensus regarding the optimal components of induction and consolidative therapy. Outside a clinical trial, the choice of a regimen is based on a patient's organ function, age, and comorbidities, as well as local institutional preferences.

The combination of chemoimmunotherapy using 5 to 7 cycles of rituximab, HDMTX, procarbazine, and vincristine (R-MPV) is considered one of the standards of care.[117] In this approach, patients have historically received consolidation with reduced-dose whole-brain radiation therapy (rdWBRT) of 23.40 Gy if they are in complete remission, although there is controversy regarding the role of RT. Lower doses of radiation have decreased the long-term neurotoxicity seen in prior studies.[118] In the previously mentioned approach with R-MPV and rdWBRT, patients receive consolidation with two cycles of high-dose cytarabine after completion of RT. Patients who could complete this whole therapy presented a 2-year PFS of 77% and 3-year OS of 87%.[117]

Based on different trials, efficacy of consolidative high-dose chemotherapy (HDCT)/autologous stem cell transplant (ASCT) is similar to WBRT, but the latter

approach carries a higher incidence of neurotoxicity. For instance, in the second phase of the IELSG32 trial, patients who had responsive or stable disease after induction with HDMTX/cytarabine-based therapy assigned to the HDCT/ASCT arm presented a 2-year PFS of 80% and a 2-year OS of 85%; patients assigned to the WBRT arm with 36 Gy presented a 2-year PFS of 69% ($P = .17$) and a 2-year OS of 71% ($P = .12$). As expected, hematologic toxicity was more common in patients treated with HDCT/ASCT, and neurotoxicity was more common in patients who received WBRT.[119]

PCNSL with leptomeningeal lymphoma can be treated with additional IT MTX.

Patients may present with intraocular lymphoma (IOL) either as part of primary IOL (without CNS involvement) or as part of PCNSL with ocular dissemination, which happens in 15% to 25% of cases.[120] Standard treatment of such cases remains unclear but includes MTX-based systemic chemotherapy with ocular external beam radiotherapy and intravitreal chemotherapy with MTX. Intravitreal rituximab is often used to decrease the frequency of methotrexate injections or for MTX-resistant IOL.[121]

For further information about AIDS-related B-cell lymphomas, please see Chapter 52, The Acquired Immunodeficiency Syndrome–Related Cancers.

Primary Cutaneous DLBCL, Leg Type

R-CHOP with or without IFRT 36–40 Gy for solitary or localized disease is considered the first line of treatment in these lymphomas.[122,123] According to some series, PCDLBCL-LT have increased risk for CNS involvement at the time of diagnosis or at relapse, and CNS prophylaxis may be warranted.[124]

EBV-Positive DLBCL, Not Otherwise Specified

Patients with EBV+ DLBCL–NOS should be managed following comparable guidelines as patients with EBV-negative DLBCL. EBV+ DLBCL–NOS, though, has a worse prognosis than EBV-negative DLBCL in the era of chemoimmunotherapy. There is an opportunity to study and develop targeted therapy such as CD30 antibody therapy in the treatment of patients with EBV+ DLBCL–NOS.[52,125]

DLBCL Associated With Chronic Inflammation

DLBCL-CI is very rare and can exhibit variable presentation and clinical course, including an indolent behavior for some cases. Moreover, there is a paucity of data regarding optimal management, which can include excisional surgery (such as pleuropneumonectomy with or without resection of adjacent involved tissues), systemic therapy such as R-CHOP, RT, or a combination of these. In a Japanese series, clinical stage was an important variable in the choice of therapy. Indeed, for limited stage, surgery resection alone was curative in two of four patients. However, advanced DLBCL-CI had a poor prognosis.[126] Because of the rarity of the disease and the multiple types of presentation, referral to a center with experience with DLBCL-CI multidisciplinary management is recommended.

EBV-Positive Mucocutaneous Ulcer

EBVMCU presents an often-benign course, including frequent spontaneous regressions and excellent responses to conservative treatments such as reduction of immunosuppression. If these measures are unsuccessful, some series reported patients responding to systemic therapy such as bendamustine rituximab, R-CHOP, or RT.[127,128]

Lymphomatoid Granulomatosis

Given the rarity of LYG, no standard treatment consensus exists, and treatment has varied widely from observation to systemic corticosteroids, interferon--2b, intravenous gamma globulin, anti-CD20 monoclonal antibody therapy such as rituximab, and/or chemotherapy such as DA-EPOCH-R.[58]

Large B-Cell Lymphoma With IRF4 Rearrangement

Patients with follicular neoplasms often have indolent disease and an excellent prognosis after tumor excision; chemotherapy may not be needed. Patients with purely diffuse neoplasms also have a good prognosis but require chemotherapy. Further studies are needed to determine whether chemotherapy can be reduced or whether a watch-and-wait strategy can be used for patients with localized disease after excision.[26,129]

Primary Mediastinal (Thymic) B-Cell Lymphoma

Because PMBL is uncommon and has been only recently described, there is a paucity of prospective treatment data and a lack of randomized studies.[64] A rituximab and anthracycline–containing frontline regimen is commonly used at most centers in the United States. Notably, DA-EPOCH-R without RT, as described in the phase 2 study of Dunleavy et al showed an excellent outcome with a 5-year EFS of 93% and a 5-year OS of 97%.[130] Alternatively, R-CHOP with RT can be considered equivalent in terms of lymphoma-related outcome, but it carries the risks associated with RT.[131] Nevertheless, a retrospective study of the BC Cancer Lymphoid Cancer Database showed that a PET-guided approach could reduce the use of RT by over 60% without compromising cure rates.[132] Randomized studies are required to validate the optimal approach.

Intravascular Large B-Cell Lymphomas

These lymphomas have a high incidence of CNS relapse. In the phase 2 PRIMEUR-IVL, IVDLBCL patients without apparent CNS involvement at diagnosis received three cycles of R-CHOP, followed by two cycles of rituximab with HDMTX, then three additional cycles of R-CHOP, with IT (methotrexate 15 mg, cytarabine 40 mg, and prednisolone 10 mg) administered four times during the R-CHOP phase. Overall, the 2-year PFS was 76% and the cumulative incidence of secondary CNS involvement was 3%.[133] This regimen warrants further investigation but presents promising clinical outcome.

ALK-Positive Large B-Cell Lymphoma

Because of the rarity of this malignancy, the data are limited to retrospective studies. In the case series of Pan et al, most patients received CHOP, CHOEP, EPOCH, or Hyper-CVAD, and some also underwent RT and HDCT/ASCT. However, patients with ALK+ LBCL showed a dismal outcome, with a 5-year OS of 34% and a median survival of 1.83 years. However, patients with stage I–II disease and/or patients younger than 35 years of age had a significantly better OS.[62] Whenever possible, these patients should be included in a clinical trial.

Plasmablastic Lymphoma

Overall, EPOCH is widely used to treat PBL, with complete response rate (CRR) of 71%.[134] Alternatively, a retrospective study with 16 patients showed that adding bortezomib to EPOCH could lead to a CRR of 94% and a 5-year OS of 63%.[135] However, added toxicity was an issue. Alternative regimens include CODOX-M/IVAC and Hyper-CVAD. Patients may benefit from HDT/ASCT in their first remission.[136] Nevertheless, further studies are required, and patients should be enrolled in a trial whenever possible.

For further information about AIDS-related B-cell lymphomas, please see Chapter 52, The Acquired Immunodeficiency Syndrome–Related Cancers.

HHV8-Positive Diffuse Large B-Cell Lymphoma

Patients with HHV8-positive DLBCL may be treated with similar regimens as patients with HIV-positive large B-cell lymphoma, such as EPOCH or CHOP, with rituximab in case of CD20 positivity.[137] There is a lack of data regarding optimal management of this uncommon malignancy. For further information about AIDS-related B-cell lymphomas, please see Chapter 52, The Acquired Immunodeficiency Syndrome–Related Cancers.

Primary Effusion Lymphoma

There are no prospective studies of PEL. However, in a retrospective study, modified EPOCH resulted in 3-year cancer-specific survival of 47%.[138] Nevertheless, such outcomes of EPOCH or CHOP-like are still unsatisfactory, and an effort to further improve outcomes is needed.[139]

For further information about AIDS-related B-cell lymphomas, please see Chapter 52, The Acquired Immunodeficiency Syndrome–Related Cancers.

High-Grade B-Cell Lymphoma

High-Grade B-Cell Lymphoma, With MYC and BCL2 and/or BCL6 Rearrangements

There is a lack of prospective data to help establish an optimal induction regimen. Multiple retrospective studies have suggested that intensification of upfront therapy such as DA-EPOCH-R, R-CODOX-M/IVAC (cyclophosphamide, doxorubicin, vincristine, methotrexate/ifosfamide, etoposide, high-dose cytarabine, also called "Magrath regimen"), and R-Hyper-CVAD may be superior to R-CHOP, notably with longer PFS.[31,140] At MDACC, our approach to double-hit DLBCL currently includes DA R-EPOCH outside of a clinical trial. CNS prophylaxis is warranted. Retrospective data suggest that there is no improvement of OS with consolidative ASCT in the first remission in patients who were treated with intensive induction regimens.[141] Because of the inferior prognosis of DHL, participation in a clinical trial is highly recommended.

Interestingly, in a retrospective study with DHL stage I/II patients treated with R-CHOP–like therapy, with or without radiation, double-hit status was not significantly associated with inferior PFS or OS. It is possible that early-stage DHLs have a different biology and a more favorable outcome not requiring more intensive therapies.[112]

High-Grade B-Cell Lymphoma, Not Otherwise Specified

HGBL–NOS is associated with a short survival period and substantial extranodal involvement. High-intensity chemotherapy such as DA-EPOCH-R, R-CODOX-M/IVAC, or R-Hyper-CVAD may improve outcome compared with R-CHOP, as shown in the retrospective study of Li et al. CNS prophylaxis is recommended. Consolidative RT for localized disease can be considered. Participation in a clinical trial is suggested.[142]

B-Cell Lymphoma, Unclassifiable

B-Cell Lymphoma, Unclassifiable, With Features Intermediate Between DLBCL and Classical Hodgkin Lymphoma

There is no standard of care regarding the management of patients with GZL. The prospective study of Wilson

et al, with 24 untreated MGZL patients treated with 6 to 8 cycles of DA-EPOCH-R, showed a 59-month EFS of 62% and a 59-month OS of 74%.[143] However, there is no study proving the superiority of R-CHOP to R-EPOCH, and R-CHOP is a valid therapy.[63] Consolidative RT can be considered for bulky or localized disease.[63,144]

Burkitt Lymphoma

The optimal therapy of BL has yet to be defined in a prospective, randomized trial, but R-CHOP is not an adequate therapy. However, if a patient cannot be enrolled in a clinical trial, we use aggressive combination chemotherapy such as DA-EPOCH-R, R-CODOX-M/IVAC, or R-Hyper-CVAD with CNS prophylaxis (Table 9-9). However, in a multi-institutional retrospective study, the risk of CNS recurrence differed according to chemotherapy regimen and was significantly higher for patients treated with DA-EPOCH with intrathecal chemotherapy (12% at 3 years vs CODOX-M/IVAC [4%] or Hyper-CVAD/MA [3%]).[145] Nevertheless, R-EPOCH is less toxic than R-CODOX-M/IVAC or R-Hyper-CVAD and might be an acceptable alternative for patients without evidence of CNS disease, who are unable to tolerate more intensive regimens. However, adequate CNS prophylaxis, notably with HDMTX, should be evaluated.

Patient with low-risk disease (ECOG 0–1, normal LDH, stage I–II, and mass <10 cm) may be treated with a shorter course of chemotherapy.[146–148]

AIDS-related BL should be treated with similar regimens as for HIV-negative patients with BL. Antiretroviral therapy can be safely administered with chemotherapy.[149] For further information about AIDS-related B-cell lymphomas, please see Chapter 52, The Acquired Immunodeficiency Syndrome–Related Cancers.

Burkitt-Like Lymphoma With 11q Aberration

BLL-11q is rare and its optimal management is undefined, although it is most often treated like typical BL.[68,150] Further studies are needed.

Table 9–9 R-Hyper-CVAD Regimen Used in Mantle Cell Lymphoma and Highly Aggressive Lymphomas[a]

Regimen	Dose/Route	Days	Interval
Hyper-CVAD/Methotrexate/ Ara-C			21–28 days
Cycles 1, 3, 5, 7			
Rituxan	375 mg/m^2 IV by slow infusion	1	
Cyclophosphamide	300 mg/m^2/dose over 3 h q 12 h × 6 doses	1–3	
Mesna	600 mg/m^2/day CIV over 24 h daily (Start 1 h prior to cyclophosphamide and complete by 12 h after last dose of cyclophosphamide)	1–3	
Doxorubicin	25 mg/m^2/day CIV over 24 h daily (Begin at 12 h after last dose of cyclophosphamide)	4–5	
Vincristine	1.4 mg/m^2 IV (max 2 mg) (Give 12 h after last dose of cyclophosphamide and on day 11)	4 and 11	
Dexamethasone	40 mg PO daily	1–4 and 11–14	
Cycles 2, 4, 6, 8			
Methotrexate	200 mg/m^2 IV over 2 h then 800 mg/m^2 IV over 22 h	1	
Solumedrol	50 mg IV q 12 h × 6 doses	1–3	
Ara-C	3 g/m^2 IV over 2 h every 12 h × 4 doses	2–3	
Leucovorin	50 mg IV followed by 15 mg IV q 6 h × 8 doses (start 12 h after completion of methotrexate)		
Intrathecal therapy[b]			
Ara-C	100 mg	2	
Methotrexate	12 mg (6 mg if Ommaya reservoir)	7	

[a]Dose reductions for renal insufficiency, age, and previous toxicity are required. Intrathecal chemotherapy is more frequent for proven CNS disease.
[b]Mantle cell lymphoma is not typically treated with intrathecal therapy.

Therapy in Older Adult Patients

As has been repeatedly shown, patients with aggressive NHL over the age of 60 years have a worse prognosis, notably because of comorbid conditions, lower treatment tolerance, and administration of inadequate therapy. We suggest screening for clinical trials with novel therapies. Outside a clinical trial, we recommend full-dose R-CHOP with growth factor support for patients older than 60 years. In the REMARC study, lenalidomide maintenance versus placebo given to 60- to 80-year-old patients with DLBCL after completion of R-CHOP therapy increased the PFS but not the OS, and at the cost of increased toxicity.[151] Alternatively, attenuated immunochemotherapy regimen (R-miniCHOP) can be considered in adult patients older than 80 years.[152]

Patients With Cardiac Disease

Patients with cardiac disease showing a contraindication to doxorubicin can be treated with an alternative regimen. There is a paucity of data to guide the choice of therapy. In a retrospective study with R-CEOP (etoposide substituted for doxorubicin), patients treated with R-CEOP presented a 5-year OS of 49% versus 64% for patients treated with R-CHOP.[153]

Therapy of Refractory or Relapsed Aggressive Non-Hodgkin B-Cell Lymphoma

General Management of Large B-Cell Lymphomas and High-Grade B-Cell Lymphomas

First Relapse

Approximately 10% of patients treated for aggressive NHL fail to achieve a complete remission after induction therapy; their disease is termed *primary refractory* (see Fig. 8–20). A larger portion of patients with aggressive NHL, up to one-third of all patients, will relapse after initially responding to chemotherapy, usually within the first two years.

In the SCHOLAR-1 study, which was done before chimeric antigen receptor (CAR)-T cell therapy, patients with refractory DLBCL had an ORR of 26% (CRR of 7%) to the next line of therapy, and the median OS was 6.3 months. Overall, 20% of patients were alive at 2 years.[89]

Before proceeding to further therapy, the relapse needs to be histologically proven and restaging completed. Participation in a clinical trial is highly recommended.

Intention to Proceed to Transplant

Outside a clinical trial, the standard of care is salvage therapy and HDCT followed by ASCT in chemosensitive patients. Notably, the PARMA trial examined autologous bone marrow transplantation versus salvage chemotherapy in patients with relapsed, chemotherapy-sensitive NHL. Patients were randomly assigned to receive four more cycles of DHAP (rituximab, cisplatin, dexamethasone, high-dose cytarabine) versus high-dose therapy with stem-cell support, showing an EFS rate of 46% in the high-dose arm but only 12% in the DHAP-alone arm.[154]

Conventional salvage therapies include rituximab combined with standard chemotherapeutics such as ifosfamide, etoposide, taxanes, and platinum compounds. Among the most commonly used are R-DHAP, R-ICE (ifosfamide, carboplatin, and etoposide) (Table 9-8), R-GDP (gemcitabine, dexamethasone, and cisplatin), TTR (paclitaxel, topotecan, and rituximab), and R-ESHAP (etoposide, methylprednisolone, cytarabine, and cisplatin). The best chemotherapy regimen would provide the highest response rates with the most tolerable toxicity. There remains no clear evidence regarding the superiority of one regimen over another in randomized studies. Moreover, failure to collect peripheral stem cells is around 10% and does not seem, in the first relapse, to be different from one regimen to another. In particular, the CORAL trial found no difference between R-DHAP and R-ICE. Overall, only 50% of the patients could proceed to HDCT/ASCT, mainly because of an insufficient response to second-line treatment. The rate of collection failure of stem cells was 10% in both arms.[155]

In relapsed disease, the prognostic impact of COO remains less clear. Although the Bio-CORAL study suggested that GCB DLBCL treated with R-DHAP had an improved 3-year PFS compared with those treated with R-ICE, multiple other studies have failed to reproduce these results, including in patients who went on to receive consolidative ASCT.[156] The topic of ASCT if discussed in further detail in Chapter 18, Autologous Hematopoietic Progenitor Cell Transplantation.

Patients who respond to second-line treatment, but who are unable to mobilize stem-cell treatment, should be considered for alternative options such as chimeric antigen receptor T-cell therapy (see Chapter 17, Cellular Therapy for Lymphomas) or donor transplant (see Chapter 19, Allogeneic Transplantation).

Noncandidates for Transplant

Overall, most such patients cannot tolerate the platinum-containing salvage regimens described above, and other salvage regimens are unlikely to achieve a complete and/or sustained remission. The choice of therapy depends on different factors, including performance status, organ function, pathologic features of the disease, and the patient's preferences. We favor participation in a clinical trial, or when a clinical trial is not available, we suggest either ibrutinib (ORR 40%[157]) or lenalidomide with or without rituximab (ORR 28.6%–33%[158,159]) for ABC-subtype lymphomas.

Other acceptable options for second-line salvage therapy include bendamustine rituximab (ORR 62.7%, CRR 37.3%, median PFS 6.7 months),[160] lenalidomide with or without rituximab or rituximab-gemcitabine-oxaliplatin (ORR 61%, CRR 44%).[161]

Second Relapse and More

Optimal treatment for patients who experience failure of at least two different systemic therapies is unknown, and selection of treatment depends on prior therapies, performance status, available resources, institutional preferences, and patient wishes. We recommend participation in a clinical trial. Some patients will choose palliation of symptoms, which may include chemotherapy or immunotherapy as described above.

Outside of a clinical trial, we recommend CAR–T cell therapy, if good performance status and acceptable organ function.

Currently, CAR–T cell therapy is FDA approved after failure of two lines of systemic therapy; however, several trials enroll patients after failure of one systemic therapy. CAR–T cell therapy is explained in further details in Chapter 17, Cellular Therapy for Lymphomas.

When CAR–T cell therapy is not available, we offer allogenic HCT for patients who are medically eligible (see Chapter 19, Allogeneic Transplantation).

For patients ineligible for trials, CAR–T cell therapy, or transplant, who have failed two lines of systemic therapy, polatuzumab-vedotin-BR is FDA approved and presents significant activity (ORR 45%, CRR 40%, median OS 12.4 months).[162]

In addition, the combination of tafasitamab (MOR208), an Fc-enhanced humanized anti-CD19 monoclonal antibody, with lenalidomide showed an ORR of 60% and CRR of 43% in the L-MIND trial.[163]

Alternatively, brentuximab vedotin can be considered for CD30-positive DLBCL (ORR 44%, CRR 15%, median PFS 4 months).[164]

Special Types of Aggressive B-Cell Lymphomas

Transformed Follicular Lymphoma

Patients with a history of follicular lymphoma with subsequent transformation to DLBCL, who had prior doxorubicin-based treatment, should be treated with salvage therapy for recurrent DLBCL.

Recurrent Primary Central Nervous System and Ocular Lymphoma

The treatment of recurrent primary CNS lymphoma is limited because of the inability of many drugs to penetrate the CNS. Moreover, the choice of therapy will depend on the performance status, organ reserve, and patient preferences. Outside a clinical trial, retreatment with high-dose methotrexate (ORR 91%, median PFS after first relapse 61.9 months) with or without rituximab can be attempted if there was a long duration of the first remission.[165] Patients with recent prior whole-brain RT may be at high risk for methotrexate-induced encephalopathy.

In case of refractory disease or short duration of remission after HDMTX, alternative therapies including lenalidomide and rituximab (ORR 32.0%, median PFS 7.8 months[166]), ibrutinib (ORR 52%, CRR 19%, median PFS 4.8 months[167]), HD cytarabine and etoposide (ORR 47%[168]), and rituximab and temozolomide (ORR 53%, median OS 14 months[169]) should be considered.

Responding patients may benefit from consolidation with high-dose chemotherapy (especially with preparative regimens including thiotepa), followed by ASCT.

Primary Mediastinal B-Cell Lymphoma

Relapsed/refractory PMBL should be managed like aggressive B-cell lymphoma. However, some cases with localized disease can be salvaged with RT only. Moreover, in the CHECKMATE-436 trial, patients with relapsed refractory (rr) PMBL that failed at least two lines of therapy presented an ORR of 70% and CRR 43% with brentuximab vedotin, and nivolumab.[170] Alternatively, in the trial KEYNOTE-170, a similar population presented an ORR of 45% when treated with pembrolizumab.[171]

ALK-Positive Large B-Cell Lymphoma

There is a paucity of data regarding optimal management of rr-ALK+LBCL, and participation in a clinical trial is recommended. Outside a clinical trial, there have been reports of short response with ALK inhibitors such as crizotinib[172] or nivolumab.[173] Outcome is generally poor.

B-Cell Lymphoma, Unclassifiable, With Features Intermediate Between DLBCL and Classic Hodgkin Lymphoma

Optimal therapy of rr-GZL is unknown and participation in a clinical trial is recommended. Because of some common biological features with PMBL, there are reports of activity of checkpoint inhibitors[174] and brentuximab vedotin.[163]

Burkitt Lymphoma

Prognosis is poor for patients with rr-BL,[175] and participation in a clinical trial is highly recommended. Outside a clinical trial, for patients with relapse longer than 6 months after completion of appropriate first-line therapy, a second-line therapy such as R-ICE should be considered. If a complete response is achieved, consider HDT/ASCT or allo-SCT. However, patients who do not receive appropriate frontline therapy may respond to a dose-intensive regimen such as R-CODOX-M/IVAC, or R-Hyper-CVAD.

RESPONSE AND FOLLOW-UP

Definitions of Response

Response to therapy is assessed according to criteria based on the anatomic and metabolic changes that occur in disease-involved nodal and extranodal sites.[69] A recent consensus statement was issued by leading clinical investigators to attempt standardization of response criteria to be used in clinical trials. There remains controversy about what constitutes an abnormal PET scan, and it is generally recommended that uptake be compared with the mediastinal blood pool and liver as internal controls and that the results be scored based on these results (Table 9–10).

The use of interim PET/CT is controversial, notably because of false-positive and inter-reader variability, and is not recommended for treatment decisions as part of routine clinical practice.[176]

Restaging

Fluorodeoxyglucose-PET has proven very useful in assessing responses to therapy and is now considered standard of care for initial post-therapy restaging in FDG-avid lymphomas.[69] Despite this recommendation, FDG-PET/CT should not be used for long-term follow-up imaging after initial response is confirmed (Fig. 9–13).

Surveillance

Follow-up of patients with aggressive NHL after complete remission and cessation of therapy is

Table 9–10 Response Definitions for Clinical Trials

Response	Definition	Nodal Masses	Spleen, Liver	Bone Marrow
CR	Disappearance of all evidence of disease	(a) FDG-avid or PET positive before therapy; mass of any size permitted if PET is negative (b) Variably FDG-avid or PET negative; regression to normal size on CT	Not palpable, nodules disappeared	Infiltrate cleared on repeat biopsy; if indeterminate by morphology, immunohistochemistry should be negative
PR	Regression of measurable disease and no new sites	≥50% decrease in SPD of up to 6 largest dominant masses; no increase in size of other nodes (a) FDG-avid or PET positive prior to therapy; one or more PET positive at previously involved site (b) Variably FDG-avid or PET negative; regression on CT	≥50% decrease in SPD of nodules (for single nodule in greatest transverse diameter); no increase in size of liver or spleen	Irrelevant if positive before therapy; cell type should be specified
SD	Failure to attain CR/PR or PD	(a) FDG-avid or PET positive prior to therapy; PET positive at prior sites of disease and no new sites on CT or PET (b) Variably FDG-avid or PET negative; no change in size of previous lesions on CT		
Relapsed disease or PD	Any new lesion or increase by ≥50% of previously involved sites from nadir	Appearance of a new lesion(s) >1.5 cm in any axis, ≥50% increase in longest diameter of a previously identified node >1 cm in short axis Lesions PET positive if FDG-avid lymphoma or PET positive prior to therapy	>50% increase from nadir in the SPD of any previous lesions	New or recurrent involvement

CR, complete remission; CT, computed tomography; FDG, [^{18}F] fluorodeoxyglucose; PD, progressive disease; PET, positron emission tomography; PR, partial remission; SD, stable disease; SPD, sum of the product of the diameters.
Reproduced with permission from Cheson BD, Pfistner B, Juweid ME, et al: Revised response criteria for malignant lymphoma, *J Clin Oncol*. 2007 Feb 10;25(5):579-586.

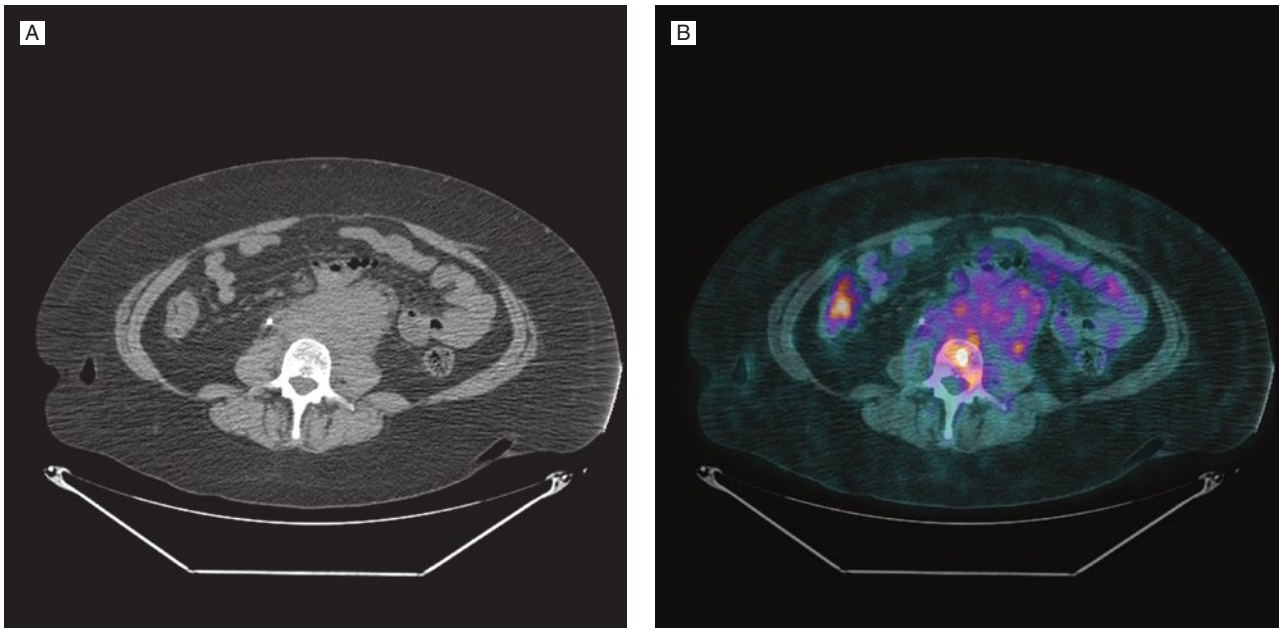

FIGURE 9–13 **Residual mass, not residual lymphoma. After completing chemotherapy, this patient had a residual soft tissue abnormality in the retroperitoneum. A. This was previously positive on FDG-PET, but now does not have activity above background levels and is considered negative. B. Biopsy of this mass was negative, and it was stable on follow-up studies. Previously, this would be considered a partial response (PR) or unconfirmed complete response (CRu). Under the revised criteria, considering the FDG-PET findings, this is considered a complete response (CR).**

typically done every 3 to 6 months for 2 years, then annually until year 5, although there is significant controversy about optimal use of surveillance imaging. A large retrospective evaluation of the utility of surveillance imaging to detect recurrence, compared with patient-reported complaints, found that most DLBCL recurrences were identified based on symptoms and not imaging alone and that outcomes were not different between imaging and symptom-identified recurrences.[177] The emergence of blood-based minimal residual disease detection techniques may ultimately make the debate about the utility of imaging moot.

Relapse or Recurrence

The presence of a new lesion, either by anatomic criteria or on FDG-PET scan, is highly suspicious for relapsed or progressive disease. However, a biopsy to confirm imaging findings is essential. FDG-PET is nonspecific, and uptake may occur in both benign and malignant tumors, in inflammatory or infectious lesions, and with normal physiologic processes. Sarcoidosis and fungal infections may mimic lymphoma, and biopsy is often necessary to exclude recurrence (Fig. 9–14). A single persistent or new focus of activity, with paradoxical response at other sites of disease, requires further evaluation with a biopsy, because findings may represent a premalignant lesion, such as a thyroid or colonic adenoma, or an incidental second malignant tumor (Fig. 9–15).

NEW DIRECTIONS

Over the last 30 years, remarkable advances have been made in the diagnosis, characterization, and treatment of patients with aggressive NHL. It is our strong recommendation that all patients be considered for clinical trials to move the field forward.

The multitude of the dysregulated circuits, the overall complexity and heterogeneity of aggressive B-cell lymphomas (which may also involve nongenetic mechanisms), and the interplay with the microenvironment underscore the need for more precise patient stratification to improve personalized medicine. Moreover, advancements in bioinformatics and gene-editing technologies in translational medicine will lead to significant progress in this area in the near future.

In addition, significant advances may come from the use of circulating tumor DNA (ctDNA), which proved to be a reliable surrogate for simultaneously tracking multiple somatic mutations in aggressive B-cell lymphomas, with high specificity and sensitivity.[178] This approach was superior to radiographic

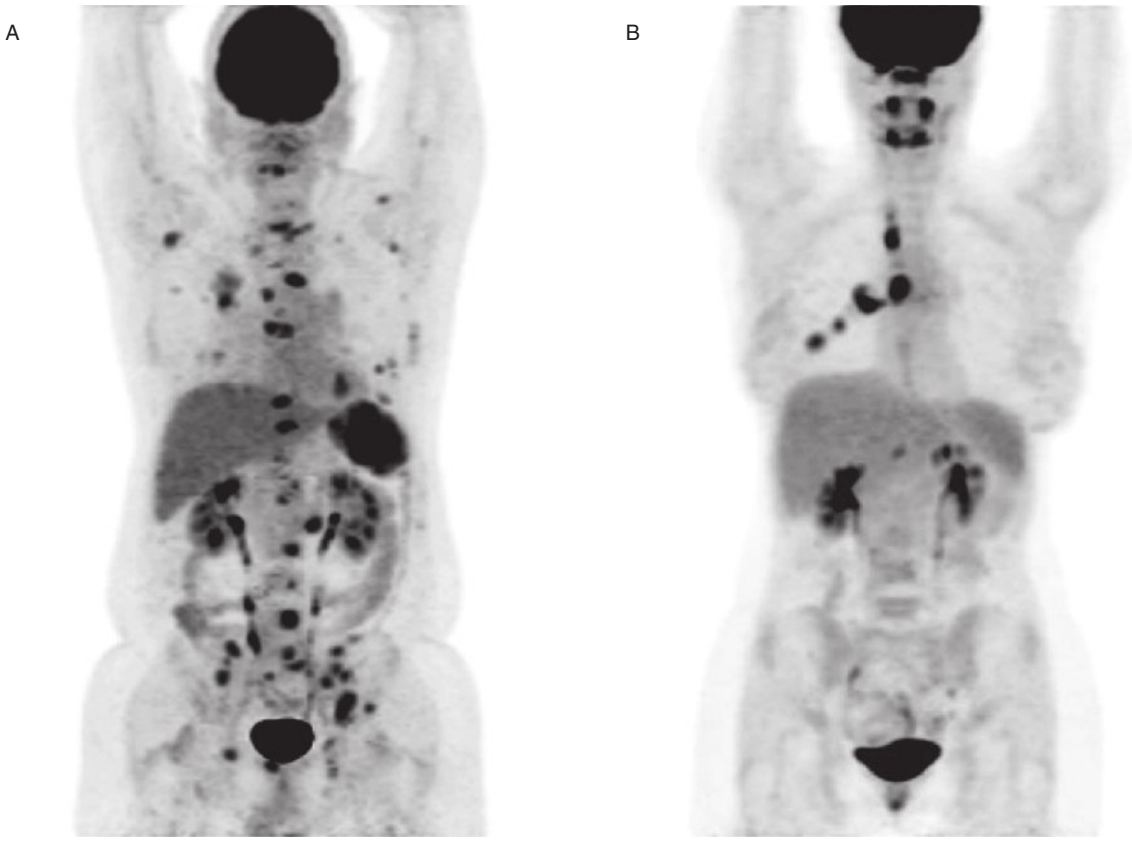

FIGURE 9–14 **Examples of false-positive FDG-PET. Restaging study is suspicious for recurrent lymphoma. A. With predominantly osseous involvement; however, biopsy revealed non-necrotizing granulomas thought to be caused by sarcoidosis. Two months later, nearly all of the FDG-avid sites resolved without any therapy. B. A second patient presented over 10 years after successful treatment for lymphoma with new lymphadenopathy and lung opacities that were positive on FDG-PET. Biopsy revealed fungal lymphadenitis.**

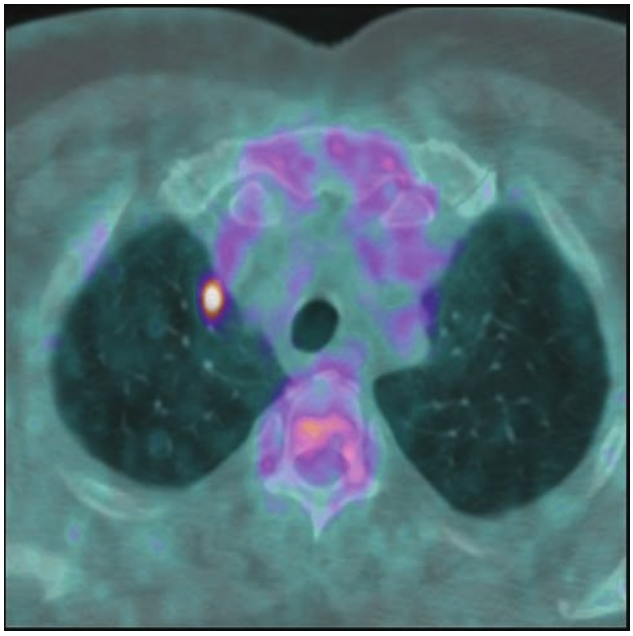

FIGURE 9–15 **Incidental significant finding on FDG-PET/CT. An enlarging metabolically active lung nodule is seen. Biopsy revealed non–small-cell lung cancer, and the patient went on to have lobectomy for stage I lung cancer.**

imaging for the detection of minimal residual disease and was independently predictive of clinical outcome in a study. Moreover, ctDNA genotyping allows the identification of distinct patterns of clonal evolution, which makes it a valuable tool in the setting of transformation or relapse, by informing individualized therapy.[179] Furthermore, the discovery of genes and pathways that are recurrently disrupted in DLBCL reveals vulnerabilities in the lymphoma cells that are often uniquely associated with distinct lymphoma subtypes and could thus be exploited for the design of more effective, targeted therapeutic approaches. It is expected that additional novel therapeutic targets will be identified as more mutational events become functionally dissected.[180]

There is an unmet need to improve the prognosis of relapsed/refractory disease, to decrease the relapse rate of frontline therapy, decrease toxicity, and to tailor treatments for rarer malignancies. Improved novel, immune, and cellular therapies such as CAR–T cell therapies will likely be moved from the last line of therapy to the second line and frontline, and use of standard cytotoxic therapy might become progressively obsolete.

MD ANDERSON PRACTICE TIPS

- Our preference is that all patients with aggressive B-cell lymphoma be evaluated for a clinical trial at each treatment stage at MDACC.
- Therapy of early-stage, favorable prognosis, nonbulky (maximal tumor diameter <7.5 cm) DLBCL can include a shorter course of R-CHOP without consolidative RT, if complete response is achieved at completion of systemic therapy.
- There is a lack of prospective data to help establish an optimal induction regimen of HGBL, with MYC and BCL2 and/or BCL6 rearrangements (double-hit lymphoma [DHL]). Our approach currently includes DA R-EPOCH with CNS prophylaxis, outside a clinical trial. However, in a retrospective study with DHL, stage I/II patients treated with R-CHOP–like therapy with or without radiation, double-hit status was not significantly associated with inferior PFS or OS. Early-stage DHL may have different biology and a more favorable outcome, not requiring more intensive therapies.[1] More studies are required.
- In the CHECKMATE-436 trial, patients with relapsed refractory PMBL who failed at least two lines of therapy presented an ORR of 70% and CRR of 43% with brentuximab vedotin and nivolumab.[2] Considering the biology of PMBL, these immune therapies present an appropriate option.
- For patients ineligible for trials, CAR–T cell therapy, or stem-cell transplant, who have failed two lines of systemic therapy, polatuzumab-vedotin-BR is FDA approved and presents significant activity (ORR 45%, CRR 40%, median OS 12.4 months). In addition, the combination of tafasitamab (MOR208), an Fc-enhanced humanized anti-CD19 monoclonal antibody, with lenalidomide showed an ORR of 60% and CRR of 43% in the L-MIND trial for a similar population.[3]
- Novel, immune, and cellular therapies such as CAR–T cell therapies will likely be moved from latter lines of therapy of aggressive B-cell lymphomas to second line, and possibly frontline, and use of standard cytotoxic therapy might become progressively obsolete.

10 Mantle Cell Lymphoma

Preetesh Jain
Michael Wang

KEY CONCEPTS

- Advances in the field of mantle cell lymphoma (MCL) have significantly changed our understanding of its pathobiology. With the treatment modalities currently available, the response rates and survival have improved but this lymphoma still remains incurable. Heterogeneity in clinical presentation of patients poses a therapeutic dilemma among the clinicians. Broadly, two distinct clinical variants are recognized—an indolent non-nodal leukemic phase, which is generally SOX-11–negative, and another nodal or extranodal SOX-11–positive conventional MCL.
- Pathogenic relevance of factors such as overexpression of SOX-11 in lymphoma cells, proliferative lymph node microenvironment, clonal and subclonal evolution, presence of mutations in epigenetic modifiers, and presence of CCND1 genes in addition to other cell cycle–associated genetic aberrancies are closely associated with survival, growth, proliferation and maintenance of MCL clones in tumor microenvironment and maintain minimal residual disease.
- An improved understanding of B-cell receptor kinase signaling pathways, such as Bruton tyrosine kinase (BTK) pathway is identified as a critical pathway for therapeutic targeting of MCL B-cells.
- Patients with MCL who exhibit high-risk features at initial diagnosis such as high-risk MCL international prognostic index (MIPI) score, blastoid and/or pleomorphic histology, high Ki-67% (≥50%), *TP53* aberrations, MYC gene rearrangement, complex genomics (*CCND1, CDKN2A, NSD2, KMT2D, SMARCA4*, and *NOTCH1* or *NOTCH2* mutations) and complex karyotype generally portend a poor prognosis and frequent relapses.
- Long-term follow-up of intensive chemoimmunotherapy studies demonstrated durable responses and remissions in a subset of patients with MCL. However, the advent of newer agents for frontline therapy, such as ibrutinib, acalabrutinib, and their combinations with rituximab and venetoclax, are very promising and under active investigation.
- The focus of treating MCL is rapidly changing toward investigation of "chemotherapy-free" agents such as BTK inhibitors, venetoclax, and rituximab. Most recently, the FDA approval of anti–CD19-chimeric antigen receptor therapy (CAR-T)—brexucabtagene autoleucel—has been a landmark advancement in treating patients with MCL.

Mantle cell lymphoma (MCL) is a distinct category of B-cell non-Hodgkin lymphoma (B-NHL). These patients generally exhibit an aggressive, albeit heterogeneous, clinical course but smoldering or indolent forms of MCL are also recognized. In this chapter, we will provide a comprehensive update on various aspects of MCL—factors associated with the etiopathogenesis, clinical and diagnostic features, advances in risk stratification, management of MCL, current challenges, and management approach at MDACC to treat MCL.

INCIDENCE AND POSSIBLE PREDISPOSING RISK FACTORS

MCL comprises about 3% to 10% of adult-onset NHL in Western countries, with an incidence of approximately four to eight cases per million persons per year, and its incidence is rising, with an estimated 3320 cases[1] diagnosed in 2016.[2–4] Its incidence appears to be rising in older adult patients (age ≥65 years) and in non-Hispanic whites.[5] The median age at initial

presentation in Western countries is 68 or 71 years old. Furthermore, the incidence of MCL in Asian countries is variable[6,7] (1%–6%) and appears to be lower than in Western countries, and MCL initially presents at a lower median age of 60 years in Asian countries.[8,9] Overall, the incidence of MCL is higher in whites.[10] A male predilection of MCL with a male/female ratio of more than 2:1 is common.[11] Precise reasons for male predisposition is unknown.

Few possible predisposing risk factors for MCL include[12] possible associations with European strains of the *Borrelia burgdorferi* when it involves skin as acrodermatitis chronica atrophicans,[13] living/working on farm houses,[14] polymorphisms in IL-10 to 1082A>G,[15] and twofold increase risk of hematologic malignancies in first-degree relatives of patients with MCL.[14,16] Autoimmune diseases (10% of MCL can be associated with autoimmune diseases),[17] and B-cell–mediated autoimmune diseases posed a negative impact on the survival of patients with MCL.[18] Similar to findings from studies in small lymphocytic lymphoma/chronic lymphocytic leukemia (SLL/CLL), antigenic drive is hypothesized to have a role in the development of MCL. This is probably related to the finding of a biased and highly restricted immunoglobulin (IGHV) gene repertoire[19] with stereotyped variable heavy chain (VH) complementary determining region (CDR3s) and recognition of superantigens[20] by the B-cell receptor (BCR) of clonal MCL B-cells. The role of micro-RNA (miR-155, miR18b, and miR-17-92) and epigenetic perturbations[21] (aberrant methylation especially for NFkB and HDAC1 and methylation status) in MCL etiopathogenesis is also being explored. Further, patients with MCL are at higher risk of developing second primary cancers (melanoma, thyroid, nonepithelial skin cancers, SLL/CLL, and other hematologic malignancies).[22]

DECODING THE ETIOPATHOGENESIS OF MCL

In the last decade, our understanding on the development, origin, and growth of MCL cells has significantly improved. Various factors[23] such as SOX-11 (SRY [sex-determining regions-Y] box transcription factor 11) nuclear transcription factor, cell cycle dysregulation, genomic instability, microenvironment, resistance to apoptosis, and epigenetic perturbations are involved.[24] Most MCL cases are postulated to derive from naïve pre–germinal center B-cells of the mantle zone, which do not demonstrate somatic hypermutation of IGHV genes, whereas a subset of MCL may originate from marginal zone or peripheral blood memory B-cells. Of note, MCL is a distinct lymphoma but demonstrates a close resemblance to SLL/CLL.[25] The heterogeneity in the clinical course of MCL is likely caused by the extent to which these factors are involved in an individual patient.

Based on these developments, two forms of MCL are recognized in the World Health Organization classification of B-NHL in 2016.[26] Figure 10–1 depicts the development of the two forms of MCL.[23]

Nodal or Extranodal

This is a conventional form of MCL with unmutated IGHV, SOX-11–positive, aggressive MCL. Naïve B-cells do not undergo germinal center reaction.[27] SOX11 has been reported to block B-cell differentiation, suggesting that it has a direct role in MCL pathogenesis, a higher degree of genomic instability, and increased frequency of *ATM*, *TP53*, *CDKN2A*, and *KMT2D* mutations.

Non-Nodal, Leukemic and SOX-11–Negative, Mutated IGHV

This form develops with a generally, indolent or smoldering clinical course. The smoldering variant is thought to develop from an antigen-experienced, memory B-cells.[28,29] These patients have a generally stable genome. Compared with conventional MCL, the non-nodal variant has fewer copy number alterations and fewer structural variants.[30] With leukemic clinical presentation, it can masquerade as CLL and CD200 can be positive.[31] TLR2 and CCND1 mutations are overrepresented. A high number of DNA methylation changes[27] and/or presence of *TP53* mutations in these patients may negatively affect the prognosis.

In addition, biopsies from patients may reveal the presence of cyclin D1+ cells in the inner mantle zone of lymphoid follicles (this is termed in situ mantle cell neoplasia).[26,32] Instances of patients with this variant are rare, with an indolent course and low risk of progression to overt MCL. These patients must be recognized to avoid inadvertent systemic therapy.

MAJOR PATHOGENETIC FEATURES OF MCL

Cyclin D1 Overexpression

Constitutive overexpression of cyclin D1 with translocation t(11;14) (q13;q32) is considered the hallmark oncogenic step in almost all MCL. This translocation is not specific to MCL and can be seen in multiple myeloma. The juxtaposition of DNA coding sequence for cyclin D1 at 11q13 with the immunoglobulin heavy chain joining region at 14q32 promotes cell cycle transition from G1 to S phase and promotes cell proliferation. Overexpressed cyclin D1 activates cyclin-dependent

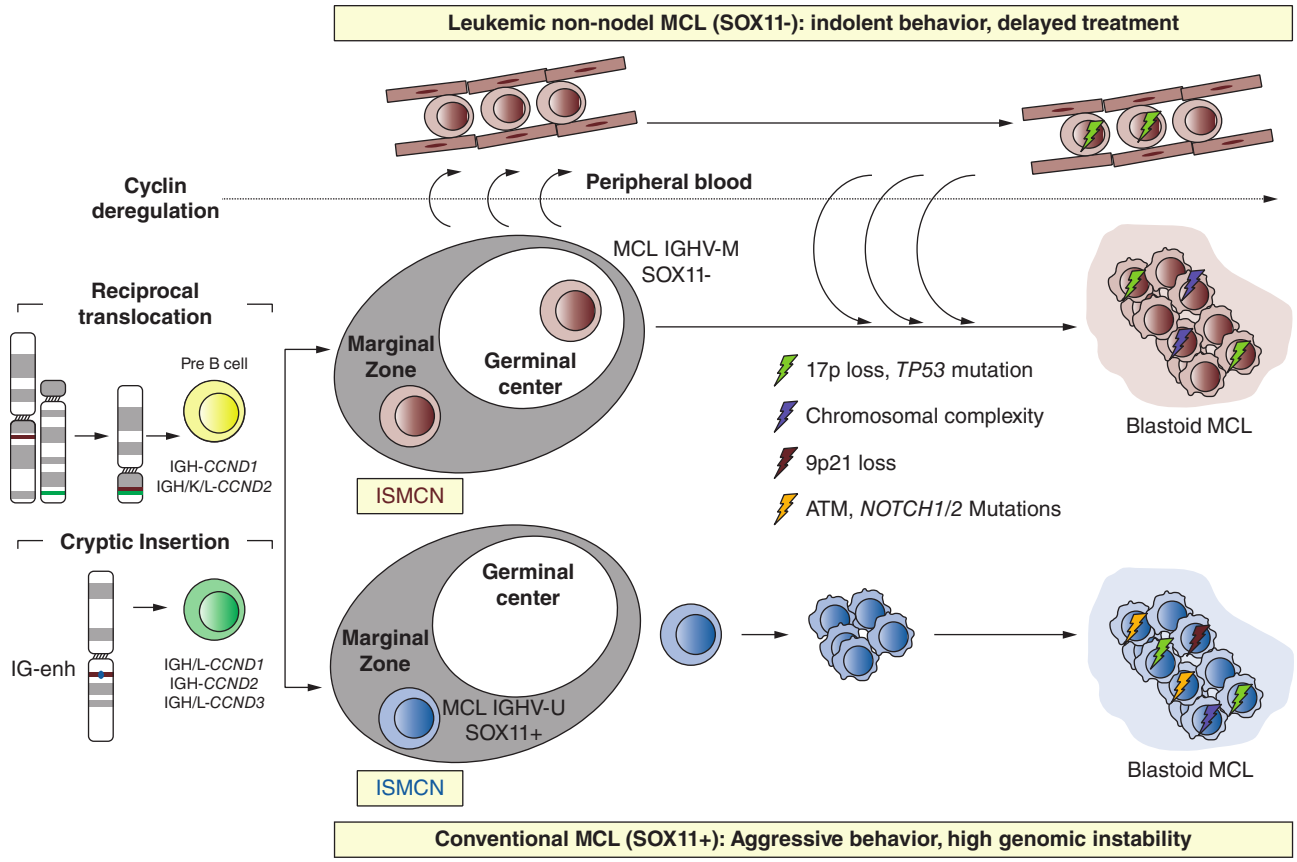

FIGURE 10–1 **Possible model for development of mantle cell lymphoma (MCL). Two major clinical forms: one is a common conventional form, which is aggressive in its clinical course and is characterized by SOX-11–positive and unmutated immunoglobulin heavy chain variable region (IGHV) and another is an indolent form of MCL, which is generally leukemic, non-nodal, SOX-11–negative, and exhibits germinal center reaction feature with somatic hypermutation of IGHV. In situ mantle cell neoplasia (ISMCN) is the presence of MCL clones in the inner mantle zone without disrupting the nodal architecture. The addition of other aberrant molecular changes such as TP53 and CDKN2A deletions are shown to alter the clinical course toward an aggressive blastoid or pleomorphic type of MCL. (Reproduced with permission from Navarro A, Beà S, Jares P, et al: Molecular Pathogenesis of Mantle Cell Lymphoma, *Hematol Oncol Clin North Am* 2020 Oct;34(5):795-807.)**

kinases 4 and 6, which in turn phosphorylate and inactivate Rb (tumor suppressor gene) and promote G1 to the S phase, leading to rapid cell proliferation. Cyclin D1 also interacts with chromatin remodeling, histone-modifying enzymes and transcription factors and modulates transcriptome. Perinucleolar localization of t(11;14)[33] or the CCND1 allele is important because these areas are rich in RNA polymerase II, leading to activation of cyclin D1 transcription.[34] Truncated form of cyclin D1 (deletion affecting the 3′ untranslated region of cyclin D1) stabilizes the cyclin D1 transcript,[35] and this results in increased cyclin D1 mRNA levels. Increase in the truncated form of cyclin D1 is associated with poor clinical outcome.[36]

Cryptic Pyclin D1-Positive MCL

Rarely, variant cyclin D1 translocations such as translocation t(2;11) (p11;q13)[37] and t(11;22) (q13;q11.2),[38] where the MCL cases show cyclin D1 rearrangement with IgK or IgL, are observed. Conventional karyotype or fusion or break-apart fluorescent in situ hybridization (FISH) probes fail to detect these variant translocations. Occasionally, cyclin D1 may not be detectable by immunohistochemistry but is detectable by FISH, and this is related to the presence of cyclin D1b isoform[39] or a mutation in C-terminal domain on cyclin D1.

Cyclin D1-Negative MCL

Rarely, cyclin D1 is negative by immunohistochemistry and t(11;14) is not detectable by FISH. Cyclin D2 or cyclin D3 gene rearrangements or an upregulation of cyclin E can be observed.[40,41] In a third of these rare cases, Ig light chain enhancer hijacking is observed as the initial oncogenic aberration. Generally, these cases are associated with SOX-11 positivity, exhibit a similar

gene expression profile, and clinical course to that of conventional MCL, but very rare cases with cyclin E dysregulation are associated with blastoid morphology and an aggressive clinical course.[41]

Other Cell Cycle Dysregulations

CDKN2A Deletions

CDKN2A gene encodes for p16 (INK4A; a cyclin-dependent kinase inhibitor that specifically inhibits CDK4 and CDK6 keeping RB1 active) and for p14 (ARF; a E3 ubiquitin-protein ligase that stabilizes *TP53* by interacting with MDM2 preventing its degradation).[42] Deletion of INK4a/ARF locus on 9p21 occurs in about 20% to 25% MCL and is associated with aggressive histology MCL.[43]

CDK4 Amplification

Gains in 12q or copy number gains in 12q are associated with promotion of cell cycle dysregulation and an aggressive (blastoid) histology MCL.[44] Inhibition of CDK4 can possibly overcome ibrutinib resistance.[45]

SOX-11 Overexpression

SOX-11 is a neural transcription factor that plays a critical role in the pathogenesis of MCL. Overexpression of SOX-11 is observed in conventional MCL and in 25% to 50% of Burkitt lymphoma.[46] SOX-11 overexpression in MCL is shown to influence MCL cells via various mechanisms—constitutive activation of PAX-5, thereby blocking the differentiation of B-cells to plasma cells by impairing BLIMP1[47]; augmented BCR signaling[48]; suppression of Bcl-6 to avoid germinal center transit of MCL cells, which exhibit unmutated IGHV[49]; promotion of angiogenesis via platelet-derived growth factor α[50]; and migration and adhesion of MCL cells to stromal cells via upregulation of CXCR4 and focal adhesion kinases, leading to enhanced PI3K/AKT signaling and promoting cell adhesion–mediated drug resistance.[51]

TP53 Mutations

TP53 gene (tumor protein 53) is a tumor suppresser gene located at 17p13.1, which, when inactivated, deleted, or mutated, can unleash genomic instability, cell cycle upregulation, inhibition of apoptosis, and promotion of cell growth. *TP53* mutations predict an aggressive disease course and inferior outcomes[52] in MCL.

ATM Mutations

Ataxia telangiectasia mutated (ATM) tumor suppressor gene is located on 11q22-q23 and ATM mutations are observed in approximately 30% to 50% of MCL cases. ATM is involved in the detection of DNA damage and plays an important role in the regulation of cell cycle progression.

Apoptosis Resistance

In MCL, resistance[53] to apoptosis may occur as a result of overexpression of B-cell lymphoma 2 (BCL2), upregulation of the PI-3 kinase/AKT prosurvival signaling pathway, and/or activation of nuclear factor-κB (NF-κB) and/or mutations in *TP53*. Gain-of-function truncating mutations in *NOTCH1* and *NOTCH2* genes are also relevant in mediating apoptosis resistance in MCL.[54,55] NOTCH activation may also induce overexpression of MYC.

Epigenetic Perturbations and Other Molecular Alterations

Integrated genomics approaches have revealed that complex genomic variants[30,56] and higher degree of DNA methylation is associated with higher proliferation and aggressive behavior of MCL cells.[27] Common mutations that affect the epigenetic pathways in MCL include *KMT2D*,[57] *NSD2*,[58] and mutations in *SWI-SNF* chromatic remodeling complex[59]; *SMARCA4, SMARCA2*, and *ARID2* mutations are associated with resistance to ibrutinib-venetoclax in MCL. Other mutations such as *MEF2B and UBR5*[60] are infrequent in MCL and influence transcription and post-transcription processes. Other aberrant somatic mutations include *MAP2K14, NOTCH2, BIRC3, KMT2D, CARD11, SMARCA4*, and *BTK*.[61] Activation of PI3K/AKT and the integrin-β1 signaling pathway[62] has been shown as another mechanism of acquired ibrutinib resistance. Of note, mutation profile in case of ibrutinib resistance or venetoclax resistance in MCL is different from that of CLL because BTKC481S mutations were infrequent in MCL[58] (10%–15%) and BCL2 mutations were also infrequent in venetoclax-resistant MCL.[63] Altered splicing of the HNRNPH1 gene associated with RNA processing is also observed in patients with MCL.[64]

Microenvironmental Impact and BCR Signaling Kinases

The tissue microenvironment cellular composition and cytokine milieu play a vital role in MCL cell growth and survival and promote drug resistance. In contrast to peripheral blood, the lymph node microenvironment in patients with MCL is unique, having a differential expression of genes involved in BCR signaling and canonical NF-κB pathways.[65] This feature in MCL provides activation signals to MCL cells and

is involved in drug resistance. In addition, because the M2 polarized macrophages (CD163+), which are tumor-associated macrophages, play an important role in promoting MCL cell survival via colony-stimulating factor-1,[66] therefore, inhibition of colony-stimulating factor-1 receptor might be clinically useful. Targeting various components of BCR signaling[67,68] and interactions with stromal cells can overcome treatment resistance and eradicate dormant residual cells.[69] Additional studies on the cytokine-chemokine milieu and its interaction with MCL cells and stromal cells in tissue microenvironment are under investigations. Finally, an immune "cold" microenvironmental signature was shown to be associated with ibrutinib resistance in MCL.[70]

Furthermore, using RNA sequencing, we showed that a dysregulated metabolic programming exists in MCL cells and contributes to ibrutinib resistance. Inhibition of oxidative phosphorylation in MCL cells can provide an opportunity to inhibit ibrutinib-resistant MCL cell growth in patient-derived mouse models.[71]

CLINICAL WORKUP AND DIAGNOSIS OF MCL

Clinical manifestations of MCL are summarized in Table 10–1[72] and commonly present as symptomatic progressive generalized lymphadenopathy, cytopenia, and bone marrow infiltration. Enlarged spleen, tonsils, and parts of the gastrointestinal tract (lymphomatous polyposis)[73,74] are common. Extranodal involvement of the kidneys and central nervous system (CNS) is rare.[75,76] The pure asymptomatic, non-nodal leukemic phase, in which the absolute monoclonal lymphocyte count is higher than 5000 cells/μL is infrequent and may masquerade as CLL. The asymptomatic indolent or smoldering nodal/extranodal[77] or leukemic non-nodal presentation[26,78] is seen in about 10% to 20% of cases and generally does not require immediate systemic treatment, and can simply be safely observed.[79] Conversely, most patients with MCL (~80%) present with symptomatic lymphadenopathy or extranodal disease requiring systemic therapy. Appropriate diagnostic workup of patients with MCL is the initial critical step to determine the diagnosis and the prognosis. Figure 10–2 outlines our clinical approach to the patient with MCL.

The initial workup includes history and physical examination, assessment of performance status, comorbidities, and B symptoms. Laboratory workup must include a complete blood cell count with differential count, comprehensive metabolic panel, serum lactate dehydrogenase (LDH) levels, β_2 microglobulin levels, and hepatitis panel. Bone marrow aspiration/biopsy and involved tissue biopsy is routinely performed at initial diagnosis. Immunophenotype on peripheral blood/bone marrow/involved tissue biopsy is critical. The typical MCL immunophenotype[26] is CD5, CD20, CD19, sIgM/sIgD, FMC-7 + B-cells with monoclonal kappa/lambda light chains, dim/negative

Table 10–1 Clinical Presentations in MCL Patients

Clinical Presentation	Clinicopathologic Features
Smoldering MCL[77]	Asymptomatic and with absence of B symptoms (drenching night sweats, unintentional weight loss of >10% of normal body weight over a period of ≤6 months or less, fever >38 °C), main indicator for smoldering MCL Normal serum LDH, β_2 microglobulin levels White blood cell count <30,000 K/μL Low MIPI (mantle cell lymphoma international prognostic index) score Ki-67% on lymphoma cells in nonmarrow tissue biopsy of <30% Nonblastoid/pleomorphic cytomorphologic pattern in tissue biopsy Maximum lymph node diameter <3 cm, spleen size <20 cm PET scan showing the maximum standardized uptake value <6 Absence of *TP53* or *NOTCH1/2* mutations by DNA sequencing Absence of deletion 17p or MYC translocation/amplification by FISH testing, absence of complex karyotype
Asymptomatic purely leukemic nonblastoid MCL	Monoclonal B lymphocytosis (with typical MCL immunophenotype and nonblastoid morphology) in peripheral blood with or without splenomegaly
Conventional MCL (most common)	Symptomatic bulky nodal/extranodal disease Classic or blastoid/pleomorphic cytomorphology At initial diagnosis or at clinical progression

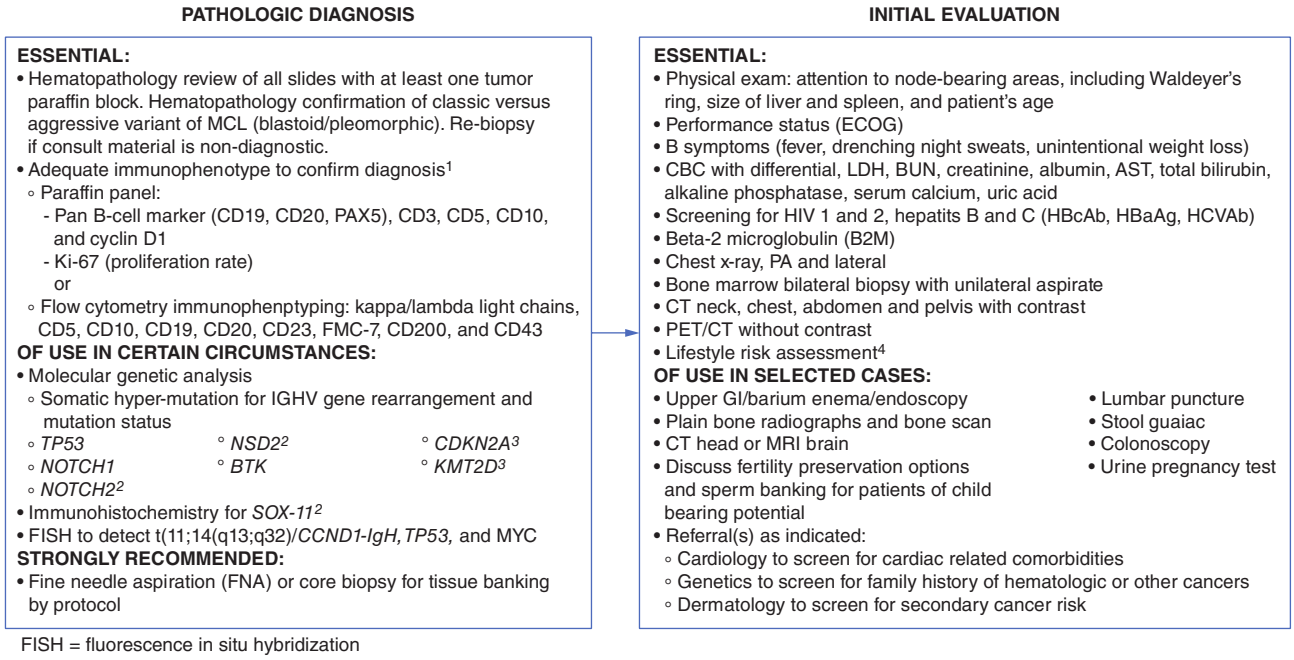

FIGURE 10–2 Outlines of our approach in the initial evaluation of a patients with a newly diagnosed mantle cell lymphoma (MCL). Immunophenotype: CD5++, CD20++, CD43++, CD23–/+/+, cyclin D 1+. Note: Some cases of MCL may be CD5–, CD10++, or CD23. If the diagnosis is suspected, cyclin D 1 staining or FISH to demonstrate t(11;14, q13, q32) should be performed. Currently approved. Currently not available for routine testing. Ongoing reassessments of lifestyle risks (smoking, physical activity, and nutrition should be a part of routine clinical practice).

CD23, dim/negative CD200, and strong cyclin D1 expression. Immunohistochemical analysis of involved nodal/extranodal tissues shows a strong nuclear staining for cyclin D1 (BCL-1 or PRAD-1), and generally MCL cells are positive for SOX-11. Cytogenetic assessment for karyotype or FISH showing translocation t(11;14) (q13; q32) is an important diagnostic hallmark of MCL (90%). At MDACC, if the BM involvement is higher than 10% by MCL cells then we also perform somatic mutation of IGHV genes, percent deviation from germline IGHV sequence, and type of VH gene usage. Targeted DNA sequencing from involved tissues for somatic mutations such as *TP53*, *NOTCH1/2*, *BIRC3, CDKN2A*, *NSD2*, *BTK*, and *ATM* genes is very useful.

Comprehensive histopathologic assessment of involved tissue biopsy is required. Morphology at initial diagnosis can change at disease progression/relapse to an aggressive morphology (blastoid/pleomorphic), ie, transformed MCL (t-MCL). Figure 10–3 shows the morphologic spectrum of MCL. The histology can vary from classic morphology (nodal, mantle zone, interstitial, diffuse) to an aggressive histology (blastoid or pleomorphic). MCL cell size can vary from small to medium with irregular nuclei to lymphoblast-like cells (medium to large) that are blastoid or pleomorphic. It is mandatory to obtain the Ki-67%[80] of MCL cells from the involved nonmarrow tissue biopsies for prognosis. Imaging studies should be obtained for staging and include assessment with whole-body positron emission tomography-computed tomography (PET-CT) scan or CT scan only. Serial imaging studies will demonstrate response to treatment (Lugano lymphoma response criteria).[81] A pregnancy test, magnetic resonance imaging of the brain, electrocardiogram, echocardiogram, and endoscopic evaluation of the gastrointestinal tract (essential to confirm stage I-II disease) should be conducted depending on the clinical presentation and/or requirement by the clinical trial protocol (if applicable). Cardiac status should be evaluated by a cardiologist before starting Bruton tyrosine kinase (BTK) inhibitor therapy. Consider stem cell transplantation (SCT) consultation for high-risk patients. Lumbar puncture is performed in cases with clinically suspected CNS involvement. In addition to morphology, immunophenotype should be performed from any fluid assessments (cerebrospinal fluid and/or ascitic or pleural fluid).

Finally, exploratory investigations in MCL would include serial plasma samples and genomic evaluation of tissue biopsies at diagnosis and relapse, analysis of minimal residual disease (MRD) and copy number changes, as well as for chromosomal aberrations and clonal evolution assessment. Multiomic assessment with single-cell sequencing is performed at MDACC.

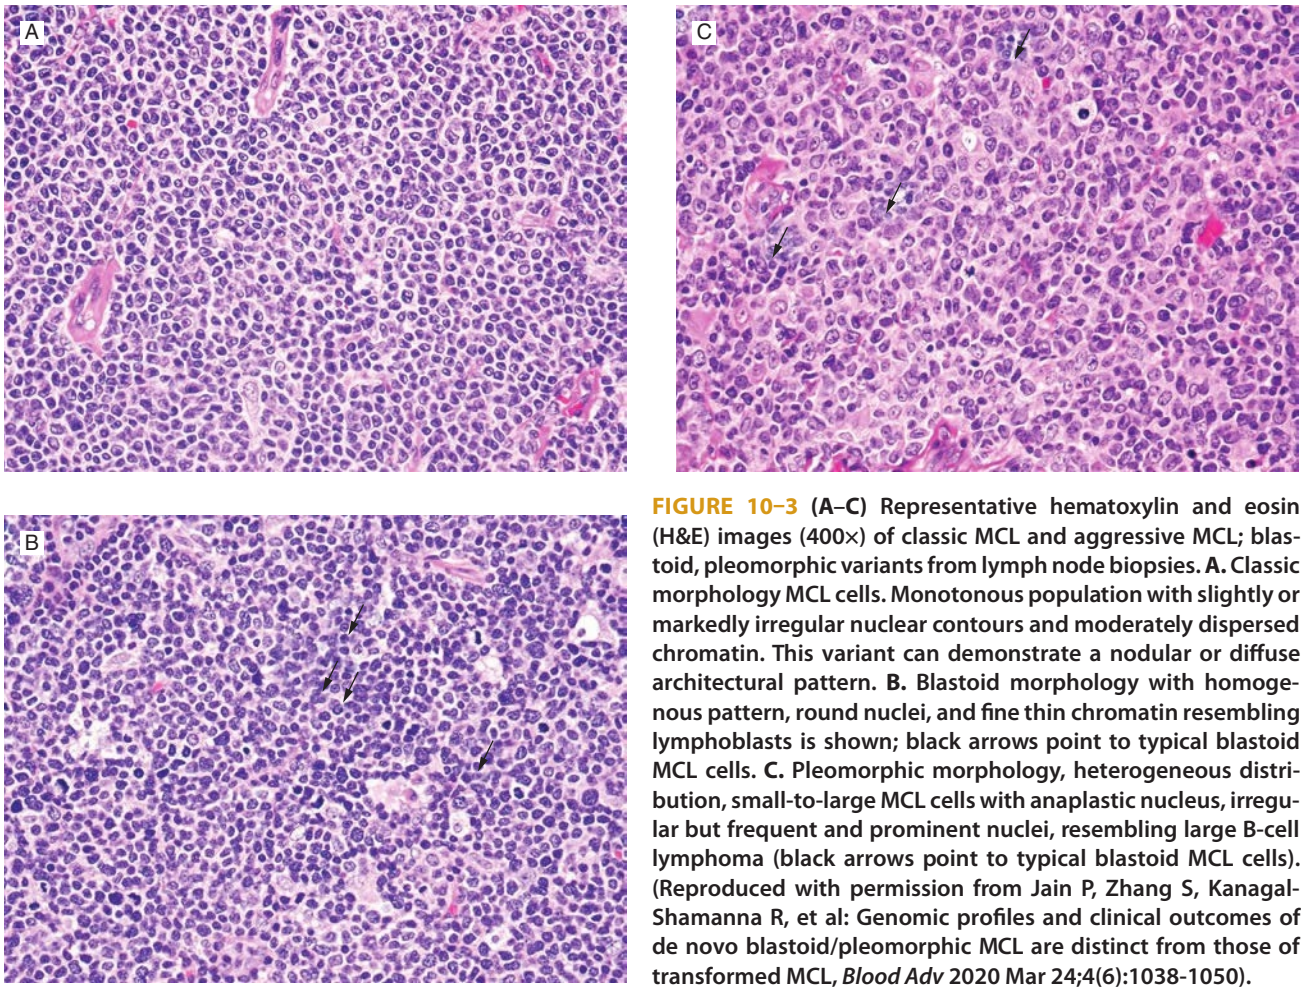

FIGURE 10–3 (A–C) Representative hematoxylin and eosin (H&E) images (400×) of classic MCL and aggressive MCL; blastoid, pleomorphic variants from lymph node biopsies. A. Classic morphology MCL cells. Monotonous population with slightly or markedly irregular nuclear contours and moderately dispersed chromatin. This variant can demonstrate a nodular or diffuse architectural pattern. B. Blastoid morphology with homogenous pattern, round nuclei, and fine thin chromatin resembling lymphoblasts is shown; black arrows point to typical blastoid MCL cells. C. Pleomorphic morphology, heterogeneous distribution, small-to-large MCL cells with anaplastic nucleus, irregular but frequent and prominent nuclei, resembling large B-cell lymphoma (black arrows point to typical blastoid MCL cells). (Reproduced with permission from Jain P, Zhang S, Kanagal-Shamanna R, et al: Genomic profiles and clinical outcomes of de novo blastoid/pleomorphic MCL are distinct from those of transformed MCL, *Blood Adv* 2020 Mar 24;4(6):1038-1050).

Differential Diagnoses

MCL can be distinguished from other masquerading lymphoid malignancies such as SLL/CLL,[25] follicular lymphoma, marginal zone lymphoma, and B-cell–prolymphocytic leukemia. Translocation t(11;14) (q13;q32) can be observed in a fraction of patients with multiple myeloma (20%–25%), SLL/CLL (2%–5%), and plasma cell leukemia and B-cell–prolymphocytic leukemia (20% with t (11;14) and cyclin D1+ cells, and these are considered as the leukemic phase of MCL[82]). Cyclin D1 expression is also observed in a subset of patients with myeloma, hairy cell leukemia, and splenic lymphoma, and SOX-11 expression can be seen in Burkitt lymphoma (20%–25%), hairy cell leukemia, and lymphoblastic lymphoma.

Atypical MCL

Variations from the typical immunophenotype of MCL are included under this category. These variations are largely based on flow cytometric evaluation of the involved tissues and include CD10+ MCL,[83] CD5-negative MCL,[84] cyclin D1–negative MCL,[40,85] CD200+ MCL,[31] SOX-11–negative MCL,[28,86] and CD23–positive MCL.[87] In some cases, biopsies may reveal presence of cyclin D1+ cells in the inner mantle zone of lymphoid follicles (termed as *in situ mantle cell neoplasia*),[26,32] which should not lead to a diagnosis of MCL.

PROGNOSTIC FACTORS IN MCL

Determining the prognosis is of vital importance. Various parameters that can reliably predict patient prognosis are summarized in Table 10–2. We have implemented the inclusion of these risk factors to select therapy in the ongoing clinical trials at MDACC. We believe that in the future, the selection of therapy will be based on risk factors. Thus far, the relevance of prognostic factors is well established in patients treated with chemoimmunotherapy. We also anticipate that with the advent of newer therapies, the prognostic impact of risk factors may change.

Table 10–2 Summary of Prognostic Markers in Newly Diagnosed Patients With MCL

Currently Used	May Be Included Under Initial Workup if Available in Clinical Practice
Performance status Advanced age with comorbidities MIPI risk categories[88] Blastoid/pleomorphic cytomorphology Ki-67% >30%[90] *TP53* mutations, *TP53* by FISH or overexpression of *TP53* by immunohistochemistry[52]	Complex karyotype[103] MYC translocation or overexpression[104] Unmutated IGHV status[28] Additional somatic hypermutations - *NOTCH1* and *NOTCH2* mutations,[55] *CCND1, NSD2 (WHSC1)*[55a], *SWI/SNF (SMARCA4)*[a], *BIRC3, KMT2D/MLL2, BTK*[a],[58] *CDKN2A*[a], *MAP3K14*[a], *CARD11*[a] MCL35 RNA expression assay[113] Tumor metabolic volume by PET-CT scans MRD testing by flow cytometry, PCR for IgH, t(11;14), IgH clonocseq or by ctDNA miRNA18b[91]

[a]Gene mutations associated with ibrutinib-venetoclax resistance in patients with relapsed MCL.

CHAPTER 10

As of this writing, the following factors are used in routine clinical practice to determine high risk in MCL patients: high-risk MIPI (mantle cell lymphoma international prognostic score), blastoid or pleomorphic histology, high Ki-67% (≥30%) score, and *TP53* mutations. In addition, in relapsed patients, t-MCL and/or complex karyotype and/or early progression within 12 to 24 months after starting first-line chemoimmunotherapy or detection of additional somatic mutations in addition to *TP53* such as *CDKN2A*, *KMT2D*, *NSD2*, *NOTCH1/2*, *BIRC3*, or *SMARCA4* are highly indicative of high-risk MCL.

The MIPI risk scoring is commonly used. The simplified MIPI score is based on a weighted sum (of performance status, age, LDH levels higher than upper limit of normal and white blood cell count) and divides the patients into low-, intermediate-, and high-risk categories.[88] The score can be used as a continuous variable. Patients with MIPI scores less than 5.70 were classified as low risk, patients with MIPI scores of at least 5.70 but lower than 6.20 as intermediate risk, and patients with MIPI score of at least 6.20 as high risk. The 5-year overall survival (OS) rate in low-, intermediate- and high-risk MIPI categories was 81%, 63%, and 35%, respectively, and this was validated in the context of European randomized clinical trials with chemoimmunotherapy.[89] The prognostic value of the simplified MIPI risk score is further improved by adding the value of Ki-67%, and this modified MIPI score is also called biologic MIPI or MIPIb.[90] In general, a Ki-67% more than 30% is considered as the high-risk category and a cutoff value of more than 50% is used at MDACC. The 5-year survival percentage in low-, intermediate-, and high-risk MIPIb categories was 81%, 83%, and 37%, respectively. Further modifications of MIPI—combined MIPI (MIPIc) with binary Ki-67% and MIPI score and MIPIb with expression of miR-18b[91]—are reported. The presence of aggressive-histology MCL, ie, blastoid or pleomorphic variants, exhibit an inferior prognosis compared with classic histology MCL. We described patients with de novo aggressive-histology MCL who had superior survival (48 months) compared with patients with t-MCL (14 months). These aggressive histologies coexist with additional high-risk features, especially with CNS involvement (5%). In addition, high-risk genomic profile is frequently observed in aggressive-histology MCL[92] (reviewed in detail in reference 93). Because most of the patients with aggressive-histology MCL also exhibit high Ki-67%, patients with either one or both of these risk factors are considered as high-risk MCL.

Finally, *TP53* gene mutations are well established in MCL.[94,95] Reported frequency of *TP53* mutations at initial diagnosis is about 15% to 25%, and the frequency of these mutations increases up to 45% at relapse.[96] High tumor burden of *TP53* mutations indicates a worse prognosis.[97] A Nordic group[52] has reported that the frequency of *TP53* mutations at initial diagnosis was 11%, and these patients have a poor response to standard frontline chemoimmunotherapy. The median OS was 1.8 years in *TP53* aberrant versus 12.7 years in patients without *TP53* aberrancy. *TP53* gene mutations may coexist with other aberrations such as *NOTCH1* mutation (71%), deletion of *CDKN2A* (del9p21) (31%), and deletion of *TP53* (del17p13) (31%). The presence of both *TP53* deletion (detected by FISH) and *TP53* mutations (by DNA sequencing) was associated with the worst survival. In addition, we have demonstrated that *TP53* mutations may coexist with *NSD2* mutations in three of four patients with ibrutinib-resistant t-MCL.[58]

Other Important Prognostic Factors

SOX-11

Absence of SOX-11 expression with mutated IGHV identified a subset of patients with MCL with a favorable prognosis.[28,98] The clinical relevance of SOX-11

in nodal MCL in the era of newer therapies remains unclear.[99] *IGHV somatic mutation status* and the type of VH gene usage type are important variables. Patients with mutated MCL (>3% deviation from the germline sequence)[100] exhibit a better outcome compared with patients with unmutated IGHV; however, the systematic studies on IGHV mutation status in MCL are lacking, especially in the context of newer therapies.[28] Complex karyotype, defined as having three or more chromosomal abnormalities in addition to t (11;14) or additional chromosomal abnormalities detected by conventional karyotype,[101] also coexist with *TP53* mutations and generally exhibit poorer outcomes.[102,103] Miscellaneous factors associated with frequent relapses and disease resistance include *CDKN2A* (locus 9p21) deletions[43,59]; *MYC* gene rearrangements; and amplification of MYC,[104–108] *NOTCH1*,[54] and/or *NOTCH2*[55] mutations; *NSD2* mutations[55,109]; *CCND1* mutations[110]; and *KMT2D*[57] *SWI/SNF* (SWitch/sucrose nonfermentable) chromatic remodeling complex mutations (including *SMARCA4* gene); these are associated with ibrutinib-venetoclax resistance,[59] *BIRC3* (Baculoviral IAP repeat containing three mutations are seen in 10%–15% of patients with MCL). *BIRC3* deletions of 11q21–q23 are common alterations in MCL, and in addition to *ATM*, *BIRC3* is also located in this region (11q22.2). *BIRC3* aberrations in MCL may result in decreased response to ibrutinib because of a failure to suppress the alternate NF-κB pathway mediated by *MAP3K14,* which is proposed as a therapeutic target in *BIRC3*-mutated lymphomas.[111] Elevated absolute monocyte count is also prognostic.[112]

Gene proliferation signature (MCL35 assay) is predictive of prognosis. Using a NanoString RNA expression–based molecular assay (MCL35[113–115]), a 17-gene proliferation signature was validated to predict prognosis in patients with MCL treated with first-line chemoimmunotherapy. In another study, a six-gene signature (*AKT3, BCL2, BTK, CD79B, PIK3CD,* and *SYK)* was predictive of poor outcome,[116] but exhibited higher sensitivity to ibrutinib.[117] Micro-RNA (miRNA) profile is investigational.[29,118] Patients with an overexpression of miR-18b[91] were identified as a high risk in the MCL3 prospective clinical trial. The impact of complete metabolic response after treatment completion is also known to correlate with a better clinical outcome[119]; however, this aspect requires further validation for MCL in prospective studies. Detailed discussion of mechanistic relevance of each prognostic factor in the context of MCL is beyond the scope of this chapter.

Post-Treatment Prognostic Factors

Early Disease Progression

Disease relapse or progression within 12 to 24 months after receiving first-line therapy such as intensive chemoimmunotherapy (with/without) SCT can portend a poor outcome and increased risk of relapse on subsequent lines of therapies.[120] Visco et al.[121] demonstrated that among the 188 patients who received intensive chemoimmunotherapies (with/without consolidative SCT), patients with early disease progression (<24 months from diagnosis; n = 90) had significantly shorter OS (from the time of disease progression after first-line therapy to death from any cause) compared with late progressors (n = 98) (median survival 12 months and not reached, respectively; $P < .001$). Patients with early failure had an increased risk of death.

MRD-Positive Status

This is proposed as an important prognostic factor to predict relapses. The optimal technique to detect MRD in MCL is investigational—either flow cytometry from bone marrow (if involved at baseline), peripheral blood polymerase chain reaction (PCR) for IgH or IgH clonoseq by next-generation sequencing, or tracking ctDNA (circulating tumor DNA or liquid biopsy). MRD estimation and optimization in MCL is investigational. In a phase 3 randomized trial,[122] patients (n = 240) who had received four cycles of rituximab – dexamethasone, cisplatin, ara-C (R-DHAP) induction followed by auto-SCT were randomly assigned to observation versus rituximab maintenance groups. The rituximab maintenance group received 375 mg/m^2 rituximab once every 2 months for 3 years. This study demonstrated that rituximab maintenance can improve survival after SCT. Achieving MRD-negative status improves outcome and may obviate the need for maintenance therapy after SCT. MRD assessment in MCL has not been systematically implemented in clinical practice; however, a few studies[123] have shown the clinical significance of MRD-positive disease status and risk of predicting future relapses.[124–126] Kolstad et al has shown that preemptive rituximab treatment has shown benefit in turning MRD-positive status post auto-SCT to MRD-negative status; however, 69% of patients relapsed after rituximab therapy. Detailed discussion of methodology of MRD and various studies in MCL with MRD is beyond the scope of this chapter and is discussed elsewhere.[127]

Progression on BTK inhibitors

The approval of the BTK inhibitor ibrutinib is a major advance in MCL[128]; however, progression an outcome of patients who progress on ibrutinib has become a therapeutic challenge as these patients generally exhibit poor outcomes. The pattern and mechanisms of resistance of ibrutinib in MCL are under active investigation. The median survival after progression on ibrutinib was 2.9 months in 114 patients with MCL.[129] In a cohort of 80 patients with relapsed MCL

at MDACC who discontinued ibrutinib,[58] the outcomes of patients who progressed on ibrutinib (n = 41) were very poor, with a median survival of 9 months (range 6–10). Response rates to subsequent treatments were about 30% with chemoimmunotherapy, bendamustine, lenalidomide, or bortezomib. Furthermore, development of anti–CD19-CAR-T has demonstrated excellent results in managing BTK inhibitor–refractory MCL[130]; however, longer follow-up of this modality is awaited.

TREATMENT OF PATIENTS WITH MCL

Various factors should be considered before selecting therapy. These include patient related factors: performance status, age, comorbidities, disease status (smoldering nodal MCL vs leukemic non-nodal vs conventional nodal MCL presentation), organ dysfunction, prior therapies (if relapsed), toxicities from prior therapy, eligibility for SCT, financial constraints, and availability of a clinical trial. Feasibility for clinical trial or referral to a specialized center that treats patients with MCL should always be explored. A recent study from the United Kingdom showed that patients who received treatment at specialized centers had better outcomes compared with those treated at nonspecialized centers.[131]

Chemoimmunotherapy still remains a standard frontline treatment in most centers. Chemotherapy-associated toxicities, prolonged myelosuppression, infection-associated mortality, therapy-related myelodysplasia, and second cancers remain a serious concern.

Considerable advances are made in the treatment for patients with MCL. Currently, the focus is headed toward chemotherapy-free treatments in the frontline and relapsed settings. In the relapsed setting, BTK inhibitors, venetoclax, and FDA approval of brexucabtagene autoleucel are major achievements. Initially, BTK inhibitors were shown as effective in canine lymphoma models.[132] This seminal study drove human trials with BTK inhibitors in lymphoma.[133] Our group led the initial clinical trial of ibrutinib in relapsed MCL.[128,134] Subsequently, we also led the FDA approval for acalabrutinib.[135] Venetoclax is also investigated in refractory MCL.[63,136,137] Furthermore, we characterized ibrutinib[58] acalabrutinib,[138] and venetoclax-refractory[139] MCL patients and their genomic features to possibly explore mechanisms of resistance. Finally, our group led the pivotal Zuma-2 study and the FDA approval of brexucabtagene autoleucel (anti–CD19-CAR-T) in relapsed or refractory MCL.

Despite these advances, more research and newer clinical trials are needed in MCL. High-risk patients, patients who are triple resistant (refractory to BTK inhibitors, venetoclax and anti–CD19-CAR-T), and patients who have CNS disease continue to remain a huge therapeutic challenge.

At MDACC, we approach patients with MCL using the following five clinical categories: (1) smoldering MCL; (2) previously untreated patients (age <65 or age ≥65 years) in all risk categories; (3) previously treated relapsed MCL–BTK inhibitor-naïve; (4) previously treated relapsed MCL–BTK inhibitor refractory; and (5) triple-relapsed-refractory MCL.

Smoldering MCL

For patients with excellent performance status (0), no B symptoms or asymptomatic, nonbulky disease (<5 cm) with normal LDH levels, low Ki-67% (<30%), and nonaggressive cytomorphology, we do not recommend systemic therapy and these patients can simply be observed.[77] These patients can also exhibit an asymptomatic, non-nodal leukemic phase or localized gastrointestinal involvement. We counsel these patients about the risks and benefits of observation alone.[140] It is also important to distinguish smoldering MCL from MCL in situ neoplasia because in situ neoplasia does not qualify to be referred to as MCL.

Observation as an initial strategy in MCL is described by eight different studies. Most recently, a series of 94 patients by Kumar et al[141] was reported. The median time of observation alone was 23 months and non-nodal clinical presentation was associated with longer time to initiate treatment. Although patients with high Ki-67% (>30%) tend to receive immediate therapy versus observation alone, among the patients who were under observation alone, the time to first treatment was similar, irrespective of Ki-67%. This finding indicated that extent of clinical symptoms and clinical features, rather than Ki-67% or *TP53* status, should determine whether patients can be observed. In another study from British Columbia,[79] 440 patients were reviewed (75 with observation alone for ≥3 months, 365 with early treatment). Overall, 80% of patients underwent observation for more than 12 months, including 10 patients who were observed for more than 5 years. The median follow-up in the observation group was 48 months, and the median time to first treatment was 35 months (range 5–79). The median OS was significantly longer in the observation group compared with the early treatment group (72 vs 52.5 months; $P = .04$). Patients with non-nodal clinical presentation or those with negative *TP53* by immunohistochemistry had longer survival in the observation group. Another study using the National Cancer Database reported that among 8029 patients with MCL, 492 were deemed as wait-and-watch-alone. Younger age, male gender, and lack of comorbidities were predictive of OS.[142]

A group from Spain reported the initial results of ibrutinib with rituximab in indolent MCL (n = 40).[143] They demonstrated that in patients with indolent MCL, ibrutinib with rituximab therapy led to deep MRD-negative responses (87%). At MDACC, we are conducting a phase 2 study with single-agent ibrutinib in high-risk smoldering MCL (NCT03282396). High-risk smoldering MCL refers to patients who have clinically smoldering MCL but exhibit high-risk features, with *TP53* mutations and/or high Ki-67% (≥30%). In this study, we are investigating whether the use of ibrutinib in smoldering MCL instead of observation alone can prolong the time to first treatment in high-risk patients with MCL.

Limited-stage disease, ie, stages I/II, is uncommon. These patients can fall into the smoldering MCL category; however, there are patients who have limited-stage disease but significant symptoms and they need treatment—either local radiation or systemic therapy alone. Management of limited disease is detailed in reference 144.

Previously Untreated Patients (Age <65 or Age ≥65 Years)—All Risk Categories

Factors to consider before selecting frontline therapy are age, performance status, eligibility for SCT, risk categories especially for high-risk patients, and available clinical trials. Limited-stage, nonbulky disease may benefit from the addition of radiation to chemotherapy; however, this strategy has not been confirmed in large randomized studies.[145] Chemoimmunotherapy with or without autologous SCT and with or without maintenance therapy is the most commonly used standard-of-care frontline treatment; however, at MDACC, clinical trials or chemo-free therapies are the first choice. In Table–3,[72] we have summarized the findings from major frontline clinical trials in patients with MCL.

Previously Untreated Young Patients (Age <65 Years)—All Risk Categories

At MDACC, the standard of protocol treatment for physically fit, transplant-eligible patients is intensive chemoimmunotherapy with rituximab with HCVAD (hyperfractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone) as part A and methotrexate-ara-C as part B (R-HCVAD/methotrexate-ara-C). We do not recommend consolidation with SCT after R-HCVAD. At other centers, intensive chemoimmunotherapy is followed by auto-SCT and rituximab maintenance in high-risk MCL.[146] The choice of chemoimmunotherapy regimen is based on feasibility, physician choice, and patient choice.

The use of Hyper-CVAD with alternating Mtx/ara-C followed by consolidation auto-SCT, was initially reported from MDACC in 1998.[147] We conducted a phase 2 clinical trial with R-HCVAD/methotrexate-ara-C regimen in 97 patients. After a median follow-up of 13.4 years,[148] the overall response rates (ORR) and complete remission (CR) rates were 97% and 87%, respectively. The failure-free survival in young patients was 30% after 10 years and appeared to reach a plateau. In another study, bortezomib was added to R-HCVAD/methotrexate-ara-C,[149] but the response rates did not improve over R-HCVAD alone.

The R-HCVAD regimen was also tested in two multicenter phase 2 studies—one from Italy[150] (n = 60) and another from SWOG[151] (n = 49). The ORRs were 83% and 86%, respectively. Because of severe hematologic toxicities, 40% to 60% of patients could not tolerate the treatment and could not complete the regimen.

More commonly, a Nordic regimen is utilized in clinical practice.[152,153] In a phase 2 trial with R-maxi CHOP alternating with R-high dose ara-C was used and showed 97% response rate; however, 9% of patients had development of second cancers over long-term follow-up. One phase 2 French study[154] used three cycles of R-CHOP and three cycles of R-DHAP followed by auto-SCT in 60 patients, with 90% to 94% ORR. With a median follow-up of 67 months, the 5-year OS was 75%. In a phase 3 trial from the European MCL network,[155] R-CHOP/R-DHAP followed by auto-SCT was compared against R-CHOP alone followed by auto-SCT. Time to treatment failure was significantly longer with R-CHOP/R-DHAP. In one recent retrospective analysis of young patients with MCL (n = 1254),[146] consolidation auto-SCT was shown to be associated with improved progression-free survival (PFS) but not OS in a multivariate analysis. Considering the durable remissions with auto-SCT, many physicians prefer that young MCL patients receive auto-SCT after intensive induction chemotherapy. In addition, rituximab maintenance for 3 years after four cycles of R-DHAP followed by auto-SCT led to significant improvement in survival outcomes compared with observation alone.[122]

Bendamustine was combined with rituximab (BR) followed by rituximab and high-dose ara-C and auto-SCT in 23 patients.[156] The median follow-up was 13 months, and the PFS was 96%, with a median OS not reached. MRD-negative status after chemotherapy alone was 93%. We do not have data on whether BR induction is a better choice before auto-SCT compared with R-CHOP. In a randomized SWOG study, BR was compared with R-HCVAD before auto-SCT, but the study was stopped prematurely because the stem cell mobilization failure was 29% after R-HCVAD.[157]

Table 10–3 Summary of Pivotal Published Studies in the Frontline Setting in MCL

Protocol Used	Number of Patients	Median Follow-up	ORR (CR), %	Median Remission Duration/PFS	Median OS	Comments
R-HCVAD/Mtx-ara-C[148,229,230] (no auto-SCT)	97	13.4 y	97 (87)	4.8 y	10.7 y	In young (<65 y; n = 65) patients, median FFS 6.5 y and OS 13.4 whereas in older adult (>65 y; n = 32), median FFS 3 y and OS 4.9 y 6.2% rate of myelodysplasia and acute myeloid leukemia Blastoid/pleomorphic histology (n = 15) not associated with survival FFS plateaued after 10 y
R-maxi-CHOP/R-HiDAC (with auto-SCT), Nordic regimen[152,153,231]	160	11.4 y	96 (54/89*)	8.5 y	12.7 y	145 patients received auto-SCT, and median PFS and OS were 11 y and NR 9.4% rate of second cancers (n = 20 with 15 solid tumors and 5 myeloid cancers) Plateau in survival curves not reached, 50% patients relapsed after 12 y
R-CHOP + auto-SCT **R-CHOP/R-DHAP + auto-SCT[155]**	234 232	6.1 y	97 (61) vs 98 (63)	4.3 vs 9.1 y	NR vs 9.8 y	Time to treatment failure longer in ara-C group (9.1 vs 4.3 y) OS was not significantly different 2.4% secondary leukemia and 4.3% other cancers with ara-C group
R-DHAP (4 cycles) + auto-SCT followed by rituximab maintenance vs observation alone[122]	120 each	50 mo	89 (77) after 4[b] R-DHAP	4 y % (83% vs 64%)	4 y % (89% vs 80%)	Maintenance rituximab after R-DHAP induction therapy, followed by R-BEAM consolidation therapy, prevented relapses and was associated with a low risk of major infection
BR vs R-CHOP (StiL)[159]	46 vs 48	45 mo	93[b] (40) vs 91 (30)	35.1 vs 22.1 mo	NR in both	Response rates were reported from both indolent and MCL patients Trend of longer time to next treatment with BR but OS was similar in BR vs R-CHOP Long-term follow-up and detailed subset analysis is not reported

Table 10–3 Summary of Pivotal Published Studies in the Frontline Setting in MCL (*Cont.*)

Protocol Used	Number of Patients	Median Follow-up	ORR (CR), %	Median Remission Duration/PFS	Median OS	Comments
BR vs R-CHOP (BRIGHT)[160,161]	37 vs 37	65 mo	[b]97 (31) vs 91 (25)	5 y 40% vs 14%	82% vs 85% alive at 5 y	Higher second cancers in BR group Detailed subset analysis is not reported Lesser toxicities with BR
Bortezomib-R-CHOP vs R-CHOP alone[164]	[c]243 vs 244	82 mo	92 (53) vs 89 (42)	25 vs 14.4 mo	[c]91 vs 56 mo	Improved overall survival with bortezomib-R-CHOP in patients with high Ki-67% (>30%) 42% died in bortezomib group vs 57% in R-CHOP alone group Similar incidence of second cancers
Lenalidomide-Rituximab[167,168]	38	64	92 (64)	5 y 64%	5 y 77%	6 patients (16%) had second primary cancers (mostly skin cancers) 42% grade ≥3 neutropenia Th2 to Th1 cytokine/chemokine switch after 3 cycles of induction showing immune modulation and effect on inflammation

[a]CR 89% after auto-SCT
[b]In both indolent and MCL patients
[c]140 and 128 patients were included at 82-month follow-up.
The table excludes data in relapsed-refractory MCL and unpublished studies on frontline BTK inhibitors at the time of this writing.
NR is not reached, ORR is overall response rate, CR is complete response rate, yrs. Years, R-HCVAD/Mtx-ara-C (rituximab with hyperfractionated cyclophosphamide, vincristine, doxorubicin, dexamethasone alternating with highdose methotrexate and cytosine arabinoside), R-DHAP (rituximab – dexamethasone, cisplatin, ara-C), StiL (study group indolent lymphoma).

Clinical Trials at MDACC for Young MCL

We have a portfolio of clinical trials for frontline therapy in young, physically fit patients with MCL. We have incorporated orally available targeted therapies in the frontline setting to minimize or obviate the need for chemotherapy except in high-risk patients. These clinical trials include the following.

Window-1 Trial

Ibrutinib with rituximab (IR) induction (Part A) followed by short-course four cycles of R-HCVAD-Methotrexate/ara-C (Part B) were used in 131 patients. After a median follow-up of 22 months, the ORR on part A of therapy was 100% (88% CR and 12% PR) and after completion of both parts A and part B, ORR was 100% (94% CR). Overall, the median PFS and OS were not reached (3 year, 85% and 97%, respectively) and nine patients had relapse after treatment and 21 patients left the study for various reasons. None of the patients had grade 3 or higher atrial fibrillation or bleeding.[158] Longer follow-up of this study is pending. This regimen is included in the 2020 NCCN guidelines for treating MCL (NCT02427620).

Window-2 Trial

Ibrutinib and rituximab induction is followed by venetoclax and risk-stratified use of R-HCVAD-Methotrexate/ara-C. For high-risk patients (4 cycles) and for moderate risk, only two cycles of chemotherapy are approved, whereas the low-risk patients do not receive chemotherapy (NCT03710772).

Other Important Trials in Young MCL Patients in the Frontline Setting

TRIANGLE Study

The TRIANGLE study is a phase 3 trial in young, transplant-eligible patients in Europe. It is a three-arm randomized trial with six cycles of R-CHOP/R-DHAP

+ auto-SCT versus six cycles of R-CHOP + ibrutinib/R-DHAP + auto-SCT + 2 years of ibrutinib maintenance versus six cycles of R-CHOP + ibrutinib/R-DHAP + 2 years of ibrutinib maintenance. Results of this trial would indicate whether ibrutinib and ara-C–based induction is efficacious and can improve the previous results with chemoimmunotherapy alone in induction before auto-SCT (NCT02858258).

E4151 Study

This phase 3 randomized study by a United States intergroup is evaluating maintenance rituximab in patients who achieve MRD-negative CR after induction therapy and who are then randomly assigned to auto-SCT + MR versus MR alone. This study may provide insight into the role of consolidation SCT after achieving MRD-negative CR (NCT03267433).

Previously Untreated Elderly Patients (Age ≥65 Years)—All Risk Categories

Older adult patients usually exhibit comorbidities and therefore may not be eligible for SCT; their tolerability to chemotherapy is generally poorer compared with young and physically fit patients. Older adult patients (n = 32) had significantly inferior failure-free and OS compared with patients younger than 65 years in the long-term follow-up of R-HCVAD/Mtx-ara-C.[148] In general, bendamustine with rituximab (BR) combination is used in the routine clinical practice for older patients with MCL, largely because of its less intensive schedule. The BR regimen was tested in two different phase 3 randomized trials: one in Germany[159] and another in North America.[160,161] In 2013, Rummel and colleagues[159] reported that BR significantly improved PFS in patients with MCL compared with R-CHOP,[159] and showed that BR was less toxic compared with R-CHOP. A nine-year follow-up of this study confirmed these findings.[162] Similar results demonstrating superiority of BR over R-CHOP for improved PFS were reported after a 5-year follow-up of the BRIGHT study.[161] The incidence of second cancers was 19% in the BR group versus 11% in the R-CHOP group in the BRIGHT study. One of the caveats of the BRIGHT study was that this included a combination of patients—indolent and MCL. BR was also studied in combination with low-dose ara-C[163] (R-BAC-500; n = 57; BR + ara-C 500 mg/m^2 on days 2–4 4 weekly), the ORR and CR were 91%, with 50% of patients developing grade 3–4 neutropenia. R-BAC followed by venetoclax as consolidation in high-risk elderly MCL is evaluated (NCT03567876).

Promising OS was noted in a combination of bortezomib with R-CHOP compared with R-CHOP alone, but an increase in hematologic toxicity with combination was noted.[164,165] the European MCL network demonstrated that rituximab maintenance for two years or beyond after induction with R-CHOP significantly improved PFS (5 years) and OS (9.8 years) versus no maintenance (PFS 1.9 years and OS 7 years).[166] Maintenance rituximab after BR has not shown benefit.

Lenalidomide was also investigated in older adults with MCL. A combination of lenalidomide with rituximab was investigated in 38 elderly patients. The 5-year follow-up of this study showed that the majority (75%) of these patients completed more than 3 years of treatment. In a subset of patients (8/10), MRD was negative at the last follow-up assessment.[167,168] However, lenalidomide-based regimens are currently less favored in MCL, largely because of the availability of better, well-tolerated BTK inhibitors and the concern about second cancers with lenalidomide. The combination of lenalidomide with chemotherapy was also investigated. Lenalidomide with BR in one study[169] (n = 51) reported that 42% of patients experienced grade 3–4 infections and 16% of patients developed second cancers. Lenalidomide in combination with bortezomib and dexamethasone[170] showed a 2-year PFS of 70%, but 51% of patients experienced grade 3–4 neutropenia.

Clinical Trials at MDACC for Previously Untreated Older Adults With MCL

We have incorporated orally available targeted therapies in the frontline setting to minimize or obviate the need for chemotherapy. Our clinical trials include the following.

Ibrutinib With Rituximab in Nonblastoid/Pleomorphic MCL

Our group has conducted a phase 2 clinical trial[171] with a combination of ibrutinib and rituximab in 50 patients (NCT01880567). Ibrutinib was administered as 560 mg orally daily for 28 days (one cycle) and was continued until disease progression or discontinuation for any reason. Rituximab was given on days 1, 8, 15, and 22 plus or minus 1 day by IV injection at a fixed dose of 375 mg/m^2 (Cycle 1, followed by rituximab on day 1 of every cycle starting in Cycles 3–8). After Cycle 8, rituximab was given on day 1 of every other cycle for up to two years. The ORR was 98% (60% CR, 38% PR, 2% stable disease). With a median follow-up of 28 months, the median PFS and OS were not reached. Four patients progressed during the study and two patients died. Overall, 19 patients (39%) discontinued therapy. Atrial fibrillation was noted in seven patients (3 had new onset and four had prior history of atrial fibrillation), and bleeding was noted in three patients. The combination of IR was an excellent frontline

treatment option for older adult patients; however, patients taking this combination are strongly recommended to closely follow up with a cardiologist. Longer follow-up of this study is pending.

SYMPATICO Study

This is an ongoing global multicenter phase 3 study with a combination of ibrutinib and venetoclax (NCT03112174). The efficacy of a combination of ibrutinib with venetoclax in transplant-ineligible, previously untreated patients with MCL who are 65 years or older (n = 50) and patients under the age of 65 who have *TP53*-mutated MCL is tested (n = 25). Of note, patients with blastoid variant and those with CNS involvement are excluded.

Zanubrutinib-Rituximab Versus BR Study

This is an ongoing randomized phase 3 study comparing ZR with BR in transplant-ineligible patients. Patients either between 65 and 69 years of age or 70 years or older with comorbidities precluding auto-SCT are eligible (NCT04002297).

ECOG-E1411 Study

The ECOG-E1411 study is a four-arm randomized phase 2 trial in patients age 60 years or older. Arm 1 is BR induction followed by rituximab maintenance, arm 2 is BR + bortezomib followed by rituximab maintenance, arm 3 is BR followed by lenalidomide + rituximab maintenance, and arm 4 is BR + bortezomib followed by lenalidomide + rituximab maintenance. This study will provide information on ideal maintenance strategy with lenalidomide (NCT 01415752).

MCL-R2 Older Adult Trial

This is a phase 3 randomized trial to assess the efficacy of ara-C induction and lenalidomide maintenance. This study is evaluating whether the addition of lenalidomide to rituximab maintenance is useful in older adult patients with MCL (NCT01865110).

Miscellaneous Studies

These studies are investigating various combinations of newer BTK inhibitors, with venetoclax and/or obinutuzumab with/without chemotherapy.

Previously Treated Relapsed MCL—BTK Inhibitor–Naïve

The success story of BTK inhibitors and venetoclax in MCL in the last 5 to 7 years is a landmark feat. Ibrutinib,[133,172] acalabrutinib,[135] and zanubrutinib[173] are approved BTK inhibitors[136,174] in patients with relapsed MCL. Their main advantages are oral availability, excellent efficacy, better tolerability, and safety profile compared with chemotherapy and feasibility for the older adult age group. Conventionally, after first-line failure, patients were treated with salvage regimens such as R-ICE or R-DHAP or with bortezomib (ORR 25%–50% with a CR of 4%–8%),[175–177] temsirolimus (ORR 22%),[178] lenalidomide (ORR 28% with single agent and 57% with rituximab),[179,180] or their combinations with rituximab.[181] These modalities in the relapsed setting demonstrated modest response rates, but intolerance is a major issue.[182]

Treatment Options in Relapsed BTK-Naïve MCL

Lenalidomide With Rituximab (LR)

In a phase 1/2 study,[181] the LR combination was tested in 52 patients. Forty-four patients were enrolled in a phase 2 cohort with an ORR of 57% and CR of 36%. The median PFS was 11.1 months and the median OS was 24.3 months.

Ibrutinib

This is an irreversible, covalent inhibitor of BTK (a TEC kinase) and binds to cysteine 481 on the ATP binding site of the BTK kinase domain. Ibrutinib has off-target effects on other TEC kinases (BMX, ITK, and BLK), which are distributed in various tissues, leading to off-target effects such as bleeding, cardiac arrythmias (mainly atrial fibrillation),[183,184] and ventricular arrhythmias.[185,186] Inhibition of BTK leads to abrogation of MCL cell survival, proliferation, and growth.[187] Ibrutinib also leads to redistribution lymphocytosis after interfering with the chemokine-receptor interactions and homing of MCL cells.[145] Lymphocytosis after ibrutinib is not considered a sign of disease progression.

Initial results from single-agent ibrutinib in patients with relapsed MCL (n = 111) were reported in 2013.[128] The median age of patients was 68 years, with a median of three prior lines of therapies. The ORR was 68% and CR was 21%. Grade 3 or 4 adverse events included 16% neutropenia, 11% thrombocytopenia, 10% anemia, and 5% bleeding. On the longer follow-up of 26.7 months,[134] the CR rate improved to 23%, and 22% of patients continued treatment for more than 2 years. Two-year PFS and OS were 31% and 47%, respectively, and the median duration of response was 17.5 months. Six percent of patients had grade 3 or 4 bleeding events (none fatal), 11% had atrial fibrillation (grade 3 in 6%), and second cancers developed in 5%.

Ibrutinib was also compared with temsirolimus (m-TOR inhibitor) in a randomized study (RAY study[188]) and ibrutinib was superior to temsirolimus. A three-year follow-up of this study demonstrated that survival and safety data were better with ibrutinib.

Long-term follow-up from a pooled analysis of 370 ibrutinib-treated patients with relapsed MCL with

a median follow-up of 41.5 months was reported.[172] Seventeen percent of patients continued to receive treatment for more than 4 years. The median PFS and OS were 12.5 and 26.7 months, respectively. A higher number of prior lines of therapy was associated with shorter PFS in the multivariate analysis. Ibrutinib after failure of first-line therapy has a superior response rate 77% (37% CR) and longer duration of response (36 months) compared with ibrutinib administered after failure of multiple lines of therapies. Among blastoid MCL, the response rate was inferior compared with nonblastoid histology (50% vs 68%). In addition, OS was shorter in blastoid versus nonblastoid MCL (12.8 vs not reached, respectively). Of note, 14% of patients were *TP53*-mutated and demonstrated inferior response rates (55%), shorter PFS (4 months), and shorter OS (10.3 months). Patients with wild-type *TP53* showed a 70.2% response rate, PFS of 12 months, and OS of 33.6 months. Atrial fibrillation occurred in 11% of patients (any grade; 5% grade 3) but none of the patients discontinued ibrutinib owing to atrial fibrillation.[189] Ibrutinib can induce platelet dysfunction[186,190,191] and impaired thrombus formation, contributing to bleeding tendency, and concomitant anticoagulant and antiplatelet agents must be carefully evaluated in patients taking ibrutinib.[192] Cardiovascular effects, arrythmias[193,194] (mainly atrial fibrillation), and hypertension are critical to watch for in patients taking ibrutinib. These cardiac adverse events are likely associated with inhibition of other TEC kinases present in cardiac myocytes.[183,195,196]

We conducted a phase 2 study at MDACC using a combination of IR in relapsed MCL (with a median of three prior therapies). A 4-year follow-up of this study showed that the CR improved from 44%[197] to 58%[198]. The median PFS was 43 months and the median OS was not reached. High-risk patients, high Ki-67% (>50%) and/or patients with aggressive histology had inferior survival outcomes. The addition of lenalidomide to IR was investigated in the PHILEMON study, a European phase 2 multicenter trial.[199] In 50 previously treated patients with relapsed MCL, the ORR was 76% (56% CR) after a median follow-up of 17.8 months; 38% of patients had grade 3–4 neutropenia on this combination.

Finally, ibrutinib was investigated in a combination with venetoclax in relapsed MCL (AIM study from Australia). This combination of ibrutinib and venetoclax was based on preclinical data showing synergy between the two.[200] The I+V regimen was ibrutinib (560 mg daily) with venetoclax (weekly dose escalation up to 400 mg daily dose). Among 23 patients with relapsed MCL, 75% had high-risk MIPI score and 50% had *TP53* mutations. The median follow-up duration was 15.9 months. The combination[174] resulted in an ORR of 71% with 62% CR (with PET-based assessment) at week 16. In all patients, MRD-negative response was 67% by flow cytometry and 38% by PCR. The median PFS was not reached, with a 12-month PFS of 75%. Interestingly, among the patients with *TP53* mutation (n = 12), 50% achieved CR. Grade 3–4 diarrhea was noted in 71%, and neutropenia was noted in 33% of patients. Resistance mechanisms for the combination demonstrated that the mutations in the SWI/SNF chromatin-remodeling complex was associated with drug resistance.[59] In addition, ibrutinib was also investigated in combination with palbociclib. In a phase 1 trial, the ORR was 67% and CR was 37%, whereas the two-year PFS was 59%.[201]

Of interest is the activity of ibrutinib to penetrate the blood-brain barrier; it has been investigated in CNS lymphomas, and ibrutinib has a potential for further testing in MCL involving CNS.[202–205]

In relapsed MCL, various combinations of ibrutinib with chemotherapy—ibrutinib with venetoclax, and obinutuzumab and ibrutinib with anti-CD19-CAR-T therapy (because of a potential to improve CAR-T efficacy by the off-target effects of ibrutinib), and ibrutinib with palbociclib (a CDK4/6 inhibitor)[201] are being investigated. In the Australian TARMAC study (NCT04234061), ibrutinib is administered before CAR-T in patients with relapsed MCL.

Few challenges with ibrutinib include disease progression and ibrutinib discontinuation caused by side effects, patient choice,[58,129] ibrutinib-refractory MCL, and the mechanisms of ibrutinib resistance.[61] Unlike CLL/SLL, BTK C481S mutation is infrequent in ibrutinib-resistant MCL.[58,206] At MDACC, we are working to further understand the mechanisms of ibrutinib resistance[105] and strategies to overcome ibrutinib resistance in MCL.[207,208]

Acalabrutinib

A more selective, FDA-approved and orally administered agent, acalabrutinib is a covalent, irreversible inhibitor of BTK and binds to C481S in the ATP binding pocket. Minimal off-target kinase activity of acalabrutinib is a distinct advantage over ibrutinib.[209] Acalabrutinib preserves *Src* family kinase (collagen to platelet adhesion) activity and thus avoids the unstable platelet thrombus formation seen with ibrutinib therapy.[210] These activities may explain the low incidence of atrial fibrillation and less risk of bleeding compared with ibrutinib; however, randomized studies with head-to-head comparison of acalabrutinib and ibrutinib may reveal the actual risk of these adverse events.

In the pivotal multicenter phase 2 trial in relapsed MCL (n = 124), patients had a median of two lines of prior therapy.[135] After a median follow-up of 15.2 months, the ORR was 81% with 40% CR, and at the 26-month follow-up analysis,[211] the median PFS was 19.5 months, and the median OS was not reached.

About 40% of patients continued on acalabrutinib. Three patients experienced grade 3 bleeding events, and none had atrial fibrillation. Headache and diarrhea were observed in 38% and 30% patients, respectively.

Various combinations of acalabrutinib with rituximab and/or acalabrutinib-venetoclax, acalabrutinib-lenalidomide, or a combination of acalabrutinib with venetoclax and rituximab are investigated. Longer follow-up and the analysis of outcomes after acalabrutinib progression[138] are important to fully explore the potential of acalabrutinib in MCL.

Zanubrutinib

Zanubrutinib is a newly FDA-approved selective and irreversible BTK inhibitor. In the phase 1 trial,[212] with a median follow-up of about 16 months in 37 patients with relapsed MCL, the response rate was 87%, with 30% CR with single-agent zanubrutinib, whereas in eight previously untreated patients, the response rate was 87.5% with 37% CR. In a phase 2 study[213] of 86 patients from China, zanubrutinib demonstrated 84% ORR and 68% CR in relapsed MCL (median two prior lines). The median follow-up was 18 months and the median PFS was 22 months. In 15 *TP53*-mutated patients, ORR was 80% versus 87% in *TP53* wild-type, and the median PFS was 14.2 versus 22.1 months in *TP53* wild-type patients. Of note, because of minimal off-target effects, none of the patients exhibited grade 3 or higher bleeding or cardiac arrythmias.

Tirabrutinib[214] and orelabrutinib[215] are other irreversible BTK inhibitors with higher selectivity against BTK and better side effect profiles compared with ibrutinib. These are under clinical investigation.

Previously Treated Relapsed MCL–BTK Inhibitor Refractory

As our experience with BTK inhibitors is growing, we are seeing patients with BTK inhibitor–refractory MCL. Newer therapies are urgently required to treat these complex patients.

Venetoclax

This drug is an orally available, selective inhibitor of the anti-apoptotic BCL-2 protein. Initial experience with venetoclax in MCL was demonstrated in a phase 1 study.[136] Twenty-eight relapsed-refractory MCL patients (none BTK inhibitor refractory; median age, 72 years and median of 3 prior lines of treatments) were enrolled, and patients achieved an ORR of 75%, CR of 21%, and a median PFS of 14 months. Venetoclax has very promising activity in MCL. One retrospective study[137] described venetoclax monotherapy in 20 patients with relapsed MCL (median of 3 prior lines of therapy). The ORR was 53% and CR was 18%. The majority (85%) of patients in this study were resistant to BTK inhibitors, and the median PFS was 3.2 months. At MDACC, we reported our experience in 24 patients with heavily treated MCL (median 5 prior lines of therapy). The majority of patients had high-risk disease and 67% were refractory to BTK inhibitors. After a median follow-up after venetoclax of 17 months, the ORR was 50% (21% CR). The median PFS was 8 months. Using whole-exome sequencing, we demonstrated that non-BCL2 mutations (*SMARCA4, TP53, CDKN2A, KMT2D, CELSR3, CCND1,* and *NOTCH2*) were noted after progression on venetoclax. BCL2 mutations were infrequent (only one-third of patients). Venetoclax is actively investigated with various combinations in MCL, with BTK inhibitors in the frontline and in the relapsed-refractory setting.

LOXO-305

LOXO-305 is the latest and novel, reversible, noncovalent, and orally administered BTKi that inhibits both wild-type and C481-mutated BTK in preclinical studies. LOXO-305 has minimum off-target kinase and nonkinase inhibitory activity. This molecule is currently undergoing a phase 1 clinical trial in B-cell lymphoid malignancies.[216]

In the phase 1 trial, in 38 relapsed-refractory MCL patients, the median number of prior lines of therapy was two (range 2–8), and 92% of patients were treated with a prior BTK inhibitor. Among the 35 efficacy-evaluable patients with MCL treated across all dose levels, the ORR was 51%, including nine CRs. Among the subset of 20 efficacy-evaluable patients with MCL who started at 200 mg daily, the ORR was 65% including seven CRs, six PRs, four SDs, one PD, and two NEs. Because of lesser off-target effects, LOXO-305 has better safety data compared with ibrutinib. Fatigue and diarrhea were common adverse events noticed in less than 20% of patients. Final data were reported at the 2020 American Society of Hematology meeting. The phase 2 dose was 200 mg orally daily. LOXO-305 and its combinations hold great promise for patients with BTK inhibitor–refractory MCL.

R-BAC Regimen

In a multi-institutional retrospective report from 36 patients whose disease failed prior BTK inhibitors, this regimen demonstrated 83% ORR and 60% CR, and 31% bridged to allo-SCT. The median OS was 12.5 months.[217]

Stem Cell Transplantation

Autologous SCT is conventionally used as a consolidation strategy after completing intensive chemoimmunotherapy. Some retrospective and few

prospective studies have described their experience with SCT in MCL, although the data of SCT in BTK inhibitor-refractory MCL are not well described. In a multicenter retrospective analysis,[218] 70 patients with relapsed MCL who received allo-SCT were described. Patients with chemosensitive disease demonstrated superior outcomes compared with patients who had PR or no response. Allogenic SCT can be useful in high-risk, transplant-eligible *TP53*-mutated relapsed MCL. Allo-SCT can provide long-term disease control in about 30% of patients with MCL.[219,220] Ibrutinib before allo-SCT can be efficacious as a bridging therapy, as reported in a study of 22 patients.[221] Pretransplant disease response is important in predicting response to allo-SCT in MCL. As of this writing, the role of allo-SCT in relapsed MCL is limited because of its availability, mortality, morbidity, and the advent of relatively safe and efficacious brexucabtagene autoleucel an anti–CD19-CAR-T therapy.

Chimeric Antigen Receptor T-Cell (CAR-T) Therapy

CAR-T therapy is the most recent and most potent landmark development for highly refractory patients with MCL. The recent FDA approval of anti–CD19-CAR-T, brexucabtagene autoleucel (KTE-X19), was the highlight of the year 2020 and was recently approved by the FDA for adult patients with relapsed or refractory MCL.

The ZUMA-2 study is a single-arm, international, multicenter, open-label, phase 2 trial in which 68 patients with relapsed MCL received CAR-T therapy. All patients had progressed on BTK inhibitors and they had a median of 3 prior lines of therapy (range 1–5). Forty-two patients were primary refractory to BTK inhibitors, and 18 patients (26%) had relapsed after an initial response to BTK inhibitor. The patients underwent leukapheresis and lymphocyte-depleting chemotherapy followed by CAR-T infusion at a target dose of 2×10^6 CAR-T cells/kg. Patients who had high-risk MCL were included : 17 (25%) had blastoid histology, six with *TP53* mutations, and 32 had Ki-67% of at least 50%. The ORR was 93% and the CR was 67%. With a follow-up of 12 months, 57% patients remained in remission. Furthermore, the ORR was higher than 93% in blastoid, *TP53*-mutated, and high Ki-67% patients. The PFS and OS were not reached. Most common grade 3 or higher adverse events were cytopenias (69%) and infections (32%), and grade 3 or higher cytokine release syndrome in 15%, whereas neurotoxicity was noted in 31% patients. A longer follow-up on this study is required to further evaluate the durability of responses achieved by this modality. The process with CAR-T is less complicated and well tolerated compared with similar data from traditional allo-SCT. Conversely, the cost of CAR-T, limited experience in the community, and its availability at specialized centers are the major limitations.

Newer Cellular Therapies

Lisocabtagene maraleucel (JCAR-017)[222] is a CD19-directed 4-1BB CAR-T product undergoing clinical trials in MCL. In the phase 1 study, median follow-up was 18 months (n = 17) and the ORR was 71% (CR 53%). Grade 3 or higher toxicities were 6% cytokine release syndrome and 12% neurotoxicity. Other newer cellular therapies include CD19 CAR-NK cells,[223] allogeneic CAR-T, and humanized binding domain in CD19 CAR-T cells (Hu19-CD828Z).[224] Most recently, clinical trials have also started investigating the combination of BTK inhibitors with anti–CD19-CAR-T. Other antigens relevant in MCL and being investigated are CD20, CD22, ROR1, BAFF,[225] and CD79b,[226] or bispecific antibodies (CD3-CD20).

Triple-Refractory Relapsed MCL

Recently, in our clinical experience, we have also observed a very-high-risk subset in patients with MCL that we call "triple-refractory MCL," referring to patients who have progressed on BTK inhibitors, venetoclax, and CAR-T therapy. Treatment options for these patients are highly limited. Currently, newer clinical trials are required to address the issue of triple resistance. In the coming years, we will be able to observe the pattern of resistance observed in triple-resistant MCL patients.

CNS Prophylaxis in MCL

This is controversial and no definitive guidelines exist. The practice varies at different centers, especially in patients with aggressive-histology MCL. Few retrospective studies[76,227,228] demonstrated that some baseline characteristics of patients with MCL (blastoid MCL, very high LDH levels, high Ki-67%) correlate with a higher frequency of CNS involvement. The outcomes of CNS-MCL are very poor. In one study with 57 patients who developed CNS involvement by MCL,[76] 20% had prior intrathecal chemotherapy and 18% had prior R-HCVAD; therefore, complete prevention of CNS involvement by routine intrathecal chemotherapy may not be attainable. However, patients with blastoid MCL are advised to undergo prophylactic intrathecal chemotherapy by some physicians. In addition, because ibrutinib has been shown to penetrate the blood-brain barrier[202,205] and is increasingly used in MCL, the role of CNS prophylaxis in ibrutinib-treated MCL patients remains unknown. As of this writing, we do not administer intrathecal chemotherapy in patients if they have received ibrutinib-based therapies, and/or have had

R-HCVAD therapy; however, in specific clinical situations such as patients with high-risk MCL receiving only chemotherapy, paraspinal disease, or paranasal involvement, we consider intrathecal chemotherapy.

SUMMARY

The field of MCL is changing rapidly. Advances in our understanding of the pathobiology, molecular events, and tissue microenvironment have improved our understanding of MCL, leading to improvement in risk stratification, further advances in the field, and help in accurately predicting the prognosis. In addition, newer therapies have significantly improved survival outcomes and response rates. The evolution of BTK inhibitors, venetoclax and anti-CD19 CAR-T, have demonstrated phenomenal results and are shifting the focus to investigate these therapies in the frontline setting. We hope that this momentum of advancement in understanding MCL will continue and we may find a cure for it in the coming years.

MD ANDERSON PRACTICE TIPS

- To obtain full risk factor assessment with relevant investigations and collect various parameters at initial diagnosis (outlined in Fig. 10–2). This is important for determining prognosis and future considerations on clinical trials.
- To obtain information on the high-risk features at initial diagnosis: high-risk MIPI score, blastoid/pleomorphic histology, high Ki-67% at least 30%, and *TP53* mutation status. This information is highly relevant because it can affect the clinical outcome.
- To obtain a detailed cardiology assessment and cardiology clearance before starting BTK inhibitors on any patient with MCL. Cardiac arrythmias, hypertension, and bleeding tendencies can be life threatening for older adult patients with MCL.
- To obtain gastrointestinal tract (upper and lower) endoscopies with random biopsies, along with PET-CT scan and bone marrow assessment (flow cytometry, cytogenetics, molecular testing) to confirm CR in patients with MCL. About 30% of MCL can have delayed clearance of the GI tract, and residual disease in the GI tract disqualifies patients to achieve CR.
- The focus in the treatment of MCL is gradually shifting from frontline chemotherapies to "chemo-free" therapies such as BTK inhibitors and venetoclax as their initial therapy. We recommend enrolling patients in clinical trials and exploring the option for recently approved anti–CD19-CAR-T (brexucabtagene autoleucel) therapy in relapsed patients and/or patients who progressed on BTK inhibitors and/or patients who are high risk and relapsed after standard therapies.
- Explore the option for enrollment in clinical trials and refer the patient to specialized centers for MCL treatment in the US or elsewhere. We have the center of excellence in MCL at MDACC. For further enquiries, please contact miwang@mdanderson.org and/or pjain@mdanderson.org.

ACKNOWLEDGMENTS

Funding for various MCL studies at MD Anderson Cancer Center was provided in part by the generous philanthropy donated to the MD Anderson Cancer Center B-Cell Lymphoma Moon Shot Program; R21 CA202104 (Michael Wang, PI); and philanthropy funds from The Gary Rogers Foundation and the Fox Family Foundation.

11 Nodal Peripheral T-Cell Lymphoma

Ranjit Nair
Francisco Vega
Swaminathan P. Iyer

KEY CONCEPTS

- Nodal peripheral T-cell lymphomas (PTCLs) are categorized into three basic subtypes: systemic anaplastic large-cell lymphoma (sALCL) anaplastic lymphoma kinase ALK (+) and ALK (-), angioimmunoblastic T-cell lymphoma; and peripheral T-cell lymphoma not otherwise specified (PTCL-NOS).
- The prognosis for patients with nodal PTCLs remains suboptimal compared with its aggressive B cell counterparts despite the use of aggressive chemotherapy. The introduction of novel agents such as CD30(+) antibody–drug conjugates and histone deacetylase inhibitors have brought unprecedented enthusiasm in bench to bedside research for this disease.
- It is recently recognized that angioimmunoblastic T–cell lymphoma has its cell of origin from CD4+ T-follicular helper (TFH) cells and as a result a third of the PTCL-NOS are more aptly diagnosed as angioimmunoblastic T-cell lymphoma because of the expression of TFH markers.
- Understanding of the genomic landscape has recently helped to identify better prognostic markers. Whereas the presence of ALK or DUSP-22 in sALCL is associated with favorable prognosis, expression of GATA-3 or GATA-3 target genes in PTCL-NOS is associated with a worse prognosis.
- Except for ALK (+) ALCL and ALK (-) ALCL with DUSP22 rearrangement, patients with PTCL generally have a chemoresistance, short-term remission, and early relapse when treated with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) or CHOP-like chemotherapy.
- Combination therapies using novel agents holds the future to improve clinical response and outcomes in both frontline and relapsed or refractory disease. Whereas BV-CHP (brentuximab vedotin plus cyclophosphamide, doxorubicin, prednisone) is currently the standard of care treatment in patients with CD30(+) PTCLs, Cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP), with or without the addition of etoposide, is commonly used in those with CD30(-) PTCLs.

Peripheral T-cell lymphoma (PTCL) comprises a rare and heterogeneous group of mature T- and natural killer (NK)-cell neoplasms with diverse clinical presentation, response to treatment, and prognosis.[1] PTCLs have historically been a challenging disease because of their rarity, often grouped by their shared immunophenotype of neoplastic T-cells, despite the biologically differences and lack of standard treatment approaches.[2] Getting a second opinion and reviews by expert hematopathologists improve the accuracy of subtyping, and referral to academic or specialty centers is recommended. Even though there is no current standard of care for patients with PTCL, first-line approaches still revolve around anthracycline-based therapy with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) or CHOP-like combination chemotherapies. Although many patients initially respond to induction chemotherapy, responses are often brief, and many patients relapse or become refractory to treatment. The introduction of agents based on the novel targets such as CD30 and brentuximab vedotin (BV) has given us tremendous hope recently leading to the only Food and Drug Administration (FDA)–approved chemotherapy combination for first-line treatment. Significant advances in our understanding of this disease biology have also led to revisions in the classification of mature T-cell and NK-cell neoplasms and introduction of provisional entities. According to the 2016 World Health Organization classification (WHO) classification of lymphoid neoplasms, based on morphologic, immunophenotypic, molecular, and clinical features,

TABLE 11–1 Summary of 2016 World Health Organization Classification of Mature T-Cell and Natural Killer Cell Neoplasms[a]

Leukemic	Nodal	Extranodal	Cutaneous
T-cell prolymphocytic leukemia	PTCL-NOS	Extranodal NK-/T-cell lymphoma, nasal type	Subcutaneous panniculitis-like T-cell lymphoma
T-cell large granular lymphocytic leukemia	AITL	Enteropathy-associated T-cell lymphoma	Mycosis fungoides
Chronic lymphoproliferative disorder of NK cells	**Follicular T-cell lymphoma[b]**	Monomorphic epitheliotropic intestinal T-cell lymphoma[b]	Sezary syndrome
Aggressive NK-cell leukemia	**Nodal peripheral T-cell lymphoma with TFH phenotype[b]**	Hepatosplenic T-cell lymphoma	Primary cutaneous CD30(+) T-cell lymphoproliferative disorders
Adult T-cell leukemia/lymphoma	Anaplastic large-cell lymphoma, ALK (+)	Systemic EBV (+) T-cell lymphoma of childhood[b]	Lymphomatoid papulosis
	Anaplastic large-cell lymphoma, ALK (-)[b]	Hydroa vacciniforme–like lymphoproliferative disorder[b]	Primary cutaneous anaplastic large-cell lymphoma
		Breast implant–associated anaplastic large-cell lymphoma[b]	Primary cutaneous γδ T-cell lymphoma
		Indolent T-cell lymphoproliferative disorder of the GI tract[b]	**Primary cutaneous CD8(+) aggressive epidermotropic cytotoxic T-cell lymphoma**
			Primary cutaneous CD4(+) small-/medium T-cell lymphoproliferative disorder[b]

[a]Provisional entities are listed in bold.
[b]Changes from the 2008 classification.
AITL, angioimmunoblastic T-cell lymphoma; ALK, anaplastic lymphoma kinase; EBV, Epstein-Barr virus; GI, gastrointestinal; NK, natural killer cell; PTCL-NOS, peripheral T-cell lymphoma not otherwise specified.

there are total 19 subtypes of mature T-cell and NK-cell neoplasms and eight provisional entities that are currently recognized (Table 11–1). PTCLs, although uncommon in young individuals, can be diagnosed as early as childhood, and rates continue to increase until about age 70 years.[3]The most common subtype of nodal PTCL, aside from mycosis fungoides (MF), is PTCL not otherwise specified (PTCL-NOS) followed by systemic anaplastic large-cell lymphoma (sALCL), and angioimmunoblastic T-cell lymphoma (AITL). T-cell acute lymphoblastic leukemia/lymphoma are derived from T-cell precursors (eg, thymocytes) is not included in the mature lymphoma group and hence will not be discussed in this chapter.[4,5]

EPIDEMIOLOGY

PTCL represent approximately 10% to 15% of non-Hodgkin lymphomas (Fig. 11–1). These are further subclassified as nodal, extranodal, leukemic, and cutaneous T-cell lymphomas. The most common histologic subtype is PTCL-NOS followed by AITL and sALCL anaplastic lymphoma kinase (ALK) (+) and ALK (-). These three accounts for approximately two-thirds of the T-cell lymphomas.[6] With better diagnostic markers and molecular criteria, the combined entity of three nodal lymphomas expressing signatures typical for T-follicular helper (TFH) cells, including AITL, nodal PTCL with a TFH phenotype, and follicular T-cell lymphoma, is starting to outnumber the PTCL-NOS cases.[7,8]

There is significant geographic variation in the incidence and prevalence of the different type of PTCL, which is attributed to a combination of genetic and environmental factors. AITL tends to be more frequent in Europe (28.7% of all PTCLs) followed by Asia (17.9%) and North America (16.0%).[9] PTCL-NOS is more common in in Western countries than Asian countries (30% vs 20%–25% of PTCL). sALCL tends to be more common the United States (24% of PTCL) and with less incidence in Europe and Asia.[10] Other PTCL subtypes—adult T-Cell Lymphoma/Leukemia (ATLL) and extranodal natural killer/T-cell lymphoma (ENKL)—occur at higher frequencies in Asia and Central and South America than in Western countries, paralleling the distribution of human T-lymphotropic virus 1 (HTLV1) and the Epstein-Barr virus (EBV) respectively. Enteropathy-associated T-cell lymphoma (EATL) is seen more in Northern Europe, where celiac disease is more prevalent.[6,11]

INCIDENCE AND OUTCOMES

According to the US Surveillance Epidemiology and End Registry, the age-adjusted incidence of PTCL is fewer than one case per 100,000 people in the United States, with approximately over 10,000 new cases diagnosed each year.[3] In recent years, although the

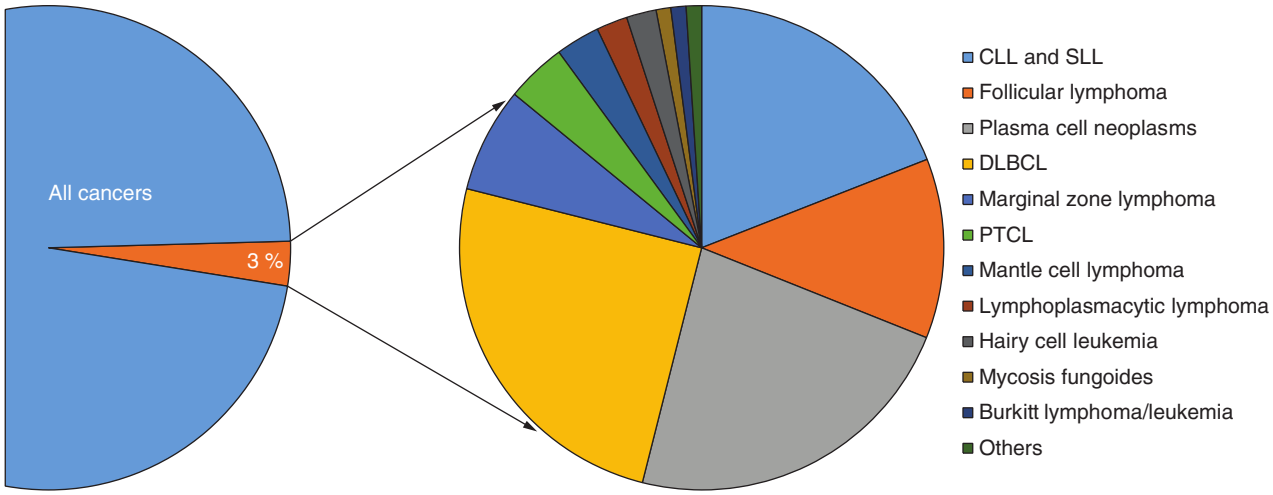

FIGURE 11–1 Distribution of subtypes of mature non- Hodgkin lymphoid neoplasms. CLL, chronic lymphocytic leukemia. DLBCL, diffuse large B- cell lymphoma; PTCL, peripheral T-cell lymphoma; SLL, small lymphocytic lymphoma. (Data from Teras LR, DeSantis CE, Cerhan JR, et al: 2016 US lymphoid malignancy statistics by World Health Organization subtypes, *CA Cancer J Clin* 2016 Nov 12;66(6):443-459.)

incidence rates of many B-cell lymphomas have begun to decline or plateau at best, the incidence rates for T-cell lymphomas have continued to rise globally. This is likely a consequence of the aging population, improved health care access, and improved diagnostics tools. Worldwide there is still no consensus on first-line or salvage therapies for patients because of the rarity of the disease and the lack of randomized clinical trials, which translates to worse overall survival (OS) among patients with nodal PTCL (36%–56% 5- year survival). In contrast, the outcomes for MF are overall better (79%–92% 5- year survival rate).[3]

PATHOGENESIS AND HISTOLOGY

The exact pathogenesis of PTCL is largely elusive, and the putative cellular derivation of the different pathological subtypes remains poorly characterized. There have been significant attempts with gene expression profiling (GEP; RNA sequencing, microarray analysis, micro-RNA profiling, mutation analysis, copy number alterations) and epigenetics analysis to help identify new biomarkers and mutations.[12–15] PTCLs are derived from mature T-cells, and deregulation at T-cell differentiation or maturation level is a critical event in lymphomagenesis. The pathogenic events in general can be classified into three categories:

1. Intrinsic or recurrent molecular events in the pivotal intracellular signaling pathways
   a. TCR/CD3 pathway
   b. Notch pathway
   c. Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway
   d. RHOA pathway
   e. Phosphoinositide 3-kinase (PI3K) pathway
   f. Epigenetic regulation
   g. AP-1–mediated transcriptional programs
2. Extrinsic or microenvironmental changes
3. Virus-mediated (eg, EBV, HTLV-1–induced T-cell neoplastic transformation)[16]

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA

AITL is characterized by its cellular derivation from CD4+ TFH cells, which is the effector T-cell subset, and the diagnostic criteria remain unchanged in the 2016 WHO classification. TFH cells are a critical peripheral checkpoint for B-cell activation and differentiation within a germinal center.[17] Dysregulated TFH cell that triggers the transformation to AITL is proposed to be the cell of origin (COO) with subsequent disruption of immunologic tolerance and uncontrolled constitutively activated immune system presenting as autoimmune phenomenon.[18] The tumor cells retain characteristic phenotype of TFH cells with the expression of markers PD-1 (programmed death-1), BCL6, CXCL13, CD10, ICOS, SAP, and CXCR5, CD279 (PD-1, PDCD1) CD40L, and NFATC1. A subset of what used to be classified as PTCL-NOS on molecular analysis expresses TFH-associated markers and shares recurrent genetic abnormalities with AITL. This has been given provisional category in WHO 2016 called nodal T-cell lymphomas with a TFH phenotype. Another category called follicular T-cell lymphoma has also been added to this group, which primarily involves the

follicles and could resemble its B cell counterpart–the follicular lymphoma (see Table 11–1). GEP has shown that the malignant TFH cell often carry mutations in the genes encoding methyl cytosine dioxygenase TET2 (47%–73%), isocitrate dehydrogenase 2 (IDH2) (20%–40%), DNA methyltransferase 3A (DNMT3A) (33%), or RHOA-G17V mutation (~60%).[19] CXCL13 produced by AITL cells has a known association with hypergammaglobulinemia and autoimmune hemolytic anemia because this protein stimulates B-cell expansion and plasmacytic differentiation in the tumor microenvironment.[20,21] EBV-positive clonal/oligoclonal B-lymphoblastoid cells are present in majority of AITL cases, but their exact pathogenetic role is elusive. Given that EBV virtually affects only B-cell population, it is postulated to rather play a protumorigenic role in the microenvironment than a primary role in the lymphomagenesis.

Microscopically (Fig. 11–2A–D), there is a polymorphic immune infiltrate in lymph node specimens with effacement of germinal centers and prominent neovascularization, with a rich microenvironment composed not only of tumor cells but also of small reactive lymphocytes, histiocytes, eosinophils, an expanded follicular dendritic cell meshwork, and prominent endothelial venules.[22] In addition to the tumor cells expressing TFH cell markers, T-cell receptor gene rearrangements (TCRs) are present in about 80% of the tumor cells, and trisomy of chromosomes 3 and 5 are the commonly observed cytogenetic abnormality. EBV positivity is universally present in the large B immunoblasts in the lymph node but not in the neoplastic T-cells.[23]

Peripheral T-Cell Lymphoma Not Otherwise Specified

PTCL-NOS is a heterogeneous entity and includes a watershed area of different mature T-cell neoplasms that do not have a characteristic immunophenotype or do not meet the criteria of a specific PTCL entity. Despite the absence of a distinct COO or recurrent cytogenetic abnormality, GEP studies have defined two novel molecular clusters in this group with distinct features using PTCL-GATA3 and PTCL-TBX21. The cluster with high expression of GATA3-related target genes (CCR4, IL18RA, CXCR7, and IK) had poorer outcomes with the 5-year OS of nearly half of the TBX21 cluster (19% vs 38%). Within the TBX21 subgroup, expression of cytotoxic CD8+ T-cells is associated with adverse outcomes.[24] Immunohistochemistry (IHC) algorithms are currently being identified to distinguish these two subtypes in paraffin tissue using antibodies to key transcriptional factors (GATA3 and TBX21) and their target proteins (CCR4 and CXCR3).[25]

The PTCL-NOS diagnosis is known to have the highest rate of dilemma and discordance rate among pathologists. This reflects the heterogeneity and the presence of different PTCL subtypes at different stages of disease progression.[6] One third of PTCL-NOS case are more aptly diagnosed as AITL because of the expression of TFH markers. The lymph nodes usually appear diffusely effaced with pleomorphic cells, which are medium-sized or large cells with irregular nuclei containing prominent nucleoli and many mitoses. There is often presence of hyperplastic endothelial venules with an admixture of eosinophils, plasma cells, small lymphocytes, B cells, histiocytes, and activated macrophages. A morphologic variant of PTCL-NOS that is known to have a favorable prognosis called lymphoepithelioid cell lymphoma (Lennert's lymphoma) presents with more abundant epithelioid histiocytes and neoplastic cells that portray a CD8-positive cytotoxic (TIA1, granzyme B, and/or perforin) phenotype.[26]

In PTCL-NOS, there is variable loss of expression of T-cell–associated antigens, more frequently CD5 or CD7 and rarely CD2 or CD3. In majority of the cases, T-cells express CD4, αβ-TCR (TCR-β positive), or both than in minority with CD8 and/or γδ phenotype. CD30 is less commonly expressed, and its prognostic impact is currently unclear. Half of PTCL-NOS cases are EBV-positive, an observation shown to be associated with a poor survival.[7] Other markers that are rarely expressed include B-cell markers such as CD20, CD19, CD79a, or PAX5. A recent genome-wide next-generation sequencing analysis of PTCL-NOS led to the identification of recurrent translocations involving rearrangements of the *TP63* gene (a TP53 family member) with *TBL1XR1* and *ATXN1* genes (10% cases).[27] These gene fusions encode proteins that inhibit the p53 pathway and are associated with adverse clinical outcomes. Screening a large series of cases for TP63 rearrangements by fluorescence in situ hybridization showed similar frequencies in ALK (-) ALCL (12.5%) and primary cutaneous ALCL (10.5%).[27]

Systemic Anaplastic Large-Cell Lymphoma

sALCL shows ALK expression in more than 30% of cases.[28] The translocation leads to the expression of the constitutively active NPM-ALK kinase, triggering downstream signaling pathways that regulate cell growth, survival, and malignant transformation.[29,30] This leads to a downward cascade involving STAT3/5, CEBPB, and AP1.[31–33] In sALCL, GEP studies of tumor cells to identify COO have largely been largely unsuccessful. A recent gene set enrichment analysis points to a Th17 origin, which is a lineage of interleukin (IL)-17–producing CD4+ T helper cell program.[34,35] Whether this Th17 expression is from an already known recurrent chromosomal rearrangements involving the ALK

gene with nucleophosmin (NPM1) (t(2;5)(p23q35)) is unclear.[36] GEP indicates that ALK (+) ALCL and ALK (-) ALCL display similar genome signatures, thus suggesting a common COO.[35] ALK (-) subtype was a provisional entity in the WHO 2008 and is now a recognized entity in the 2016 WHO classification. The prognosis is intermediate between ALK (+) ALCL and PTCL. One third of ALK (-) ALCL harbors the DUSP22-IRF4 locus on a 6p25.3 rearrangement and has a favorable prognosis with survival comparable to ALK (+) ALCL

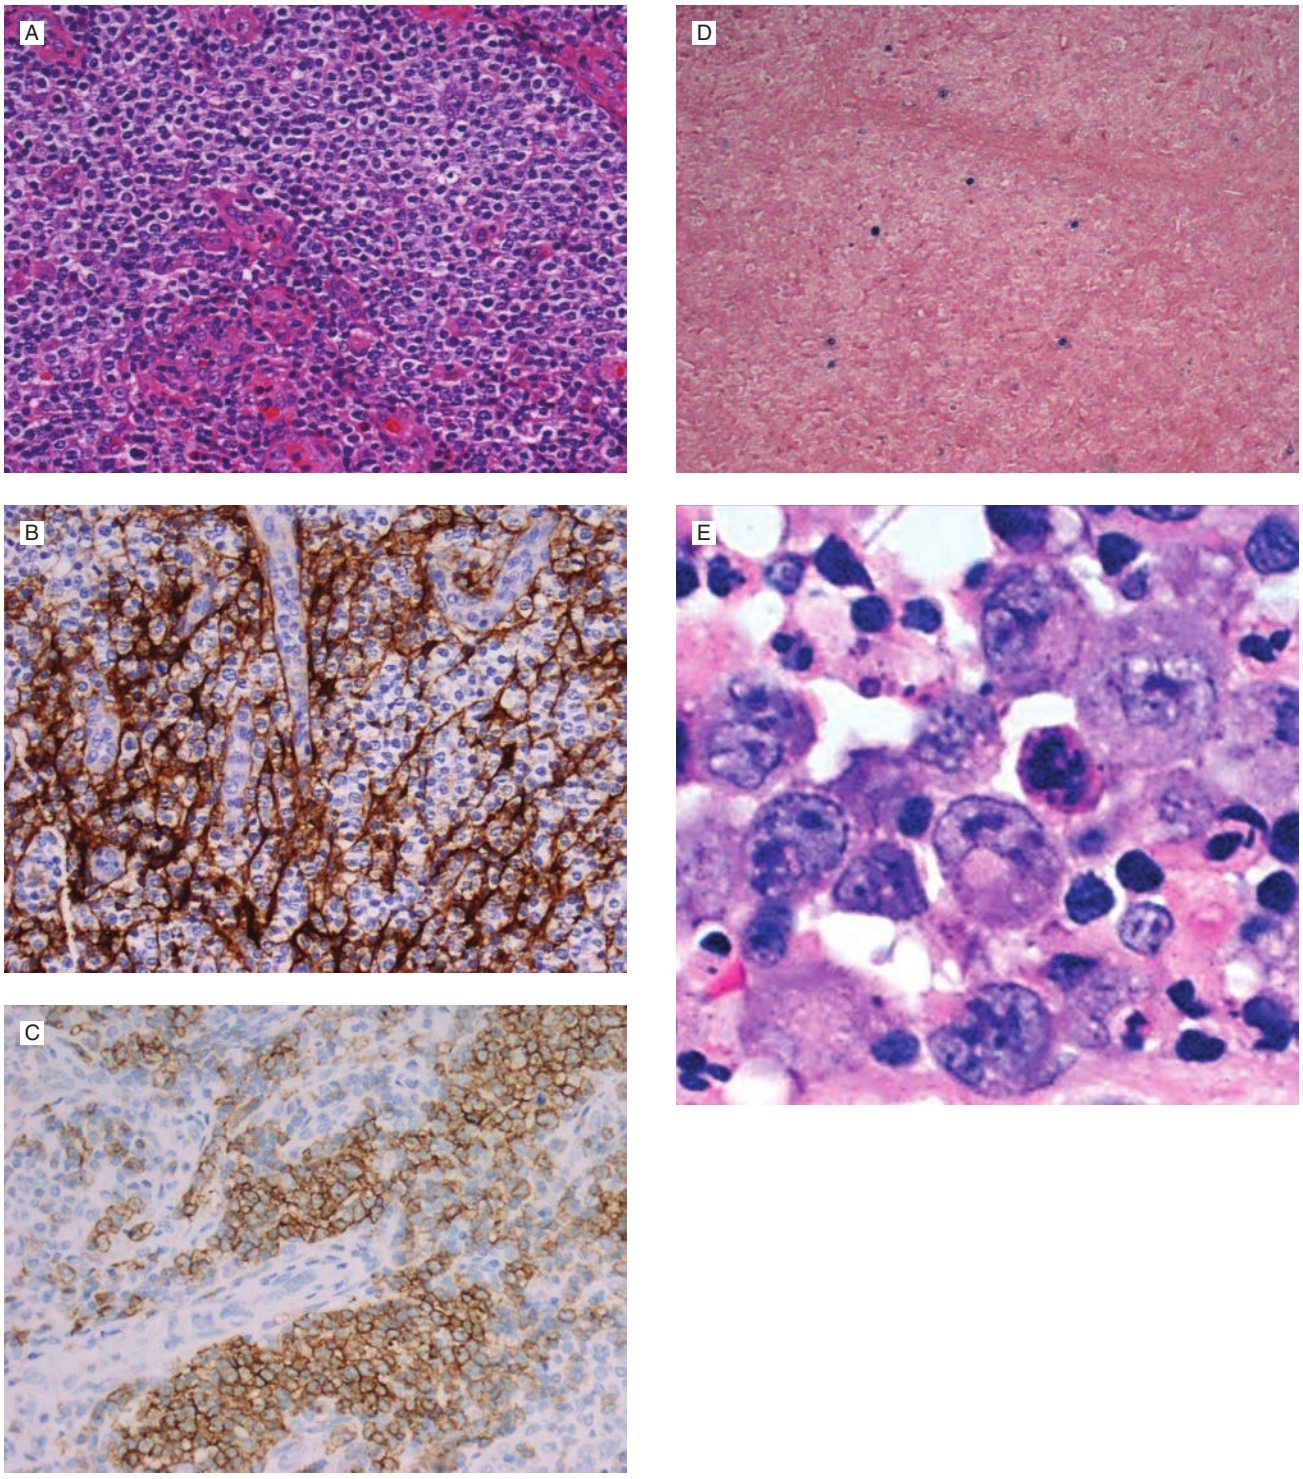

FIGURE 11–2 Microscopic histopathology of peripheral T-cell lymphoma. Angioimmunoblastic T-cell lymphoma (AITL): AITL (**A**; hematoxylin and eosin [H&E] stain), immunohistochemistry (IHC) for CD21 (**B**), ICH for PD1 (**C**), and in situ hybridization for Epstein-Barr virus (EBV)-encoded RNA (**D**). Systemic anaplastic large-cell lymphoma (sALCL): sALCL (**E**; H&E), IHC for CD30

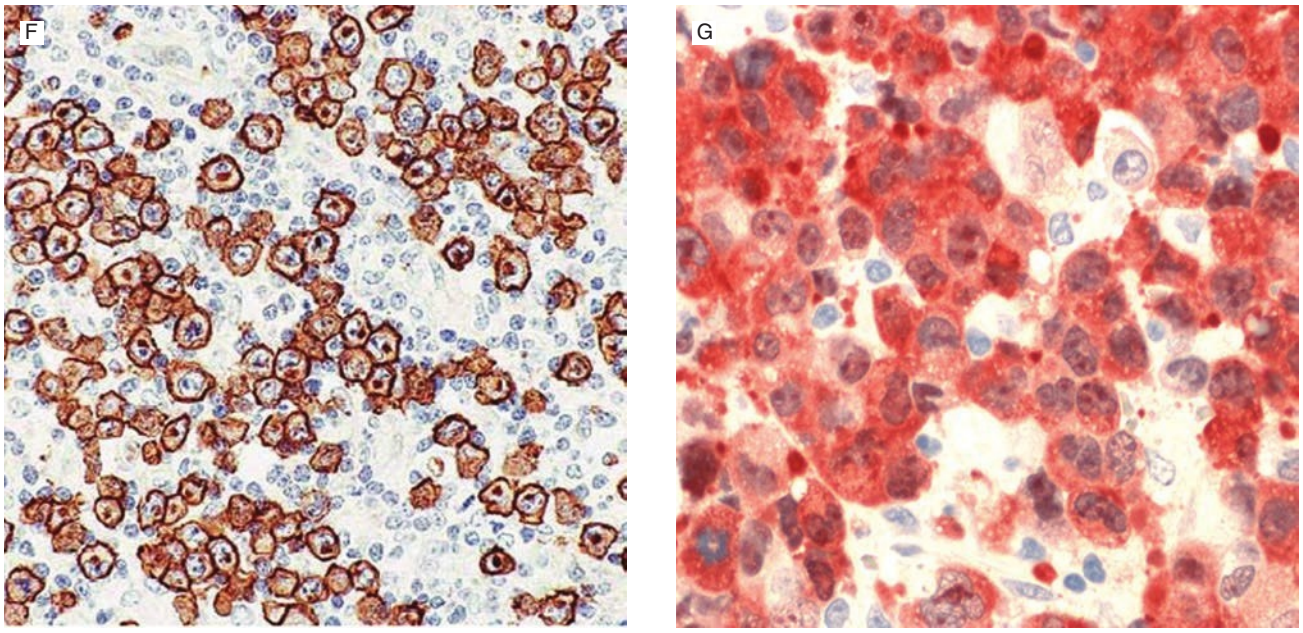

FIGURE 11–2 (Continued) (F), and IHC for anaplastic lymphoma kinase 1 (ALK1) (G). (Used with permission from Dr. Francisco Vega, MDACC.)

counterpart. About 8% to 12% cases demonstrate the TP53 homolog TP63 on 3q28 and are associated with an aggressive clinical behavior and poor outcomes (5-year OS rate, 17%).[37] The subset of ALK(-) ALCL that does not carry none of the above rearrangements is termed triple-negative ALCL (ALK, TP63 and DUSP22 negative) and carries an intermediate prognosis (5-year OS rate, 33%), poorer than ALK(+) ALCL and DUSP22-rearranged ALCL but better than TP63-rearranged ALCL and similar to ALK(-) ALCL as a whole.[37]

The majority of the cases of ALCL display a classical morphology under the microscope characterized by the presence of large cells with abundant cytoplasm (see Figure 11–2E–G). The common or classic type is characterized by sheets of large pleomorphic tumor cells and the presence of hallmark cells with eccentric kidney-shaped nucleus (with multiple prominent nucleoli) and a prominent and pale Golgi region (paranuclear halo). Variations of multinucleated cells, Reed-Sternberg–like cells, and doughnut cells that often preferentially involve the lymph node sinuses and paracortex are often seen. Uncommon morphologic variants include small-cell, monomorphic, lymphohistiocytic, neutrophil-rich, clear cell, signet ring cell, giant cell–rich, Hodgkin-like, and sarcomatoid variants. On IHC, CD30 is universally and strongly expressed in a membrane and Golgi pattern, with frequent expression of TIA1, granzyme B, perforin, EMA, and low expression of CD8 and CD56. Cells are negative for B-cell surface markers (CD19, CD20, CD22). There is heterogenous expression of T-cell antigens and in some cases is defined as a null group none of the lineage-specific markers are detected. Whereas the majority of ALCL have clonally rearranged TCR genes, roughly 10% in the null group have no rearrangement of TCR.[10,38,39]

CLINICAL COURSE

The clinical presentation of mature T-cell lymphomas is extremely variable and largely depends on the subtype (Table 11–2). PTCL-NOS, AITL, and ALCL

TABLE 11–2 Five-Year Outcomes by Different Peripheral T-Cell Lymphoma Subtypes

	ITCP: 5-Year FFS (%)	ITCP: 5-Year OS (%)	BCCA: 5-Year FFS (%)	BCCA: 5-Year OS (%)
AITL	18	32	13	36
PTCL-NOS	20	32	29	35
ALK (-) ALCL	36	49	28	43
ALK (+) ALCL	60	70		

AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; ALK, anaplastic lymphoma kinase; FFS, failure-free survival; ITCP, International T-Cell Project; OS, overall survival; PTCL-NOS, peripheral T-cell lymphoma not otherwise specified.

all often present with generalized lymphadenopathy and B symptoms and can involve extranodal sites, including the skin, gastrointestinal tract, liver, spleen, and bone marrow. Patients commonly present with advanced-stage disease (stages III and IV; AITL, 89%; PTCL-NOS, 69%; ALK (+) ALCL, 65%; ALK (-) ALCL, 58%).[10] It is common for PTCL to be mistaken for other types of lymphoma, which often can lead to a delay in diagnosis because of suboptimal rates of concordant pathological diagnosis.[40] Infrequently, patients present with or develop during the course features of hemophagocytic lymphohistiocytosis (HLH) and can have a high fatality rate. In one series, 23% patients had PTCL was associated with lymphoma-associated hemophagocytic syndrome, PTCL-NOS accounted for the majority.[41]

Angioimmunoblastic T-Cell Lymphoma

Patients with AITL are typically middle-aged to older adults. There is a nearly equal incidence between both genders. The majority of patients present with an aggressive clinical course characterized by generalized lymphadenopathy, B symptoms (fevers, unintentional weight loss, drenching night sweats), bone marrow involvement, and hepatosplenomegaly. There are anecdotal reports of a patients presenting with a smoldering course with waxing and waning lymphadenopathy. This is one of the commonest lymphomas that masquerades as other pathologic entities, posing a diagnostic challenge and presenting with atypical symptoms. This includes symptoms of immunodeficiency, opportunistic infections, skin rash, and hemolytic anemia.[42] Skin rash can be a presenting symptom, usually pruritic. Rash is seen in 20% to 50% of patients with AITL, ranging from urticarial lesions to nodular tumors. Hematologic abnormalities (eg, Coombs-positive hemolytic anemia and polyclonal hypergammaglobulinemia) can be seen in up to 45% of cases.[9]

Peripheral T-Cell Lymphoma Not Otherwise Specified

The median age of the patients with PTCL-NOS is 60 years. The male-to-female ratio is 2 to 1, and it has an aggressive clinical course .Although the majority of patients have nodal sites of involvement (87%), extranodal disease can be present in 62%.[43] Biochemical abnormalities include the presence of circulating tumor cells (10%); elevated serum β2-microglobulin (36%), C-reactive protein (50%), or calcium (5%) levels; hypogammaglobulinemia (9%); monoclonal serum immunoglobulin (4%); hemolytic anemia (3%); and hemophagocytic syndrome (3%).[43]

Anaplastic Large-Cell Lymphoma

ALK (+) ALCL is clinically distinctive with a more common incidence in younger patients (median age, 34 years).[10,44,45] Both ALK (+) and ALK (-) have frequent B symptoms, and one in five affected patients has involvement of the bone marrow, skin, soft tissues, bone, bone marrow, liver, and lungs. In adults, breast involvement has been described, with most cases being ALK (-) ALCL and frequently seen in association with breast implants. The outer shell of the implant (smooth vs textured) is implicated in the risk of Breast implant–associated - ALCL with no risk reported in patients who had smooth implants.[46–48] Primary cutaneous ALCL are morphologically similar but a clinically distinct subtype of ALCL without systemic involvement at the time of diagnosis. They lack the expression of ALK and do not have gene rearrangements involving the *ALK* gene.[49,50]

DIAGNOSIS AND STAGING

The diagnosis of PTCL is often challenging because of the spectrum of clinical manifestations, heterogenous pathological appearance, and often overlap with more common nonmalignant conditions, both clinically and pathologically. The workup of all patients who may have PTCL includes excisional lymph node biopsy if feasible, which is the gold standard test. The pathologic diagnosis is based on characteristic morphologic features and immunohistochemical patterns in correlation with the clinical signs and symptoms on presentation. Several factors add to a diagnostic gap in this lymphoma, including its rarity and need for detailed immunophenotypic markers. Current guidelines support the use of diagnostic panels to improve diagnostic accuracy and often require an expert hematopathologist. The initial workup of patients with PTCL should include physical examination; complete blood counts; and chemistry, including lactate dehydrogenase (LDH), β_2-microglobulin, bone marrow aspirate, and biopsy. Serologic tests for human immunodeficiency virus, HTLV11, hepatitis B and C can aid in identifying the subtypes of PTCLs. Positron emission tomography (PET) with 2-deoxy-2-[fluorine-18] fluoro-D-glucose should be considered at diagnosis, and further imaging should be done with PET or computed tomography scan for treatment monitoring at mid-treatment and the end of therapy in all cases. One should have a low threshold to workup if there is any suspicion of HLH and should consider tests including EBV polymerase chain reaction (PCR), ferritin, fibrinogen, triglycerides, and cytokine 12 profile, including soluble interleukin-2 receptor (IL-2sR). In men and women of childbearing potential, the possibility of infertility should be

discussed, and referral for fertility preservation consultation and therapy should be considered.

PROGNOSIS

The specific subtypes of aggressive PTCL along with the molecular markers discussed so far can provide information on the prognosis, with ALK (+) ALCL having the best prognosis. Clinical factors are also developed such as B-cell lymphoma to risk stratify patients called the International Prognostic Index (IPI), which is based on age, performance status (PS), LDH, stage, and extranodal involvement.[6] This was developed in aggressive B lymphomas and is less popularly used in T-cell lymphomas because of its limited ability to identify PTCL patients with their risk of treatment failure. They were validated in smaller studies, and the prognostication was not so satisfactory for the nodal entities. Hence, scores based on the biologic features of the tumors are currently being explored. An Italian cooperative group proposed a revision of the IPI for PTCL-NOS, the Prognostic Index for T-cell lymphoma (PIT) score, which includes age, PS, LDH, and bone marrow involvement.[51] The National Comprehensive Cancer Network (NCCN)-IPI, which subspecified features with respect to age, serum LDH, and inclusion of specific extranodal sites (central nervous system, bone marrow, liver, gastrointestinal tract, lung), seemed to separate prognostic groups slightly better on a visual scale. Both the PIT and the NCCN- IPI are able to discriminate the risk groups better in PTCL- NOS and ALCL than in AITL.[51,52] Although these clinical models are useful in estimating the prognosis, they have not impacted treatment approaches, and better tools incorporating immunophenotypic and molecular markers are much needed.

CLINICAL MANAGEMENT

Despite the advancements in the knowledge of the biology of PTCLs, the clinical course varies extensively depending on PTCL subtype and therapeutic intervention. It is imperative that the choice of frontline treatments to be critically appraised based on the subtype and the expression of CD30. Except for ALK (+) ALCL and ALK (-) ALCL with DUSP22 rearrangement, patients with PTCL generally have a chemoresistance, short-term remission, early relapse when treated with chemotherapy with CHOP or CHOP-like chemotherapy.[53] Historically, most of our knowledge on the treatment outcomes from the International T-Cell Project (ITCP) and the British Columbia Cancer Agency (BCCA) series (see Table 11–1). In the BCCA group, the majority of patients with ALK (+) disease had low-risk IPI scores and had an excellent 5-year OS (75%). However, the remainder of the patients with PTCL mostly had IPI scores greater than 2, and the 5-year OS rate were 25%, underscoring the high unmet need in this group.[39,43]

Expression of CD30

CD30 is a transmembrane glycoprotein belonging to the tumor necrosis factor receptor superfamily. It is expressed normally in activated B and T lymphocytes and in pathological states on many PTCL subtypes, including sALCL, in which it is characteristically uniform and high. Ligation of CD30 activates downstream nuclear factor κB (NF-κB) signaling pathways to promote cell growth and survival. Because signaling through CD30 can be oncogenic in some T-cell lymphomas, with limited expression in normal cells, it is one of the ideal targets. The CD30-directed antibody–drug conjugate BV has changed the approach to PTCL, essentially drawing a therapeutic line between CD30(+) and CD30(-) groups.

CD30 + Peripheral T-Cell Lymphoma

BV is an antibody–drug conjugate with the CD30-specific monoclonal antibody attached by a linker peptide to the chemotherapeutic agent monomethyl auristatin E (MMAE). Upon binding to CD30, BV undergoes endocytosis and is taken up by the lysosomal complexes. Under low pH conditions, the proteases cleave the linker and release MMAE to cytoplasm. Single-agent BV was approved for patients with sALCL after failure of one or more previous multiagent chemotherapy regimens. A phase I study evaluating BV in combination with CHP (CHOP without vincristine) in newly diagnosed patients with CD30(+) T-cell lymphomas showed an overall response rate (ORR) of 86%, with complete response rate (CRR) of 57%. The toxicities were manageable; adverse events (AEs) of grade 3 or higher commonly included neutropenia (21%), thrombocytopenia (14%), peripheral sensory neuropathy (12%), and anemia (7%). The long term 5-year follow-up in 38 patients who achieved CR showed progression-free survival (PFS) of 57% and OS of 79%.

A large, randomized, phase III study (ECHELON-2) comparing BV-CHP with CHOP BV plus CHP demonstrated superior response rates, higher rates of PFS, higher and OS without added toxicity for BV-CHP.[54] This is an important practice changing milestone in PTCL history, and BV-CHP is currently the standard of care treatment in patient with CD30 (+) PTCLs. CD30 is universally expressed in ALCLs, both ALK (+) and (-). In non-sALCL subtypes, CD30 expression is estimated to be approximately 58% to 64% in PTCL-NOS and 43% to 63% in AITL.[55,56] The ECHELON-2

study required the expression of CD30 to be at least 10% or greater in the neoplastic cells to be included in the study. About 75% of the patients in the ECHELON-2 study had advanced-stage disease, 30% were 65 years of age or older, and 70% had sALCL (48% ALK (-)). Twenty-two percent of patients were ALK (+) were required to have IPI scores of 2 or greater. Others in the study included patients with PTCL-NOS (16%), AITL (12%), ATLL (<2%), and EATL (<1%). The ORR and CRR were significantly higher with BV-CHP than CHOP (ORR, 83% vs 72%; CR rate, 68% vs 56%). The study met the primary endpoint showing significant improvement of PFS with BV-CHP. With a median follow-up period of 36.2 months, the median PFSs were 48.2 months versus 20.8 months (BV-CHP vs CHOP; hazard ratio [HR], 0.71, 95% confidence interval [CI], 0.54–0.93; $P = .011$). There was also a significant improvement in OS with HR (0.66; 95% CI, 0.46–0.95; $P = .0244$ for BV-CHP versus CHOP). The OS benefit was predominantly seen in sALCL but not in PTCL-NOS (HR, 0.83; 95% CI, 0.38–1.80) and AITL (HR, 0.87; 95% CI, 0.29–2.58). The treatment-related AE rates were similar between the two groups: AEs of grade 3 or greater occurred in 66% of the BV group versus 65% of the CHOP group. Febrile neutropenia occurred in 18% versus 15% and any grade peripheral neuropathy in 52% versus 55%. Serious AE occurred in 39% vs 38%; treatment discontinuation because of AEs occurred in 6% and 7% of patients in BV-CHP and CHOP arms, respectively. Treatment-related AEs leading to death were similar in both cohorts (3% vs 4%). The study clearly breaks the traditional norm in PTCL trials and established CD30-based treatment for frontline treatment of patients with T-cell lymphomas. However, it remains to be noted that AITL and PTCL-NOS subgroups were suboptimally represented, so the study is not powered to compare efficacy between histologic subtypes along with the potential benefit of BV in non- ALCL CD30(+) PTCL subtypes.[54] In November 2018, the FDA approved BV with CHP for patients with previously untreated sALCL or other CD30-expressing PTCLs, including AITL and PTCL-NOS (Fig. 11–3).

CD30-Negative T-Cell Lymphoma

For the vast majority of both cases of AITL and PTCL-NOS that are CD30 (-), CHOP-based chemotherapy remains the standard of care. Although more intensive therapies have been attempted, these did not fare better than those treated with CHOP therapy.[57] Both the registry study from Sweden and the German High-Grade Non-Hodgkin Lymphoma Study Group's ad-hoc analysis showed improved event-free survival (EFS) with the incorporation of etoposide in CHOP, especially if age is younger than 60 years, and normal

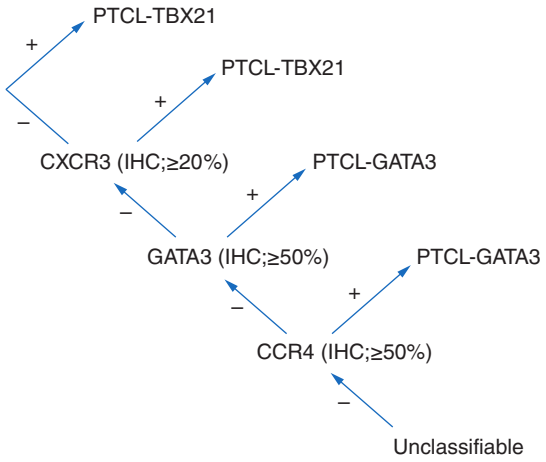

FIGURE 11–3 Cell of origin for peripheral T-cell lymphoma (PTCL) not otherwise specified. IHC, immunohistochemistry.

levels of LDH. The positive effect of etoposide on EFS was confirmed when patients with ALK(+) ALCL were considered (3-year EFS, 91.2% vs 57.1%; $P = .012$); the comparison showed a similar numerical trend when the other subtypes were taken together (3-year EFS, 60.7% vs 48.3%; $P = .057$).[58,59] In older adult patients, the addition of etoposide is considered debatable and can often cause toxicity; its use should be evaluated on a case-by-case basis. Many centers use it to achieve deeper remissions rates in anticipation for consolidation with high-dose chemotherapy with hematopoietic stem-cell transplant (HDC SCT). More intensive induction regimens (eg, infusional EPOCH, hyper-CVAD [hyperfractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone]) provide comparable clinical outcomes, but no prospective studies have directly compared the regimens. Moreover, these intensive regimens are associated with increased AEs.[60] CHOP is generally administered every 3 weeks, similar to Cyclophosphamide, Doxorubicin, Vincristine, Etoposide and Prednisone (CHOEP), in which the additional etoposide is administered on days 1 through 3 every 3 weeks[58] (Fig. 11–4).

UPFRONT CONSOLIDATION AND MAINTENANCE

The majority of patients receiving frontline chemotherapy (see Fig. 11–4), except for those with ALK (+) ALCL, fail to achieve long- term remissions in PTCL.[61] Studies have looked at the role of consolidation with radiation therapy (RT) and HDC SCT in eligible patients; however, it is worth noting that there is a lack of adequately powered randomized controlled trials to make a strong recommendation.

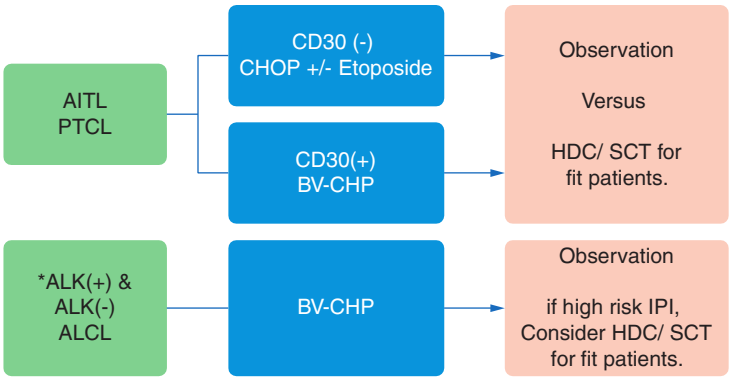

FIGURE 11–4 Frontline treatment algorithm for peripheral T-cell lymphoma (PTCL). AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; ALK, anaplastic lymphoma kinase; BV, brentuximab vedotin; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; CHP, cyclophosphamide, doxorubicin, and prednisone; HDC SCT, high-dose chemotherapy with stem-cell transplantation; IPI, International Prognostic Index.
*Universal expression of CD30

In early stage and low IPI group, RT is generally an accepted mode of consolidation based on retrospective analyses and anecdotal experience.[62–64] There are many limitations to these studies, including their small sample size, selection bias of different chemotherapies used, and inclusion of primary refractory disease. The current national guideline- (the NCCN guidelines) recommend consolidative RT in all patients with stage I or II PTCL disease who achieve remission after standard anthracycline-based chemotherapy.

In advance stage with high IPI, studies have supported HDC SCT as a consolidation treatment in patients with all major subtypes of PTCL with noted significant benefit in the first remission compared with subsequent remission (Table 11–3).[65–71] In the ECHELON-2 trial, at the discretion of the investigator, patients underwent consolidative HDC SCT (22% patients in the BV +CHP group and 17% in the CHOP group); however, the study was not designed to look at the effect of transplant.[54] An exploratory analysis was further reported of the patients in CR after BV + CHP who received SCT and those who did not showed a numerical PFS benefit in favor of SCT.[72] The Center for International Blood and Marrow Transplant Research retrospectively evaluated HDC SCT, and the results suggested better outcomes when consolidation was offered earlier in the disease course and limited utility in multiply relapsed disease.[69] Although there is a role for consolidative HDC SCT in the primary treatment of nodal PTCLs, further studies are needed based on clinical and genetic stratification, particularly patients with high-risk features. Allogeneic transplant carries a high transplant-related mortality (TRM) rate and is generally not considered in first remission. Improvements in TRM may permit the role of upfront allogeneic SCT in appropriately designed clinical studies with high-risk characteristics.[73]

TABLE 11–3 Outcome of High-Dose Chemotherapy Autologous Stem-Cell Transplantation in First Remission in Peripheral T-Cell Lymphoma from Landmark Studies

Reference	Patients (*n*)	Frontline Treatment	PFS and EFS	OS
Mercadal et al[66] (2008)	41	High-dose CHOP/standard ESHAP	4-year PFS, 30%	4-year OS, 39%
Corradini et al[68] (2006)	62	(1) 32 patients received APOx2 + DHAPx2 followed by HDT/ASCT (2) 30 patients received MACOP-B for 8 weeks with intensification with a 3-day course of mitoxantrone and ara-C, followed by HDT/ ASCT	ALK-positive lymphomas: 12-year EFS, 54%	ALK-positive lymphomas: 12-year OS, 62%
d'Amore et al[65] (2012)	166	Biweekly CHOEP for six cycles	5-year PFS, 44%	5-year OS, 51%
Reimer et al[68] (2009)	83	CHOP	3-year PFS, 36%	3-year OS, 48%
Rodriquez et al[71] (2007)	74	CHOP-based regimen	5-year PFS, 63%	5-year OS, 68%

ALK, anaplastic lymphoma kinase; APO, doxorubicin, vincristine, prednisone; CHOEP, cyclophosphamide, doxorubicin, etoposide, vincristine and prednisone; CHOP, cyclophosphamide, doxorubicin, vincristine and prednisone; EFS, event-free survival; ESHAP, etoposide, methylprednisolone (solumedrol), high-dose cytarabine (ara-C), and cisplatin; MACOP-B, methotrexate-doxorubicin-cyclophosphamide-vincristine-prednisone- bleomycin; OS, overall survival; PFS, progression-free survival

RELAPSED OR REFRACTORY DISEASE

A substantial number of patients with nodal PTCL either relapse or fail to achieve remission, as shown in the 153-patient BCCA series, and have poor outcomes with short survival times.[74] For patients who are fit and eligible, intensive salvage chemotherapy options are considered with the intention to consolidate with HDC SCT. The ORR for the various salvage regimens is in the 40% to 50% range; only a few patients manage to achieve CR, and the window to get these patients to HDC SCT is often short. In the BCCA series, the median PFS and OS after the first relapse or disease progression were only 3.1 and 5.5 months, respectively, without HDC SCT. Moreover, the patients who did receive chemotherapy at relapse had longer OS, but the difference was only 3 months compared with those who did not (6.5 vs 3.7 months, respectively).

Multiple studies suggest that outcomes of patients who have chemotherapy-sensitive disease have better outcomes with HDC SCT. However, there is a lack of randomized controlled studies, and most data on the role of HDC SCT and the types (autologous vs allogeneic) come from phase II and retrospective studies, which have inherent bias because of patient selection, heterogenous pathology, and inclusion of patients with more favorable PTCL subtypes. In addition, most studies include patients who went on to receive HDT SCT.[69—72] Patients who achieve a CR with salvage regimens could be consolidated with an HDC autologous SCT, but those with a PR should be considered for allogeneic HCT or additional salvage therapy.

Another major challenge in PTCL is that at the time of relapse, many patients are not eligible for intensive chemotherapies because of age, comorbidities, performance status, or personal preferences. In these patients, many new drugs are being investigated to extend the duration of response. The US FDA has approved four drugs with novel mechanisms of action for the treatment of patients with relapsed or refractory nodal T-cell lymphoma based on ORR. These include pralatrexate, romidepsin, belinostat, and BV.[75—81] Response rates with pralatrexate, romidepsin, and belinostat range from 25% to 54% in relapsed or refractory PTCL populations, and the ORR is as high as 86% (CR, 57%) with BV for patients with ALCL (Table 11–4). The actual impact on survival outcome for the single agents remains unclear. There have been attempts made to incorporate these novel agents into the salvage chemotherapy backbone with the intention of providing higher CR rates without an increase in toxicity. This can in turn facilitate subsequent consolidation with HDC SCT.[82]

The role of these novel agents to improve disease-related outcomes is actively being investigated in the frontline induction, disease salvage, and high-dose consolidation or in a maintenance setting. Mature clinical data are needed to show their impact on survival curves.

EMERGING HORIZONS

Clinical trials remain an integral part of the care of patients with PTCL, and participation is therefore highly encouraged. Understanding of the molecular and epigenomic markers has provided targetable mutations and pathways and has the potential to transform the current treatment landscape to more personalized care for patients. Overall, there is a need for effective treatments for most PTCL subtypes, and this requires increased understanding of the biology of PTCL to improve diagnosis and provide biomarkers for assessment of response or relapse. Several novel therapeutic agents are under investigation in relapsed or refractory PTCL, which has shown to result in deeper responses, potentially improving outcomes; however, this discussion is beyond the scope of this chapter. Using these agents, single-agent therapy for palliative intent or combination therapies followed by HDC SCT consolidation is actively being investigated. These investigational agents include ALK inhibitors (crizotinib and ceritinib), alisertib (selective inhibitor of aurora A kinase), panobinostat (pan-HDAC [histone deacetylase] [class ½/4] inhibitor), bortezomib (proteasome inhibitor), denileukin diftitox (IL-2–diphtheria toxin fusion protein), lenalidomide(immunomodulatory, synthetic thalidomide derivative), alemtuzumab (humanized anti-CD52 monoclonal antibody), mogamulizumab (defucosylated, humanized, monoclonal antibody targeting CC chemokine receptor 4), duvelisib and tenalisib (phosphoinositide-3 kinases δ and γ inhibitors), cyclosporine (immunomodulatory), and Selinexor (oral selective inhibitor of nuclear export).[3] Innovative therapies such as chimeric antigen receptor (CAR) T-cell therapy (an adoptive T-cell therapy approach that uses genetically engineered T cells transduced to express an artificial receptor against a target antigen on the tumor) are among the most promising immunotherapies for cancer. They have produced remarkable response rates in patients with B-lymphoid malignancies and are currently in phase ½ trials in patients with PTCL. These approaches have the potential to move rapidly to the frontline clinical investigation; many of these are currently underway.

TABLE 11–4 Targeted Agents and the Pivotal Trials That Led to Approval for Peripheral T-Cell Lymphoma

Study	Drugs	Mechanism of Action	Patients (*n*)	ORR	CR	PFS or EFS	Median OS
PROPEL	Pralatrexate	Novel selective antifolate agent Competitively inhibits dihydrofolate reductase and thymidylate synthase Thereby disrupts the DNA/RNA synthesis required for lymphoma cell proliferation	109	29% PTCL-NOS: 32 sALCL: 35 AITL: 8	11%	3.5 months	14.4 months
BELIEF	Belinostat	Potent IV (class 1/2/4), epigenetic-modifying HDAC inhibitor	129	25.8% PTCL-NOS: 23% AITL: 46% ALK (-) ALCL: 15%	10.8 AITL: 18%	1.6 months	7.9 months
Phase II	Brentuximab (R/R systemic ALCL after treatment failure of at least one prior therapy)	ADC directed against CD30, a cell-surface antigen	58	86%	57%	20 months	Not reached 1 year: 70% 3 years: 63% 4 years: 64%
Phase II	Romidepsin	Epigenetic-modifying agent that alters chromatin, specifically as a potent IV class 1 HDAC inhibitor Interferes with the acetylation pattern of chromatin on histone lysine residues Prevents gene transcription and disrupts protein function in malignant lymphoma cells	130	25% PTCL-NOS: 29% AITL: 30% ALK (-) ALCL: 24%	15%	4 months	11.3 months

ADC, Antibody-drug Conjugates; AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; ALK, anaplastic lymphoma kinase; Phase II BELIEF (CLN-19) Study; CR, complete remission; EFS, event-free survival; FFS, failure-free survival; HDAC, histone deacetylase; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; Phase II, PROPEL; PTCL-NOS, peripheral T-cell lymphoma not otherwise specified; R/R, Relapsed / Refractory; sALCL, systemic anaplastic large-cell lymphoma.

CONCLUSIONS

PTCL is a heterogenous group of rare lymphomas with poor prognoses and a lack of large, randomized trials to dictate treatment options. The immediate goal of therapy is to achieve a rapid and complete response and follow different treatment consolidation strategies to maintain this remission. As the field moves toward individualized therapies, large cooperative efforts are needed to advance the research to understand the different molecular subtypes and develop genome-driven clinical trials. Several new therapies, including CAR T-cell therapies, are likely to make a positive impact on survival outcomes in the next few years.

MD ANDERSON PRACTICE TIPS

- Excisional lymph node tissue biopsy is strongly recommended for the diagnosis of PTCL and is considered the gold standard test. Many centers perform core biopsy to provide pathological diagnosis in clinical presentations with time-sensitive requirements. Fine-needle aspiration is considered suboptimal for establishing the diagnosis.
- The presence of neoplastic T-cell infiltrate is determined based on morphology, aberrant T-cell phenotype (loss of expression of antigens normally expressed by T-cells or expression of antigens normally not associated with normal T-cells). Demonstration of T-cell clonality of PTCL is routinely evaluated with a PCR-based method using genomic DNA; however, the absence of an identifiable T-cell clone does not definitively rule out a diagnosis of PTCL.
- For patients 60 years of age or younger with normal LDH, especially for ALK (+) sALCL, addition of etoposide to CHOP may be more efficacious than CHOP according to the subgroup analysis from large, prospective, randomized clinical trials from The German High-Grade Non-Hodgkin Lymphoma Study Group and the analysis of the Swedish Lymphoma Registry. There was a trend toward improved EFS in favor of CHOEP in the other subsets as well, which was not statistically significant.
- For patients older than 60 years, intensive regimens are associated with increased toxicity without the benefit of improvement in outcomes. There was no benefit of CHOP-14 compared with CHOP-21, and adding etoposide CHOP chemotherapy was more toxic in the older adult group; hence, BV-CHP and CHOP continues to be the standard in older adult patients with CD30(+) and CD30(-) PTCL, respectively.
- Because of the high relapse rates in PTCL, high-dose chemotherapy with autologous SCT should strongly be considered for consolidation after the first remission except in the ALK (+) subtypes.
- The US FDA has approved four drugs with novel mechanisms of action for the treatment of patients with relapsed or refractory PTCL. These include pralatrexate in 2009, romidepsin in 2011, BV (for sALCL) in 2011, and belinostat in 2014.

12 Cutaneous Lymphomas

Auris Huen

KEY CONCEPTS

- Cutaneous lymphomas are a heterogenous group of B- and T-lymphocyte infiltration to the skin with varying clinical behaviors and prognoses.
- Mycosis fungoides (MF) is the most common subtype of cutaneous T-cell lymphoma (CTCL) with typical indolent course, but a subset of patients can progress to more advanced stages involving nodal and blood compartments.
- Sézary syndrome (SS) is a leukemic variant of CTCL with a more aggressive course. In many patients, skin biopsy is nondiagnostic because it does not reveal malignant cells, and diagnosis is made by peripheral blood flow cytometry or Sézary cell count.
- The treatment of patients with CTCL is guided by stage and distribution of the skin involvement. The initial treatment approach to skin-limited disease is embodied by the use of skin-directed treatment modalities.
- Two newly approved treatment options for patients with relapsed refractory MF and SS include brentuximab vedotin and mogamulizumab, which target skin and blood compartments of disease, respectively.
- Primary cutaneous B-cell lymphomas should be distinguished from secondary metastasis of B-cell lymphoma to the skin and are typically associated with an indolent disease course and a favorable prognosis.

Cutaneous lymphoma is an umbrella diagnosis consisting of multiple subtypes involving malignant mature B- or T-lymphocyte infiltration in the skin. It should be distinguished from secondary metastasis of systemic lymphoma to the skin where involvement in the skin is considered advanced stage. Cutaneous T-cell lymphoma (CTCL) is considered a rare entity consisting of approximately 4% of all cases of non-Hodgkin lymphoma.[1] In the majority of patients with CTCL, the disease course is typically indolent; however, in a subset of patients, the prognosis is less favorable, and progression to advanced-stage disease with nodal, blood, and visceral compartments can develop. The cutaneous B-cell lymphomas are less common than their T-cell counterparts, also with a favorable prognosis in the majority of patients.[2,3]

In 2008, the World Health Organization (WHO) established the classification of cutaneous lymphomas. This classification was updated in 2016 and again by the WHO–European Organization for Research and Treatment of Cancer (EORTC) and provides the basis for subcategorization of this disease (Table 12–1).[2] Each subtype carries differing clinical presentation, histopathologic features, prognoses, and treatment approaches. The various subtypes of cutaneous B and T-cell lymphomas can be separated into aggressive and less aggressive forms (Table 12–2). Mycosis fungoides (MF), pagetoid reticulosis, and CD30+ lymphoproliferative disorders are considered relatively indolent diagnoses. For B-cell lymphomas, marginal zone and follicle center cell lymphomas are favorable subtypes. In indolent cutaneous lymphoma, skin lesions can wax and wane for years and sometimes even self-resolve without treatment. In more aggressive subtypes such as Sézary syndrome (SS), primary cutaneous γδ T-cell lymphoma (pcGDL), and primary cutaneous CD8+ epidermotropic cytotoxic T-cell lymphoma, diffuse large-cell lymphoma, eg type (DLBCL leg type), patients characteristically develop rapidly progressive skin lesions and systemic involvement pertaining to a poor prognosis.[4,5] It is critical to determine the patient's subtype to accurately provide prognosis and treatment. Appropriate classification of the patient's disease can prevent overtreatment of indolent forms of disease.

TABLE 12–1 World Health Organization–European Organization for Research and Treatment of Cancer 2018 Classification of Cutaneous Lymphomas

Cutaneous T-Cell Lymphomas	Frequency (%)	5-Year DSS (%)
Mycosis fungoides (MF)	39	88
MF variants		
Folliculotropic MF	5	75
Pagetoid reticulosis	<1	100
Granulomatous slack skin	<1	100
Sézary syndrome	2	36
Adult T-cell leukemia/lymphoma	<1	NDA
Primary cutaneous CD30+ lymphoproliferative disorder		
Primary cutaneous anaplastic large-cell lymphoma	8	95
Lymphomatoid papulosis	12	99
Subcutaneous panniculitis-like T-cell lymphoma	1	87
Extranodal NK/T-cell lymphoma, nasal type	<1	16
Chronic active EBV infection	<1	NDA
Primary cutaneous peripheral T-cell lymphoma, rare subtypes		
Primary cutaneous γ/d T-cell lymphoma	<1	11
Primary cutaneous CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma	<1	31
Primary cutaneous CD4+ Small/medium pleomorphic T-cell lymphoproliferative disorder (P)	6	100
Primary cutaneous acral CD8+ T-cell lymphoma (P)	<1	100
Primary cutaneous peripheral T-cell lymphoma, NOS	2	15
Primary cutaneous marginal zone lymphoma	9	99
Primary cutaneous follicle center cell lymphoma	12	95
Primary cutaneous diffuse large B-cell lymphoma, leg type	4	56
EBV+ mucocutaneous ulcer (P)	<1	100
Intravascular large B-cell lymphoma	<1	72

DSS, disease-specific survival; EBV, Epstein-Barr virus; MF, mycosis fungoides; NDA, no data available; NOS, not otherwise specified; P, provisional.

TABLE 12–2 Lymphoma Subtypes

A. T-Cell Lymphoma Subtypes	
Indolent	Aggressive
Mycosis fungoides	Sézary syndrome
Folliculotropic mycosis fungoides	Primary cutaneous natural killer/T-cell lymphoma, nasal type
Pagetoid reticulosis	Primary cutaneous aggressive CD8+ T-cell lymphoma
Granulomatous slack skin	Primary cutaneous γ/δ T-cell lymphoma
Primary cutaneous anaplastic large-cell lymphoma	Primary cutaneous peripheral T-cell lymphoma, unspecified
Lymphomatoid papulosis	Primary cutaneous CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous CD4+ small/medium pleomorphic T-cell lymphoproliferative disorder	
B. B-Cell Lymphoma Subtypes	
Indolent	Aggressive
Marginal zone	Diffuse large B-Cell Leg type
Follicle center cell	Intravascular lymphoma Other

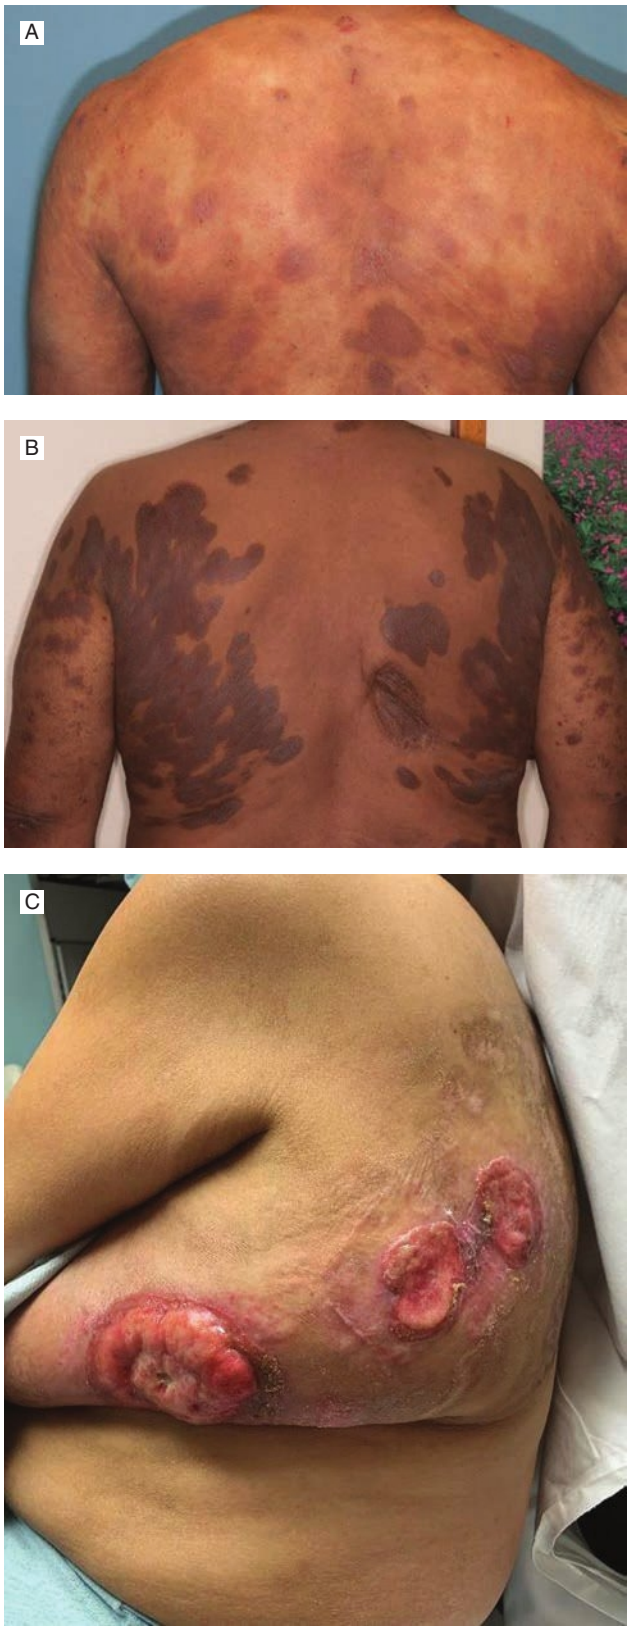

FIGURE 12–1 Patches (A), plaques (B), and tumors (C) of mycosis fungoides.

CUTANEOUS TUMOR TYPES

Patients with cutaneous lymphoma typically present with patches, plaques, and tumors on the skin. Patches are characterized by flat, nonpalpable erythematous involvement in the skin. If lesions become thickened and palpable, they are considered plaques. More advanced stages are associated with tumors in the skin that are more indurated or ulcerated. (Fig. 12–1). Other less common cutaneous findings associated with CTCL include leonine facies, palmar plantar hyperkeratosis (Fig. 12–2), poikiloderma, and

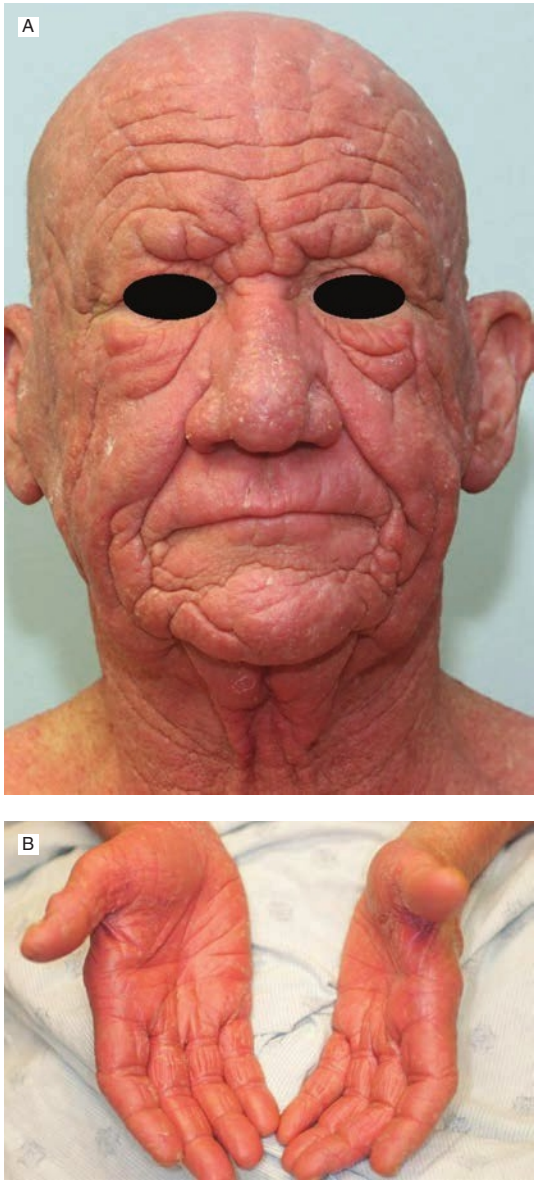

FIGURE 12–2 Leonine facies (A) and palmar plantar keratoderma (B) of Sézary syndrome.

FIGURE 12–3 Hypopigmented mycosis fungoides.

hypopigmentation.[6,7] (Fig. 12–3) These findings are unique to certain subtypes of CTCL and are discussed in individual sections.

EVALUATION OF PATIENTS WITH CUTANEOUS LYMPHOMA

Patients with cutaneous lymphoma are ideally evaluated by a multidisciplinary team with expertise in the disease consisting of dermatologists and oncologists, with support from pathologists and radiation oncologists.[8,9] Patients typically present with skin lesions as the initial presenting sign. Multiple skin biopsies are sometimes needed for the diagnosis of cutaneous lymphoma, especially in patients with thin lesions, often requiring immunohistochemistry markers and clonality studies for diagnosis. Skin lesion examination assessing extent of skin involvement and complete clinical history is vital to aid in classification of disease into subtypes. Quantifying cutaneous involvement of CTCL involves determining body surface area (BSA) and the modified severity-weighted assessment tool (SWAT), which adds the influence of the lesion type. The modified SWAT is the most recognized method of measuring cutaneous involvement with CTCL and is often used clinically and in clinical trials for skin assessment. The patient's hand size is used to estimate about 1% BSA (Table 12–3). Patches are weighted with factor of 1, plaques are weighted with factor of 2, and tumors are weighted with factor of 4 to determine the modified SWAT. This weighted model takes into consideration changes in skin lesions type and more

TABLE 12–3 Sample Form for Body Surface Area (BSA) Calculation and Modified Severity-Weighted Assessment Tool (mSWAT)

Area	BSA for Region (%)	BSA Patch (%)	BSA Plaque (%)	BSA Tumor (T)
Head	7			
Neck	2

Modified with permission from Olsen EA, Whittaker S, Kim YH, et al: Clinical end points and response criteria in mycosis fungoides and Sézary syndrome: a consensus statement of the International Society for Cutaneous Lymphomas, the United States Cutaneous Lymphoma Consortium, and the Cutaneous Lymphoma Task Force of the European Organisation for Research and Treatment of Cancer, *J Clin Oncol* 2011 Jun 20;29(18):2598-2607.

accurately reflects the severity of the patient's cutaneous involvement.[10]

Taking a complete medication history for recently started medications and history of recent exposures to viral or infectious organisms can help rule out pseudolymphoma. All patients with B-cell cutaneous lymphoma should undergo screening for systemic disease, including computed tomography (CT) with contrast of the chest, abdomen, and pelvis and blood work with a complete blood count (CBC).[11] In patients with CTCL, laboratory workup should include CBC, comprehensive metabolic profile, lactate dehydrogenase (LDH), and screening for infectious triggers such as syphilis, human immunodeficiency virus(HIV), hepatitis B and C, and in select patients, human T-cell leukemia/lymphoma virus-1 (HTLV-1) if applicable. Flow cytometry for aberrant T-cells in the peripheral blood should also be assessed in all patients with erythrodermic and advanced-stage CTCL.[9] In patients with indolent CTCL such as MF, early-stage disease with patch-only involvement, no imaging or bone marrow studies are typically performed unless the patient reports systemic symptoms or has laboratory abnormalities. In patients with thicker plaques, tumors, and erythroderma, full staging evaluation, including CT or positron emission tomography–CT (PET-CT) should be done.[3] Lymph nodes greater than 1.5 cm by palpation or imaging should be evaluated for potential disease involvement with core or excisional biopsies. Fine-needle aspiration of lymph nodes should be avoided so that the lymph node architecture and effacement of the sample can be evaluated.[12]

CUTANEOUS T-CELL LYMPHOMAS

Mycosis Fungoides

The most common subtype of CTCL is MF, which accounts for approximately 50% to 60% of cases of cutaneous lymphoma and typically carries an indolent course. In the United States, the annual age-adjusted incidence is reported at 7.5 cases per million and is considered a rare diagnosis.[13] Patients present with patches and plaques, which are often mistaken for other dermatoses such as atopic dermatitis or psoriasis for years before the correct diagnosis is made. The median delay in diagnosis of 36 months was recently reported in a large series of patients. This is largely due to challenges in evaluating early-stage disease clinically with mimickers and on histopathologic review.[14]

No definite cause or association leading to the development of MF has been identified. However, it is believed that it is triggered by chronic antigenic stimulation, leading to expansion of clonal skin homing T lymphocytes to the skin.[15] This theory is supported by increased dendritic cell such as antigen-presenting cell (APC) ligands B7 and CD40 and their costimulatory ligands CD28 and CD40L in MF lesions.[14] Other studies show elevated Toll-like receptor (TLR) expression by keratinocytes and expression of human leukocyte antigen class II alleles in patients with MF.[16] Stimulation from *Staphylococcus aureus* enterotoxins may contribute to MF. Studies have found high rates of colonization of the bacteria in erythrodermic patients with MF and SS and improvement in their disease with treatment of infection.[17] Viral etiologies such as Epstein-Barr virus (EBV) and cytomegalovirus (CMV) have been investigated.[18,19] Patients receiving immunosuppressive treatment or in immunocompromised state has been reported to be vulnerable to development of cutaneous lymphoma and have a more aggressive course.[20–24]

Several genetic alterations have been linked to MF, including dysregulation in the nuclear factor κ light chain enhancer of activated B-cells (NF-κB) as well as aberrant gene methylation and histone deacetylation.[25,26] Alterations in p16 and p53 tumor suppressor genes have also been associated with MF tumors.[27,28]

MF can be associated with a composite lymphoma where a second unrelated lymphoma can occur concurrently.[29–32] An increased risk for other cancers has also been linked to MF, which can precede, appear concurrently, or appear subsequent to its diagnosis.[33,34]

Clinical Presentation

Patients are typically adults (median age at diagnosis, ~55–60 years), but it can occur rarely in children.[35,36] They typically present with erythematous patches on the skin, which in some patients progress over years to plaques and tumors. The majority of patients present with early-stage disease with 30% of patients presenting with tumors and erythroderma at diagnosis.[37] The lesions favor a "double-hidden" distribution in non–sun-exposed areas beneath underwear. The patches are often described as finely scaly with "cigarette paper" in appearance because of loss of elastic fibers and atrophy of the epidermis.[3] The plaques are typically dark red in appearance and can have variable amounts of scale. Tumors are often ulcerated and have a variable growth rate. Patients with advanced-stage disease may develop tumors while also having patches and plaques. The stage of disease does not only pertain to the percentage skin involvement but also the lesion type.

Other less common skin findings in patients with MF include unique variants reported in the literature. These include leonine facies, especially in patients with folliculotropic variant of the disease and in SS patients. Alopecia can also be seen in folliculotropic patients.[38] Hypopigmentation on the skin has also been associated with the hypopigmented variant of

MF. Loose floppy skin most prominent in skin folds is associated with granulomatous slack skin variant. Poikiloderma is associated with poikiloderma vasculare et atrophicans.[3,39,40]

Histopathology

The typical aberrant cell in MF is the mature small to medium-sized T lymphocytes. They have a "cerebriform" appearance. There is a hallmark epidermotropic feature with intraepidermal infiltration of these lymphocytes. Clustering of these cells are called Pautrier's microabscesses. The immunophenotype of classic MF is typically characterized by α/β T-helper central memory lymphocytes with CD3+, CD4+, CD8-, CD45Ro+, TIA-1- phenotype.[3] In plaques and tumors, the CD4 to CD8 ratio is greater than 4:1. In many cases, there is loss of CD7 and CD26 on the cell surface.[41] In rare cases, CD8+, CD4-/CD8-, γ/δ, and cytotoxic phenotypes have been reported.[42,43] Detection of monoclonal rearrangement of α/β or γ/δ T-cell receptor (TCR) can be used as a tool to support the diagnosis of MF, which can be challenging in early stages of the disease.[44] A clonal TCR has been reported in 40% to 90% of cases of MF.[14] TCR clonality is most commonly determined using polymerase chain reaction technique, but next-generation sequencing has been found to improve sensitivity in detecting a predominant malignant clone.[45] A scoring system devised by the International Society Cutaneous Lymphoma incorporating clinical, histologic, and molecular biological characteristics to support the diagnosis in early ambiguous cases of MF.[46] (Table 12–4).

In cases in which there are increased large cells exceeding 25% of the infiltrate, MF is considered to have large-cell transformation (LCT) and carries a more aggressive course. In patients with LCT, some can express CD30, which is associated with a better prognosis compared with those who are CD30 negative.[47] LCT should only be considered in a patient with preexisting MF. If no prior disease is known, consideration for alternative diagnosis such as lymphomatoid papulosis or anaplastic large-cell lymphoma should be made.

Variants

There are numerous MF variants reported in the literature. The most common variants include folliculotropic MF, granulomatous slack skin, and hypopigmented MF. Folliculotropic MF is an entity in which the malignant lymphocytes have affinity for the pilosebaceous units. Typically, mucin deposits are also seen, and there is associated follicular mucinosis. Clinically, these patients present with acneiform lesions along with scalp involvement and alopecia. Patients with folliculotropic MF were also found to have increased risk of disease progression and lower overall survival (OS) compared with those with conventional MF (82% vs 91% at 10 years; 41% vs 91% at 15 years).[48] This is likely attributed to decreased response to skin-directed therapy because of disease sanctuary in the follicles.[49]

TABLE 12–4 Algorithm for the Diagnosis of Early Mycosis Fungoides Proposed by the International Society for Cutaneous Lymphoma

Criteria	Scoring System[a]
Clinical basic	2 points for basic plus two additional criteria
Persistent or progressive patches or thin plaques Additional	1 point for basic plus one additional criterion
Non–sun-exposed location Size or shape variation Poikiloderma Histopathologic basic	2 points for basic plus two additional criteria
Superficial lymphoid infiltrate Additional	1 point for basic plus one additional criterion
Epidermotropism without spongiosis Lymphoid atypia Molecular Clonal T-cell receptor gene rearrangement	1 point for clonality
Immunopathologic <50% CD2+, CD3+, and/or CD5+T-cells <10% CD7+T-cells Epidermal/dermal discordance of CD2, CD3, CD5, or CD7	1 point for one or more criteria

[a]A total of 4 points is required for the diagnosis of mycosis fungoides based on any combination of points from the clinical, histopathologic, molecular, and immunopathologic criteria.

Modified with permission from Pimpinelli N, Olsen EA, Santucci M, et al: Defining early mycosis fungoides, *J Am Acad Dermatol* 2005 Dec;53(6):1053-1063.

Granulomatous slack skin is a rare indolent variant of MF in which there are granulomatous T-cell infiltrates in the skin and destruction of elastic fibers, resulting in loose skin folds. Given that the infiltration of malignant cells is typically deep into the dermis and subcutis, localized radiation can be used for local control of the disease. Systemic treatment is needed for advanced-stage disease.[40]

Hypopigmented MF is a unique variant of MF seen in younger patients. The median age of onset is 28 to 35 years with an overall favorable prognosis. This is predominantly a CD8+ phenotype; however, CD4+ variants have been reported. Phototherapy is an effective treatment modality in this variant.[50,51]

Staging

MF is staged using the International Society of Cutaneous Lymphoma (ISCL) and EORTC proposed TNMB system evaluating all compartments of involvement. T refers to tumor and is staged by increasing skin involvement and worsening lesion types (Table 12–5). Patients with tumors and erythroderma are considered to have advanced-stage skin disease. The lymph node stage is determined by N0 to N3 grading corresponding to increasing effacement of the lymph node by the lymphoma cells. The blood staging for patients with MF is similar to that of patients with SS using flow cytometry to evaluate the degree of aberrant cells in the peripheral blood.[12] Using flow cytometry analysis for CD4+/CD7- or CD4+/CD26- cells, the highest B2 stage pertains to those with CD4:CD8 ratio of 10 or greater, CD4+/CD26- of 30% or greater of total lymphocytes or CD4+/CD7- of 40% or greater of total lymphocytes (or ≥1000 aberrant cells).[52] The overall stage can be summarized as stage IA and IB corresponding to skin-limited involvement of less than 10% and 10% or greater of skin patches and plaques, respectively. In patients with tumors on the skin, this relates to stage IIB. Stage III corresponds to erythroderma in the skin defined as more than 80% skin involvement, and stage IV pertains to patients with significant blood and lymph node involvement.

TABLE 12–5 Staging of Mycosis Fungoides and Sézary Syndrome

Stage	T	N	M	B
IA	1	0	0	0 or 1
IB	2	0	0	0 or 1
IIA	1 or 2	1 or 2	0	0 or 1
IIB	3	0–2	0	0 or 1
IIIA	4	0–2	0	0
IIIB	4	0–2	0	1
IVA_1	1–4	0–2	0	2
IVA_2	1–4	3	0	0–2
IVB	1–4	0–3	1	0–2

B, blood; M, metastasis; N, node; T, tumor.

Prognosis

The majority of patients (~70%) present with early-stage disease (stage IA–IIA).[37] In patients with stage IA, similar life expectancy as age, sex, and race-matched control populations are predicted.[53] Patients with plaques have a poorer prognosis than those with patch disease, even in early-stage disease. The degree of skin disease involvement from stage T1 to T4 is associated with decreased OS and progression-free survival with the risk for disease progression at 5 years estimated for T1 disease at 10%, T2 at 22%, T3 at 48%, and T4 at 56%.[54]

Prognostic factors in patients with MF include advanced age at diagnosis, LCT, elevated serum LDH and β2 microglobulin, and folliculotropic disease. Poorer prognosis is also associated with presence of T-cell clonal population in the blood of patients.[55] Other factors considered to pertain to poor prognosis include high Sézary cell count, loss of T-cell markers such as CD5 and CD7, and chromosomal abnormalities in the circulating T-cells.[9,37,54]

The Cutaneous Lymphoma International Prognosis Index (CL-IPI) has been proposed as a prognostic index tool for patients with MF, enabling prediction of OS in early- and late-stage patients. Significant adverse prognostic factors in the early-stage group are male gender, age older than 60 years, presence of plaques, folliculotropic disease, and stage N1/Nx. For the advanced-stage group, adverse prognostic factors are male gender, age older than 60 years, stages B1/B2, N2/N3 and visceral involvement.[56]

Treatment

The goals of treatment for MF are similar to those of other indolent lymphomas in maintaining remission and treating symptoms, but cure of disease is rare. Treatment is guided by patient age and comorbidities, extent and progression rate of skin disease, and involvement of other compartments.[53] Figure 12–4 summarizes the approach to patients with MF separated by stage of disease. In patients with early-stage disease (stage IA to IIA) with skin-limited disease, skin-directed treatment is used frontline. Early aggressive intervention with chemotherapy and radiation for MF has not been shown to improve prognosis compared with topical therapy.[57] Most studies in early-stage disease are retrospective, single-arm studies with few patients, making comparative efficacy challenging.

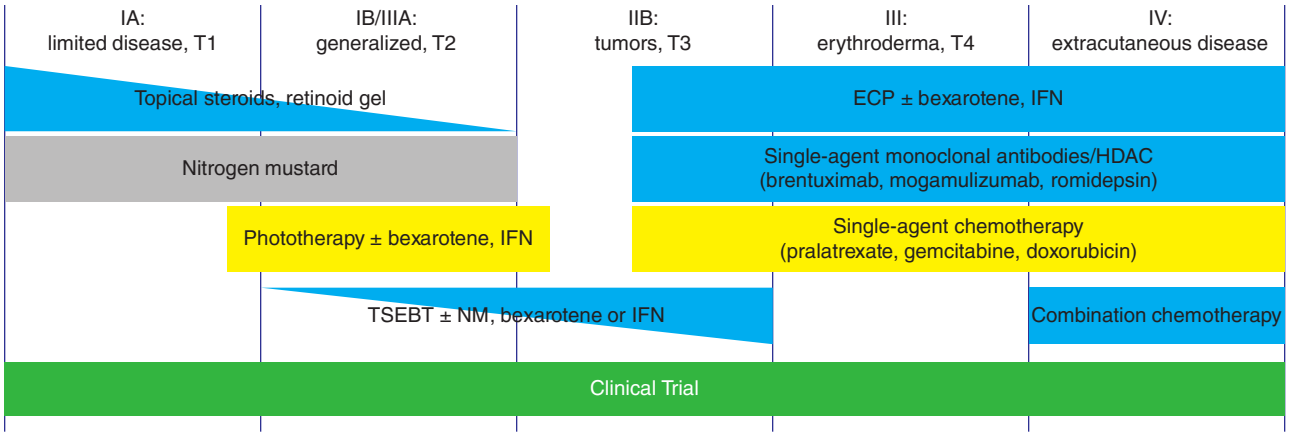

FIGURE 12–4 **Summary of treatment approach in cutaneous T-cell lymphoma. ECP, extracorporeal photopheresis; HDAC, histone deacetylase inhibitor; IFN, interferon; NM, nitrogen mustard; TSEBT, total-skin electron-beam radiation.**

In patients with advanced stages of disease (stage IIB–IVB), the disease is often treatment refractory, and the prognosis is poor. The duration of response for systemic treatment options such as immunotherapy and targeted therapy is relatively short, and in select younger patients, allogeneic stem cell transplantation should be considered when remission is achieved.[58,59] Clinical trials should be considered in patients with relapsed or refractory disease.

Skin-Directed Therapies

Topical Corticosteroids

Topical corticosteroid treatment is often used as frontline treatment in patients with early-stage disease as well as in combination with other treatment modalities.[60] The mechanism of action in cutaneous lymphoma is proposed to be that of apoptosis, interference lymphocyte adhesion to the endothelium, and downregulation of NF-κB with downstream suppression of cytokine and growth factor production.[61,62] Mid- to high-potency steroid creams and ointments have been studied in small series demonstrating effectiveness in the treatment of MF. In a large retrospective review of 163 patients treated with topical corticosteroid monotherapy for MF, 73% of patients responded to treatment with 33% achieving a complete response. Most patients in the study were treated with clobetasol 0.05% cream or ointment along with a lower potency steroid such as hydrocortisone for the skin folds.[63] In a prospective trial of 79 patients treated with mid- to high-potency steroid twice daily for 2 to 3 months, 94% of stage T1 patients and 82% of stage T2 patients achieved a response with complete remission (CR) rate of 63% and 25% in stage T1 and T2, respectively. However, a sustained result for was not maintained upon drug discontinuation. Side effects of topical steroid use include skin atrophy with prolonged use, striae, and possible hypothalamic–pituitary–adrenal axis suppression, which were observed in up to 13% of patients in this study.[64] Additionally, topical steroids also decrease erythema, pruritus, and scale in patients with CTCL.[65] Given the relatively ease of availability of topical steroids, it has become the favored initial treatment modality.

Nitrogen Mustard

Nitrogen mustard (mechlorethamine) is an alkylating chemotherapy agent that directly induces DNA damage to malignant cells. When applied to the skin, an immune-mediated antitumor mechanism or by interruption of Langerhans and epidermal cell interaction has been proposed. A retrospective trial was conducted of 203 patients receiving topical nitrogen mustard as an aqueous solution of 10 to 20 mg/100 mL in an earlier cohort and ointment formulation in similar concentration in a later cohort of patients. Overall response rates (ORRs) and complete response rates were 93% and 65% respectively for T1 stage patients 72% and 34% for stage T2 patients. The median time to complete response was 12 months, and the duration of response was also 12 months, with some patients achieving long-term remission of over 8 years.[66] Nitrogen mustard has been used in the treatment of patients with cutaneous lymphoma for several decades as a compounded medication until the availability of a new gel-based product (Valchlor, mechlorethamine 0.016%), which is commercially available. When evaluated in a multicenter trial in comparison with the ointment formulation, the gel formulation resulted similar response rates of 58.5% versus 47.7% in the ointment formulation. The time to response was superior in the gel formulation, achieving response 16 weeks sooner than the comparator.[67] The main side effects include local skin reactions similar to those seen in an irritant contact dermatitis or allergic contact dermatitis in up to 16% of patients and resulting pruritus, which should be managed by holding the medication

and using topical steroids or antihistamines. There is also reported increased risk for skin cancers in some series.[68,69]

Imiquimod

Imiquimod is a topical imidazoquinolinone immunomodulator with activity as an agonist for the TLR 7 demonstrating antiviral and antitumor effects. When applied topically, the innate immune system is activated inducing production of interferon-α (INF-α) and interleukin (IL)-12 and blocking IL-4 and IL-5.[70] In a small prospective study of six patients, 50% response was observed in patients with MF treated with the 5% imiquimod cream three times weekly for 12 weeks. An initial inflammatory response was observed at the application site only in those responding to treatment and should not be mistaken for disease progression.[71] Other smaller case reports and series have been reported effectiveness of the drug.[72] Application site reaction is the most common adverse effect, with erythema and peeling of skin reported in up to 100% of patients followed by edema, pruritus, and a burning sensation. Flulike symptoms are reported in up to 4% of patients treated with imiquimod. Imiquimod can induce psoriasis or psoriasis-like skin dermatitis in susceptible individuals possibly because of a shift toward the T-helper (Th) 1 pathway and the IL-23 and IL-17 axis and is avoided for CD8+ predominate MF at our institution because of possible risk for worsening disease from stimulation of INFs.[73]

Topical Bexarotene

The topical formulation of bexarotene is a 1% gel also approved for treatment of patients with MF. This topical gel can be applied up to four times daily, but most patients are only able to tolerate twice daily applications due to skin irritation. Patients achieved an ORR of 63% and a clinical complete response rate of 21% and median time to response was 20 weeks.[74]

Phototherapy

Phototherapy is the use of ultraviolet (UV) light for the treatment of cutaneous disorder. Patients are treated at predetermined most effective narrowband wavelength (311 nm) with UVB light and UVA light exposure at 320 to 400 nm. Patients are treated two or three times weekly at increasing time intervals to increase dosing exposure as tolerated to avoid toxicity. Uninvolved sites of the skin are shielded. When remission is achieved, treatment is tapered down or maintained at less frequent intervals. In patients receiving UVA, oral 8-methoxypsoralen is taken 60 to 90 minutes before treatment to sensitize the skin to the UV rays and thus is called PUVA. No sensitizer is needed for narrowband UVB (NB-UVB). PUVA light has been reported to induce tumor apoptosis, suppression of cytokine production, and decreasing Langerhans cells in the skin. Complete response has been reported in up to 71% of patients with early-stage disease, but it is less effective with thicker plaques and tumors. It can be used in combination with other systemic agents such as INF-α or retinoids.[75–77] Side effects associated with PUVA include nausea from the psoralen, erythema, burning, and pruritus, all improve with dose or interval adjustment. Squamous cell carcinomas have been reported in patients treated with PUVA, likely related to cumulative dose.[78]

NB-UVB has been shown to inhibit neoplastic T-cell function and proliferation through APC inhibition and increased production of keratinocyte cytokines. UVB has a shorter wavelength than UVA and therefore does not penetrate the skin as well for thicker lesions. It has greater activity toward skin patches over plaques with one series of 23 patients reporting 100% complete response to treatment for skin patches compared with 60% in patients with plaques. It is an effective modality for treatment of hypopigmented MF.[79] Other studies demonstrate complete response to NB-UVB ranging from 54% to 91%.[80] It is generally well tolerated. Side effects to treatment are related to UV-induced burning, pruritus, and erythema. Cumulative UV-induced skin aging can develop but less than with PUVA. NB-UVB can also be used in combination with retinoids successfully.[81,82]

Radiation

Radiation is one of the most effective treatment modalities for the treatment of patients with MF and other cutaneous lymphomas. Local radiation to tumors and thicker plaques has complete response rates of more than 90%. Typically, using single or two fractions of low-dose radiation (8 Gy) is sufficient to effect complete responses in most patients.[83,84] However, a longer duration of response appears to be associated with higher doses.[85] Total-skin electron-beam therapy (TSEBT) treats the entire surface of the skin radiation and with more penetration than phototherapy. Electrons can be controlled more effectively than photons, which help spare deeper tissues from exposure. TSEBT is typically reserved for patients with skin-limited disease with more significant disease burden involving plaques and tumors. Conventional doses of TSEBT (30–36 Gy delivered over 8–10 weeks) has been reported to have ORRs of 100% and complete response seen in 60% of patients with patches, plaques, and tumors. Higher CR was observed in patients with T2 (patches and plaques; 75%) versus T3 (tumors; 43%).[86] Cumulative toxicity with repeated doses of TSEBT prevent frequent retreatment with this modality. Lower dose TSEBT (10–20 Gy) has been found to be highly effective and results comparable to the conventional doses.[87,88]

Toxicity associated with TSEBT includes erythema, desquamation, xerosis, anhidrosis, skin atrophy or necrosis, alopecia, and nail dystrophy. These effects are dose dependent with significantly fewer side effects associated with low-dose versus conventional doses (5–10 Gy, 16%; 10–20 Gy, 35%; 20–30 Gy, 34%; and >30 Gy, 62%).[88] Risk for radiation dermatitis or recall should be considered in patients receiving radiation-sensitizing medications such as methotrexate, doxorubicin, or gemcitabine.

Systemic Therapies

Retinoids

The retinoids are structural and functional derivatives of vitamin A (retinol). They exert their mechanism of action by control of gene expression, affecting cell proliferation, differentiation, and apoptosis. In the treatment of patients with cancer, retinoids are considered biologic response modifiers, inducing response without immune suppression. In T-cell lymphoma cells, retinoids have been found to induce apoptosis and DNA fragmentation in affected T lymphocytes.[89,90] Several systemic and topical retinoids have been studied for treatment of patients with CTCL. Retinoids bind to two distinct families of nuclear receptors regulating gene expression called retinoic acid receptors (RARs) and retinoic X receptors.[91]

Bexarotene is a synthetic retinoid binding to retinoid X receptor. It is available as an oral capsule and approved for treatment of patients with CTCL in the United States. Patients in the advanced-stage (stage IIB–IVB) group were treated with 300 mg/m^2/day with clinical responses of 45% and 2% complete response.[92] In early-stage patients (stage IA–IIA), responses at 300 mg/m^2/day were ORR of 54% and complete response of 7%.[93] Dose response was observed in the clinical trial with highest response noted in patients receiving more than 300 mg/m^2/day; however, at our institution, most patients are unable to tolerate more than 300 mg/day because of toxicity. Bexarotene has also been studied in small combination trials with systemic chemotherapy, INFs, phototherapy, and radiation and appears to be well tolerated.[94,95]

Unique side effects associated with oral bexarotene include central hypothyroidism and hyperlipidemia occurring in the majority of patients, which should monitored in patients taking the medication. All patients should have baseline thyroid function and lipid panel assessment before starting treatment. All patients are started on an HMG-CoA reductase inhibitor "statin" such as atorvastatin 40 mg/day and levothyroxine 25 to 50 mcg/day at the start of bexarotene treatment. Free serum thyroxine (not thyroid-stimulating hormone) levels should be monitored and used for thyroid supplementation adjustment at follow-up visits. Further adjustments of thyroid and lipid medications should be performed at regular intervals.[91]

Acitretin is a retinoid also evaluated for treatment of patients with CTCL. Unlike bexarotene, it binds to the RAR receptor and therefore has a different side effect profile. In a retrospective review of 32 patients with CTCL, acitretin in varying doses of 10 to 50 mg/day used as monotherapy or combination therapy with second CTCL treatment modality achieved ORR of 59% with one patient achieving CR (although only six patients received treatment as monotherapy). It was noted that many patients who responded to treatment with acitretin also previously responded to treatment with bexarotene. Adverse effects include dyslipidemia, xerosis, alopecia, cheilitis, and depression.[96] In another more recent retrospective review of 128 patients, acitretin alone or in combination with another agent was found to have an 77% ORR with 44% complete responses seen. It was noted that acitretin was more effective as a first-line option compared with use in patients who are more refractory.[97] Isotretinoin, another RAR receptor ligand, has also been studied in patients with CTCL. Dosages ranged from 0.2 to 2 mg/kg/day have demonstrated ORR ranging from 43% to 100%.[91] Its use in patients with CTCL is limited by the burden of the iPLEDGE program's monthly laboratory surveillance requirements to have access to the medications.

Overall, all retinoids appear to have activity in CTCL, but no direct comparative trial has established a definite superior agent in this patient population. A limiting factor for use of this class of medications in younger patients is that significant precaution must be taken to prevent pregnancy while patients are taking these medications to avoid birth defects. At our institution, this class of medications is used in patients progressing through topical therapy, in those with diffuse distribution of cutaneous disease limiting topical application of medications, or for maintenance of response after radiation or chemotherapy in patients with more advanced-stage disease.

Interferons

INF-α and INF-γ are two types of INFs used in the treatment of patients with CTCL. In the human body, INFs are peptides produced by the innate immune system with antiviral and antitumor properties. The malignant T-cells in CTCL are typically skin-homing T-cells releasing IL-4, IL-5, and IL-10 cytokines, along the T-helper 2 (Th2) phenotype. It is observed that this shift toward Th2 activity propagated by the tumor cells allows for immune suppression and blocking of the antitumor response in patients with CTCL. IFN-α and -γ augment CD8+ T-cells and natural killer (NK) cells and suppresses the Th2 activity incited by

lymphoma cells.[98] In patients with CTCL, IFN-α-2b has been studied at varying doses ranging from 2 million units three times per week to 18 million units per day. ORRs noted ranged from 20% to 80% with 0% to up to 67% complete responses noted.[99] Although higher doses have been reported in the literature, IFN-α-2b is typically dosed as 3 to 6 million units given subcutaneously three times per week with titration per tolerance. In a prospectively enrolled study evaluating low (3 million units) versus high (dose escalation up to 36 million units) intramuscular injections of INF-α daily for 10 weeks, several patients in the high-dose arm required dose reduction because of toxicity.[100] A pegylated version of IFN-α-2b is commercially available and allows for weekly dosing. Evidence suggests the pegylated formulation is also effective in patients with CTCL.[98,101] Side effects associated with IFN-α-2b include flulike symptoms (fever, fatigue, chills, myalgias) in the majority of patients. Other adverse effects include anorexia, weight loss, depression, cough, and hair loss.[100]

IFN-γ's activity in T-cell lymphoma is less well understood. Fewer studies have been performed for treatment of patients with CTCL. INF-γ was studied in a phase II prospective trial with 16 patients reporting objective partial response in 31% of patients.[102] In another study from Japan, 15 patients with MF were treated with INF-γ at 2 million units daily for 5 days for 4 weeks. The ORR was 60% with a durable disease response. The median duration of response was not reached at 170 days. The drug was overall well tolerated, and flulike illness was the main adverse effect.[103] Although not formally compared, it is the author's impression that INF-γ appears to be better tolerated than INF-α and may be considered in patients who are intolerant to the α type.

At our institution, nonpegylated INF-α is typically started at lower dosages of 1.5 to 3 million units three times weekly and increased to 6 million units as tolerated. The medication is self-injected at night by the patient with acetaminophen as premedication to attenuate the flulike symptoms associated with the drug. These symptoms typically decrease in severity over time. Patients should have monitoring of the CBC and liver function tests, holding the drug if moderate or severe abnormalities occur. INF-γ is typically given at 50 to 100 μg/m^2 three times weekly. These medications should be used with caution in patients with preexisting autoimmune, mood, or cardiovascular disorders.[98]

Brentuximab Vedotin

Brentuximab vedotin (BV) is an anti-CD30 conjugate monoclonal antibody linked to a toxin monomethyl auristatin E (MMAE). The antitumor effect of the drug is assumed to be targeting CD30 and bringing the MMAE toxin to the malignant cells; however, diffusion of the toxin to the surrounding supportive microenvironment may also play a role in its mechanism of action.[104] The drug was investigated for use in CTCL in a large, randomized, phase III trial of 131 patients comparing BV with physician choice of methotrexate or bexarotene. For treatment of patients with MF, the ORR was 65% with 10% achieving complete response in the BV-treated arm compared with 16% in the bexarotene or methotrexate arm. When combined with all patients in the study, which includes patients with primary cutaneous anaplastic large-cell lymphoma (pcALCL), ORR was 67% compared with 20% in the comparator arm. BV appears to have comparable, if not higher, activity in patients with advanced-stage disease compared with early-stage patients. In the phase III trial, ORR was 69% in the advanced-stage group compared to 53% in the early-stage group. Patients qualified for the trial if their skin biopsies had at least 10% of tumor cells expressing CD3≈0.[105] Two additional phase II open-label studies also demonstrate similar activity in CTCL patients but, unlike the phase III trial, accepted patients with lower CD30 expression[106,107] (Table 12–6). Based on findings of these two studies, it is unclear if any presence of CD30 expression or

TABLE 12–6 Summary of Clinical Trials of Brentuximab Vedotin in Patients with Mycosis Fungoides and Sézary Syndrome

Reference	Phase	Trial Design	Evaluable Patients (n)	CD30 Eligibility	ORR	CR
Duvic et al (2015)	II	Open label, single center	28	CD30+ (no lower limit but expression graded)	15 (54%)	2 (7%)
Kim et al (2015)	II	Open label, investigator initiated, multicenter	30	Negligible to 100% CD30 expression levels	21 (70%)	1 (3%)
Prince et al (2017)	III	Randomized open label, multicenter, international	48	CD30+ (10% tumor cells expressing CD30)	31 (65%)	5 (10%)

CR, complete remission; ORR, overall response rate.
Data from reference 105, 106, 107.

higher expression translates to an increase in BV activity. Anecdotal report of BV activity in a CD30-negative MF patient has been reported.[108]

The dose-limiting toxicity for BV is peripheral sensory neuropathy, which was found in 45% of patients with 5% developing severe grade 3 neuropathy. Other less common side effects include nausea (36%), diarrhea (29%), fatigue (29%), vomiting (17%), alopecia (15%), and pyrexia (17%). Rash was also noted in 11% of patients.[105] Patients should be monitored closely for signs of peripheral neuropathy, and dose modification or suspension should be considered. Lower dose (<1.8 mg/kg) or alternate interval (dosing as needed) strategies have been proposed to improve tolerability of BV in patients with CTCL but have not yet been validated in trials.[109]

Mogamulizumab

Mogamulizumab is a humanized monoclonal antibody against chemokine receptor type 4 (CCR4) approved in the United States for patients with relapsed or refractory MF or SS after at least one prior systemic therapy. The cytokine CCR4 is normally involved in the trafficking of T-cells to the skin.[110] It is expressed by multiple subtypes of malignant T-cells and are most notably found in adult T-cell leukemia/lymphoma. It is also expressed in CTCL and other peripheral T-cell lymphomas, especially in advanced-stage disease with blood involvement.[111] The drug was evaluated in a randomized phase III trial comparing the drug with vorinostat in 372 patients with MF and SS. Mogamulizumab was associated with 28% ORR compared with 5% in the vorinostat arm. Notably, the best response was in the blood compartment, where the response was 68% in the mogamulizumab arm compared with 19% in patients treated with vorinostat. Skin response of 42% was also superior in the mogamulizumab arm compared with 16% for vorinostat.[112]

Mogamulizumab is generally well tolerated with mild infusion-related reaction as the most common toxicity. The drug has also been associated with causing a drug eruption, reported in 20% of patients, which can be confused with disease progression, especially in patients with erythroderma.[113,114] Skin biopsy should be performed in patients who appear to have skin progression despite improvement in other compartments or who initially have response to the drug but develop a flare to help rule out drug hypersensitivity. In patients who have CD4+ CTCL, the presence of significant numbers of CD8+ T-cells in the skin biopsy may suggest reactive dermatitis rather than lymphoma progression. Most drug hypersensitivity associated with mogamulizumab can be managed with topical steroids and holding the drug. After improvement, many patients can tolerate restarting the medication. Photosensitivity has also been reported in the literature related to the drug. Mogamulizumab treatment before allogeneic transplantation has also been associated with increased risk for graft-versus-host disease.[115]

Histone Deacetylase Inhibitors

Two histone deacetylase (HDAC) inhibitors, romidepsin and vorinostat, are approved for the treatment of patients with CTCL. HDACs are enzymes that regulate the cell cycle, apoptosis, and protein folding through acetylation and deacetylation. The equilibrium of this process is dysregulated in cancer cells.[116,117] HDAC inhibitors are small molecules that prevent removal of acetyl groups, blocking the effects of HDACs. HDACs are also implicated in oncogenic pathways by upregulation of signal transducer and activator of transcription (STAT) family of proteins, which has been implicated in the pathogenesis of CTCL and T-cell proliferation.[118] Notably, STAT 5 is important for expression of antiapoptotic proteins such as bcl-2, cell cycle genes such as cyclin-D and c-myc, and oncogenic miR-155 microRNA. STAT 6 is associated with Th2 phenotype seen in CTCL. HDAC inhibitors upregulate STAT 4, which promotes Th1 and suppresses STAT 6, restoring the imbalance.[116]

Vorinostat is an oral HDAC inhibitor that has been shown to have activity in CTCL. ORRs of 30% was noted in a phase IIb multicenter trial. Despite achieving response, the median time to progression was only 4.9 months, which is quite brief. Patients report significant gastrointestinal (GI) toxicity when taking this medication with almost half of treated patients experiencing nausea and diarrhea. Other adverse effects include fatigue (46%) and anorexia (26%). Of note, pulmonary embolism was observed in 5% of patients.[119] The drug was quite effective in improving pruritus in 32% of patients and is often used in lower doses at our institution for this purpose.

Romidepsin is given as an intravenous infusion. In a large phase II trial in patients with CTCL, romidepsin at 14 mg/m^2 weekly for 3 weeks of a 4-week cycle demonstrated an ORR of 34% with 4 of 71 patients achieving complete responses. Unlike vorinostat, the median duration of response was longer at 13.7 months.[120] Romidepsin has been reported to have activity in tumor-stage MF and its folliculotropic variant with 45% and 60% ORR observed in the respective patient groups in a phase II trial.[121] In a second phase II trial, 96 patients were treated, resulting in similar response of 34% and median duration of response of 15 months. Time to response of 8 weeks is also relatively faster than other treatment options.[122] Adverse effects appear similar to those of vorinostat, which include GI symptoms of nausea and vomiting, anorexia, and diarrhea as most common. Fatigue is also a commonly reported side effect of the drug seen in almost 50% of patients. In our institution, romidepsin is considered in patients

with advanced-stage CTCL with blood involvement or tumor-stage disease.

Alemtuzumab

Alemtuzumab is a monoclonal antibody targeting CD52 on the surface of lymphocytes. This depletes the peripheral blood of T- and B-cells, including malignant T-cells.[123] It is effective in patients with MF with blood involvement and in patients with SS. ORRs range from 38% to 100%.[124–126] Low-dose alemtuzumab is also found to be efficacious in patients with CTCL at 10 mg subcutaneously three times per week.[127] The treatment is associated with significant immunosuppression, which requires prophylaxis for opportunistic infections.[128,129]

Chemotherapy

In patients with CTCL, chemotherapy agents are typically reserved for those with aggressive systemic involvement of disease or when other options for treatment are exhausted. As previously mentioned, early aggressive intervention with chemotherapy and radiation for MF has not been shown to improve prognosis when compared with topical therapy.[57] Moreover, chemotherapy has a shorter time to next treatment compared with single-drug treatment with INF-α or HDAC inhibitors. The median time to next treatment for single or multiagent chemotherapy is only 3.9 months, and it can be associated with more toxicity.[58]

Antimetabolites

Methotrexate and pralatrexate are competitive dihydrofolate reductase inhibitors that are cell cycle S–specific chemotherapeutic agents. They exert anti-inflammatory and antitumor effects by blocking the metabolism of folic acid. Recently, methotrexate has been found to block protein and DNA methylation, resulting in control of gene regulation through this mechanism. Increase in Fas death receptor protein expression has also been noted in patients treated with methotrexate.[130]

Oral methotrexate at doses up to 100 mg per week have been reported for treatment of patients with CTCL. Clinical practice is closer to 25 mg per week.[130] Most studies evaluating the use of methotrexate in CTCL are small, and the response criteria are not well defined. One retrospective study of 29 patients report an ORR of 58% in patients with erythrodermic MF with 41% achieving CR.[131] In another review of 69 patients, 33% ORR was seen in patients with plaque MF.[132] Surprisingly, a much lower response was noted in the phase III ALCANZA trial when methotrexate (or bexarotene) was used as a comparator to BV in CD30 positive CTCL patients.[105] Patients receiving low-dose oral methotrexate do not typically require leucovorin rescue at the low doses used, but our practice has been to give patients folic acid on the days of the week they are not receiving methotrexate. Adverse reactions to methotrexate include infections, liver enzyme abnormality, nausea, dyslipidemia, and myelosuppression.[133]

Pralatrexate is a more potent antimetabolite than methotrexate with higher affinity for dihydrofolate reductase.[130,134] In patients with CTCL, lower doses of pralatrexate weekly for 3 weeks in a 4 week cycle was found to be the optimal dose between tolerability and efficacy. At this dose level, the ORR was 45% with two patients achieving complete responses.[135] All patients should receive vitamin B_{12} and folate supplementation while on treatment. In some patients, the addition of leucovorin greatly reduced the incidence of mucositis when treated with pralatrexate.[136]

Gemcitabine

Gemcitabine is a pyrimidine analog that incorporates into DNA causing disruption of DNA replication. In a phase II prospective study of gemcitabine in 30 previous treated patients with MF and 14 patients with peripheral T-cell lymphoma, an ORR of 70% was observed with 11% achieving complete response.[137] Specific to CTCL, gemcitabine at 1000 mg/m^2 as monotherapy achieved an ORR of 68% in 25 patients. Eight percent of patients achieved complete responses.[138] The most common adverse effect of gemcitabine is myelosuppression, which is seen in 56% of patients. Gemcitabine was found to have an ORR of 75% as frontline therapy for patients with CTCL, but the median duration of response was only 10 months.[139] Increase hepatitis transaminases, fatigue, radiation recall, and mucositis was also reported.[138]

Pegylated Liposomal Doxorubicin

Pegylated liposomal doxorubicin is a different formulation of doxorubicin in which the drug is encapsulated in liposomes and stabilized by the attachment of polyethylene glycol to the liposomal surface, resulting in improved accumulation in tumor tissues. In a phase II trial in patients with advanced-stage MF, a 41% ORR was observed. Significant side effects include hand–foot reaction and other skin reactions, hypersensitivity reaction, and GI toxicity.[140] Other studies demonstrating response rates of 56% to 88% have been reported in other trials.[141–143]

Combination Chemotherapy

Combination chemotherapy with CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) or CHOP-based treatments for CTCL was found to have ORR of 40% with 25% complete response, but the median duration of response is only 5.7 months and with more toxicity.[144]

Other Modalities

Extracorporeal Photopheresis

Extracorporeal photopheresis (ECP) was developed when patients with CTCL were treated with leukapheresis and their blood was treated with PUVA. In early investigative research, evidence of anti-idiotypic response to malignant TCRs were discovered when these cells were exposed to UVA light and 8-methoxsalen, a photosensitizer. Patients receiving ECP first undergo leukapheresis; then the buffy coat is treated with methoxsalen photosensitizer and irradiated with UVA (320- to 400-nm wavelength). The mechanism of action was initially considered to be due to DNA crosslinking and apoptosis. However, upon reinfusion of the treated and likely apoptotic cells, there was conversion of circulating monocytes to immature dendritic cells, presentation of tumor-loaded dendritic cells to cytotoxic T-cells, and expansion of the cytotoxic T-cells against the malignant clone.[145–147] ECP is established as a frontline treatment of patients with blood involvement of CTCL.[145] In a meta-analysis, ECP was found to have a response rate of 55% and CR rate of 18% with higher response seen in patients with lower disease burden.[145,146] Multimodality treatment using ECP in combination with other immunomodulatory treatments may enhance its effects.[148]

Stem Cell Transplantation

Hematopoietic allogeneic stem cell transplantation may induce durable remission in patients with advanced CTCL likely because of the donor T-cell and NK cell graft-versus-tumor effect. Long-term response durations of more than 5 years have been reported after transplant; however, transplant-associated toxicity and mortality can occur in up to 30% of patients because of infections and graft-versus-host disease.[59,149,150] Lower intensity nonmyeloablative conditioning regimens may be associated with less toxicity and still maintain graft-versus-tumor response.[151] In comparison, autologous transplantation is associated with frequent and early relapses.[152]

PAGETOID RETICULOSIS

Sometimes also referred to as Woringer-Kolopp disease, this indolent form of CTCL presents as localized psoriasiform plaques, usually in the extremities, favoring the acral sites. The lesions may clinically be mistaken for warts or other benign lesions of the skin. Histopathologic features include epidermal hyperplasia and typically CD8+ cytotoxic neoplastic cells with marked exocytosis of cells in the epidermis. A CD4- and CD8- case has also been reported in the literature without poor prognosis observed.[153] It is important to differentiate this condition with more aggressive cytotoxic NK or T-cell lymphomas of the skin by history. Treatment is primarily radiation or excision because superficial treatment modalities are insufficient for controlling the deeper extension of the disease in the skin.[3] Successful treatment with phototherapy in combination with INF-α-2b has been reported.[154]

CD30 LYMPHOPROLIFERATIVE DISORDERS

Lymphomatoid papulosis (LyP) and primary cutaneous anaplastic large-cell lymphoma (pcALCL) are two entities on the spectrum of CD30 lymphoproliferative disorders that are associated with good prognoses.[155] On one end of the spectrum is LyP, which are clinically small (<1 cm), red, grouped papules or nodules that spontaneously resolve within 1 to 2 months. This condition is considered to be benign, but in 10% to 20% of patients, it can appear along with another type of lymphoma, most commonly in MF. It is also reported in patients with other hematologic malignancies such as Hodgkin lymphoma or pcALCL.[156,157] Although clinically similar, histopathologic features can be divided into five main subtypes, all with CD30 as prominent feature. Type A is the "conventional" and most common type; it is described as a wedge-shaped infiltrate with large atypical anaplastic cells admixed with histiocytes, eosinophils, and neutrophils. Type B is MF-like and resembles a wedge-shaped infiltrate with CD4+ bandlike epidermotropic cells. Type C is indistinguishable from pcALCL by histopathologic features alone and diagnosis is made by correlation with clinical history. Type D is similar to aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma. Epidermotropism is very prominent as is CD8 and CD30 positivity, but the clinical course is indolent like other LyPs. Type E has angiocentric or angiodestructive features and may be mistaken for vasculitis or NK T-cell lymphoma. Lesions can be monitored for resolution. In patients with widespread involvement, improvement has been reported with phototherapy, methotrexate, or bexarotene.[158–160] More recently, treatment with BV is associated with high response rates.[161]

Primary cutaneous ALCL is often histologically indistinguishable from LyP. Unlike systemic ALCL, pcALCL does not express anaplastic lymphoma kinase and if positive suggests a secondary ALCL in the skin. This condition typically presents as single ulcerated tumor or cluster of tumors. In contrast to LyP, there is rarely spontaneous resolution, but the prognosis is good with the estimated 5-year survival rate at more than 90%.[155] Frontline treatment

for localized disease is radiation. For more extensive disease, systemic treatment with BV has demonstrated superiority over methotrexate or bexarotene in the recent ALCANZA study. Overall response for pcALCL in the BV arm was 75% compared with 33% in the comparator arm.[105]

CD4 SMALL-MEDIUM PLEOMORPHIC LYMPHOPROLIFERATIVE DISORDER

CD4 small-medium pleomorphic lymphoproliferative disorder is an indolent condition previously listed as "CD4 small-medium pleomorphic lymphoma" but downgraded to lymphoproliferative disorder in 2016 by the WHO. It manifests clinically as a solitary lesion on the upper body, face, or neck without systemic involvement. Histologic features include CD4+ lymphocytes with αβ phenotype and absence of CD30 and background of reactive cells. These patients are successfully treated with radiation or surgery. Radiation may be preferred in some sites to avoid excessive scarring from surgery.[162,163]

SÉZARY SYNDROME

SS is a leukemic variant of CTCL in which patients present with new-onset erythroderma, lymphadenopathy, and aberrant cells in the peripheral blood compartment. Unlike patients with erythrodermic MF who progressively develop worsening blood involvement at advanced stages of disease, patients with SS typically do not report a history MF-like lesions preceding the diagnosis. Histopathologic findings on skin biopsy can be nondiagnostic in 30% of patients with known erythrodermic CTCL, and the diagnosis is made by flow cytometry analysis of peripheral blood.[164] A matching T-cell clone in the skin and blood compartment helps support the diagnosis in ambiguous cases. SS is associated with a poor prognosis and aggressive disease course with 5-year survival rate estimated to be 36% in the updated 2018 WHO-EORTC classification of cutaneous lymphomas.[2] Genetic variation in *CDKN2A* and *CDKN2B* genes have been linked to shorter survival periods in patients with SS.[165] The expression of FOX-P3 by SS cells has also been associated with a poor prognosis.[166] Unique clinical features of this variant include hyperkeratosis of the palms and soles, nail dystrophy, and ectropion.

Treatment of patients with SS is similar to the management of patients with advanced-stage MF with blood compartment involvement. Frontline treatment incorporating the use of ECP in the setting of multimodality therapy in combination with retinoid or INF produces high overall responses of 75% with a 30% complete response.[167] Mogamulizumab can also be considered in this group of patients given its high blood compartment response of 68% in the MAVORIC trial.[112] Supportive care is crucial in the care of patients with SS because of the high risk for skin infections and severe pruritus associated with the disease. See the Supportive Care section for review.

γδ T-CELL LYMPHOMA

γδ T-cell Lymphoma (GDTCL) is a rare aggressive primary cutaneous lymphoma presenting as fast-growing nodules and tumors with ulceration. Unlike MF tumors, in which there is a preceding history of lesions that have been present for years, lesions in GDTCL typically develop over weeks to months. The median survival associated time with this condition is 15 months, and it carries a poor response to conventional chemotherapy.[2] Histologic features include CD4-CD8- double-negative phenotype with strong expression of cytotoxic markers granzyme B and TIA-1.[168] Treatment with combination chemotherapy is typically used, but there are insufficient data to dictate a preferred course of management.

A subset of patients demonstrating γδ TCR staining but behaving in a more indolent fashion has also been reported. In one series, average survival from onset of symptoms was 7.3 years. A proposed hypothesis is that expression of CD4, CD30, or βF1 in some of the cases was associated with good prognosis.[169]

PRIMARY CUTANEOUS CD8+ CYTOTOXIC AGGRESSIVE EPIDERMOTROPIC T-CELL LYMPHOMA

Primary cutaneous CD8+ cytotoxic aggressive epidermotropic T-cell lymphoma is a rare cutaneous lymphoma with a poor prognosis; median OS was 12 months with 5-year OS of 32% in one series.[170] Histologic features include CD8+ lymphocyte full-thickness exocytosis into the epidermis in pagetoid pattern. Expression of at least one cytotoxic marker (TIA-1) and granzyme B was noted in almost all biopsies. Clinically, patients present with plaques on the skin with ulceration related to the cytotoxic granules released by the malignant cells. Treatment with standard CTCL treatment is ineffective in most cases, and the scarceness of data on this entity prevents the development of treatment recommendations and management guidelines.

SUBCUTANEOUS PANNICULITIS T-CELL LYMPHOMA

Subcutaneous panniculitis T-cell lymphoma (SPTCL) is a rare form of CTCL presenting as deep painful inflammatory nodules, resulting in atrophic plaques in involved sites. There is usually no surface change to the skin. The median age at diagnosis is in the third or fourth decade of life, occurring in younger female patients. The αβ subtype has an indolent course presenting histologically as a lobular lymphocytic panniculitis with tumor cells rimming around the fat lobules. The malignant lymphocyte is typically CD4-, CD8+, βF1 + and expresses cytotoxic granules. A history of autoimmune disorder was found in 25% of patients, with the most common being systemic lupus erythematosus. Because lupus panniculitis also presents as a lobular panniculitis and difficult to distinguish from SPTCL, patients should be screened for lupus at diagnosis.[171] Patients who develop hemophagocytic lymphohistiocytosis with this condition have a poorer prognosis. A more aggressive course is also seen patients with the γδ phenotype.[172] A variety of treatment options have been reported benefit, but corticosteroids with immunosuppressive therapy are frequently used as the initial treatment. The 5-year disease-specific survival rate is about 85%.[173]

PRIMARY CUTANEOUS B-CELL LYMPHOMAS

Primary Cutaneous Marginal Zone Lymphoma and Primary Cutaneous Follicle Center Lymphoma

The cutaneous B-cell lymphomas are less common than their T-cell counterparts. We will discuss the three most common types in this review. Because they are so rare, all patients should be screened for systemic B-cell lymphoma. Primary cutaneous marginal zone lymphoma (pcMZL) and primary cutaneous follicle center lymphoma (pcFCL) are both indolent subtypes of B-cell lymphoma in the skin associated with an excellent prognosis. The 5-year disease-specific survival rates are 99% for pcMZL and 95% for pcFCL.[2] PcFCL presents as reddish-brown papules and nodules with preference for the head and neck. Histologic features include nodular or diffuse infiltrates of lymphocytes, which are CD20+, Bcl-6 +, with monoclonal rearrangement of Ig genes detected. In contrast, pcMZL prefers the trunk and upper extremities. Histologic features include patch, nodular, or diffuse lymphocytic infiltrates without germinal centers with central nodular dark area of small reactive lymphocytes. The immunohistochemistry profile is CD20+, Bcl-2 +, CD5-, and Bcl-6 -.[3] Monoclonal Ig genes are present in only half of cases. In patients with the lymphoplasmacytic variant of pcMZL, association with *Borrelia burgdorferi* has been reported and should be screened.[174] Although no definitive link has been established between other infections such as *Helicobacter pylori*, hepatitis C virus, or Epstein-Barr virus, we screen all patients to rule out treatable infections. Treatment for pcMZL and pcFCL is similar and entails low-dose radiation, intralesional corticosteroids, intralesional INF, or rituximab. Systemic rituximab or chemotherapy is reserved for widespread or progressive systemic involvement.

Diffuse Large B-Cell Lymphoma, Leg Type

Primary cutaneous diffuse large B-cell lymphoma, leg type (PCDLBL-LT), is a rare entity of primary cutaneous B-cell lymphoma with more aggressive course, resulting in a relatively lower 5-year disease-specific survival rate of 56%.[2] Despite the name of the condition, PCDLBL-LT can develop outside of the lower extremities and may be associated with improved survival.[175]A unique histologic feature is the predominance of centroblasts staining MUM-1 + along with CD20+, CD3-, and Bcl-2+.[176] Patients are typically treated with combination chemotherapy and radiation, with one review series demonstrating an improved 2-year survival rate in patients treated with rituximab plus anthracycline-based chemotherapy.[175]

SUPPORTIVE CARE

Pruritus

Pruritus is a cause of significant morbidity in patients with cutaneous lymphoma. In a retrospective analysis, a high prevalence of severe pruritus was found in patients with advanced-stage MF (83%) and SS (94%).[177] In patients with CTCL, multiple cytokines such as IL-4 and IL-5 have been upregulated, consequently leading to recruitment of eosinophils. Eosinophils in the blood can drive skin inflammation and pruritus.[178] More recently, IL-31 has been found to be upregulated in patients with CTCL and to correlate with itch.[179] Patients with CTCL-associated pruritus are best treated with treatment of the underlying lymphoma; however, many patients have treatment-refractory disease or are slow to respond to lymphoma treatment. Although pruritus caused by CTCL does not typically respond to antihistamines, multiple other nontraditional treatments for pruritus can be tried. Gabapentin is an anticonvulsant that dampens the release of neurotransmitters, promoting itch. Doses up to 2400 mg in divided doses daily

can be used.[180] Other options, such as aprepitant, naloxone, mirtazapine, and thalidomide, have been suggested.[178,180] In very pruritic patients, phototherapy may be helpful in select patients.

Infections

Patients with cutaneous lymphoma have decreased natural barrier to infection because of the disease and further breakdown from scratching. In addition, host immunosuppression and decrease in cell-mediated immunity put patients at risk for skin infection and colonization with bacteria and herpes virus.[181–183] *S. aureus* infections are common and can promote worsening of disease.[17,184,185] Treatment of skin infections has been reported to improve disease severity.[181,186]

MD ANDERSON PRACTICE TIPS

- Patients with cutaneous lymphoma should be ideally evaluated by a multidisciplinary team consisting of dermatologists, oncologists, radiation oncologists, and pathologists at a referral center with expertise in the disease.
- Imaging using CT or PET-CT should be performed in patients with thicker plaques, tumors, or erythroderma to rule out systemic involvement of CTCL. No imaging is typically needed for patients with early patch-stage disease unless there are systemic symptoms or rapid progression of disease.
- Peripheral blood flow cytometry should be obtained on all erythrodermic patients to rule out SS. Many patients with SS do not have positive skin biopsy results for lymphoma but rather reactive dermatitis on histopathology.
- In patients with skin-limited indolent cutaneous lymphoma, the frontline treatment is skin-directed therapy. Early aggressive intervention with chemotherapy and radiation for MF has not been shown to improve prognosis compared with topical therapy.
- Mogamulizumab is highly effective for blood compartment disease especially, in patients with SS, but has lower response rates in the skin and lymph node compartments.
- BV may be effective for patients with MF with low expression of CD30.

13 Hodgkin Lymphoma

Collin K. Chin
L. Jeffrey Medeiros
Fredrick B. Hagemeister
Hun J. Lee

KEY CONCEPTS

- Nodular lymphocyte–predominant Hodgkin lymphoma (HL) usually presents in early stages. Therapy depends on disease extent, but localized radiotherapy is the usual choice for early-stage disease. Rituximab is also an effective agent, but it should be given in combination with chemotherapy.
- Staging by positron emission tomography is standard, and marrow biopsy is generally unnecessary. Response after two cycles of therapy is a standard to assess response, and the Lugano (Deauville score) response criteria should be followed. Patients with DS 1 or 2 should be considered as having a metabolic complete response. Those with DS 4 or 5 should be considered to have likely had failure of therapy, and those with persistent positivity after four cycles of therapy are at a high risk of failure. German Hodgkin Lymphoma Study Group criteria and the International Prognostic Score should be calculated for all patients to assess outcomes of therapy.
- Standard of care for favorable early-stage classical HL is two cycles of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) and 20-Gy involved site radiation therapy (ISRT). For unfavorable early-stage disease, it is four cycles of ABVD and 30 Gy ISRT. The ABVD regimen remains the preferred regimen for most patients with advanced disease treated in the United States even though BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) has proven to be a better regimen for unfavorable early-stage and advanced-stage disease. BEACOPP is associated with a higher risk of neutropenia and hospitalization and in the United States is administered to only selected patients.
- Brentuximab vedotin (BV) has been studied as adjuvant therapy for early-stage disease, as a single agent and in combinations for relapsed and refractory disease, as prophylaxis after autologous stem cell transplant (ASCT), and in combinations for initial treatment of classical Hodgkin disease. The drug causes some peripheral neuropathy but is generally tolerable, and the A (BV)-AVD regimen provides better progression-free survival results for most patients with advanced disease than ABVD.
- PD-1 (programmed death-1) inhibitors (nivolumab, pembrolizumab) are also effective single agents for relapsed disease and in combinations improve responses for relapsed and untreated disease even in patients who have previously received BV. The most effective combinations using this and other targets are still under investigation.
- High-dose therapy followed by ASCT remains the standard of care for patients with relapsed HL. However, proof of adequate response, usually by PET and in most patients by biopsy, is necessary before this therapy. Patients with refractory disease should be offered alternate therapies, and novel agents and therapies, including T-cell and other immunotherapy, are under investigation for this small group of patients.

Hodgkin lymphoma (HL) was recognized in the first half of the 19th century by Thomas Hodgkin and Samuel Wilks.[1] HL usually arises in lymph nodes, preferentially in the cervical area, and the majority of HLs manifest clinically in young adults in their third and fourth decades of life. In 2018, 79,990 new cases of the disease were described, and 34,984 persons were reported to have died of the illness worldwide from 185 countries.[2] In a recent report, the incidence of HL was 3.0 per 100,000 person-years in the United States; it is higher in Western countries than in Asian countries.[3] Biological and clinical studies have shown that HLs include two disease entities: nodular lymphocyte–predominant HL (NLPHL) and classical HL (cHL). The two entities differ in their clinical features and behaviors. Within cHL, four subtypes have been described:

nodular sclerosis (NS), mixed cellularity, lymphocyte rich, and lymphocyte depleted. These four subtypes differ in their clinical features, growth pattern, presence of fibrosis, and frequency of Epstein-Barr virus (EBV) infection but share the immunophenotype of tumor cells.

In 2019, it was estimated that 8110 Americans would be diagnosed with HL, and as of January1, 2019, there were 234,890 survivors of the disease.[4] HL has been traditionally defined as a hematopoietic neoplasm composed of diagnostic Hodgkin and Reed-Sternberg (HRS) cells within a reactive cell background. An HRS cell is large, 30 to 60 μm, containing a bilobed vesicular nucleus, with each lobe containing a prominent round eosinophilic nucleolus surrounded by a clear zone or halo; it also has abundant cytoplasm. However, HRS cells often comprise less than 1% of the involved tumor tissue and are absent in NLPHL. HRS cells are believed to be derived from germinal center (GC) B cells that have unfavorable immunoglobulin V gene mutations, whereas lymphocyte-predominant (LP) cells, which were previously termed lymphocytic and histiocytic (LH) cells, are thought to originate from antigen-selected GC B cells.[5]

IMMUNOPHENOTYPIC FINDINGS IN HODGKIN LYMPHOMAS

NLPHL is immunophenotypically distinct from other types of HL. LP cells usually express leukocyte common antigen (LCA; CD45), immunoglobulin J chain, B-cell antigens (CD19, CD20, CD22, CD79A, and BCL-6), and epithelial membrane antigen (EMA) and are negative for CD15 and CD30 (Figs. 13–1C and D). These results suggest that the LP cells are B cells that arise from the GC. LP cells are negative for T-cell antigens but are often surrounded by a rosette of small, reactive T cells that may be positive for pan-T-cell antigens and CD57 (Fig. 13–1E). EBV is almost always absent in the LP cells of NLPHL.

Immunophenotypic findings in classical HL differ from those observed in NLPHL. Overall, the mature B-cell origin of the HRS cells is not readily apparent because HRS cells have a very unusual phenotype and have expression of genes that are seen on many hematopoietic cell types. The neoplastic cells are positive for CD15 and CD30 and negative for LCA (CD45) (Fig. 13–2) and EMA.[1] B-cell antigens, such as CD20, CD79A, PAX-5/BSAP, and MUM1/IRF4, are expressed in a subset of cases. CD20 expression is often weak. T-cell antigens are usually not expressed by the neoplastic cells. BCL-2 is positive in up to half of cases and has been correlated with poorer prognosis.[6] EBV is relatively common in cHL, but its frequency varies greatly among different types.

The management of patients with HL continues to evolve. Before the widespread use of modern polychemotherapy, large-field radiation therapy (RT) was able to cure patients with cHL. However, reliance on radiation alone required extensive radiation portals to treat nearly the entire lymphatic system with radiation doses up to 44 Gy. With long-term follow-up, many patients developed cardiac toxicity and second malignancies. Therefore, efforts have been made to reduce the long-term toxicities of treatment for HL while maintaining excellent cure rates. With modern chemotherapy, multiple randomized studies have shown that radiation portals can be safely reduced from extended-field radiation therapy (EFRT) to involved-field radiation therapy (IFRT) and, now, even smaller fields of radiation, including involved-node radiation.

Currently, the treatment of patients with cHL is stratified by risk groups—early-stage favorable, early-stage unfavorable, and advanced-stage disease—according to the clinical stage and the presence or absence of adverse clinical features. This chapter reviews advances in the management of HL, including recent publications about strategies of management of patients with the rarer diagnosis of NLPHL.

CLINICAL SUBTYPES OF HODGKIN LYMPHOMA

Over the past decade, investigators have made significant progress in the diagnosis, classification, staging, prognosis, and treatment of HL. In past years, the true lineage of the neoplastic cells in HL was unknown; hence, the term *Hodgkin disease* was used. It is now recognized that almost all cases of HL are of B-cell lineage; hence, the name was changed to HL. However, the classification of HL has remained relatively stable over the past 40 years, and the World Health Organization (WHO) classification of lymphoid neoplasms was updated in 2016 (Table 13–1).[1] The current WHO classification recognizes that NLPHL is distinct from the other types that can be grouped together under the rubric of cHL.[1]

Nodular Lymphocyte–Predominant Hodgkin Lymphoma

Clinical Features

Approximately 5% of patients with HL have NLPHL. This disease is usually localized and most often involves cervical or axillary lymph nodes.[1,7] The disease affects patients of all ages, males more often than females, and is clinically indolent (Table 13–2). Systemic symptoms such as fever, weight loss, and nights sweats (also known as B symptoms) are infrequent. Patients with

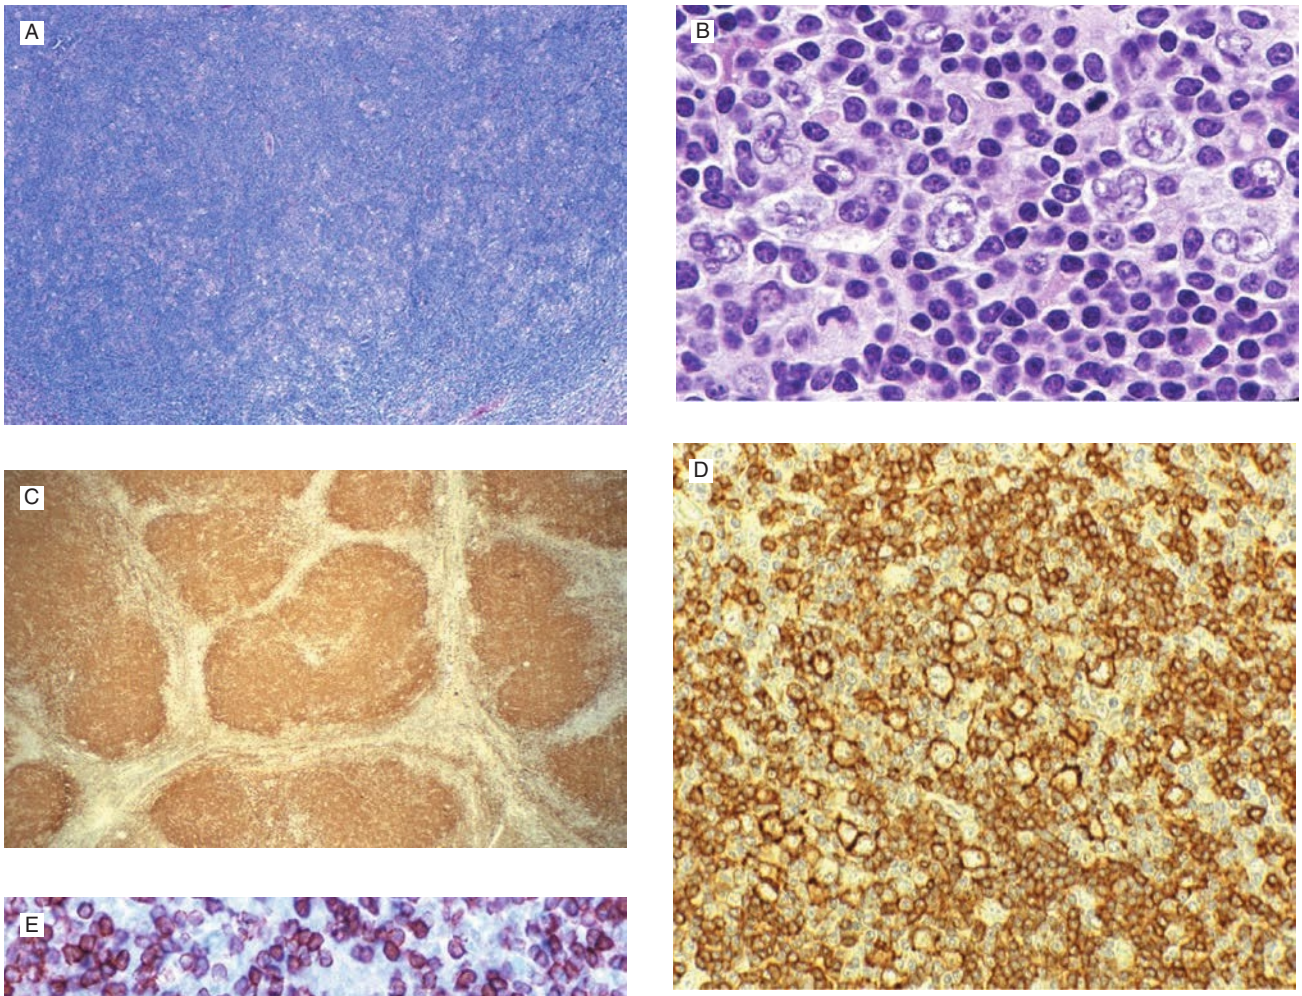

FIGURE 13–1 **Nodular lymphocyte–predominant Hodgkin lymphoma. A. At low-power magnification, the neoplasm is vaguely nodular. B. At high-power magnification, large lymphocytic and histiocytic (LH) cells, resembling popped kernels of corn, are identified in a background of reactive lymphocytes and histiocytes. C and D. Immunohistochemical stain for CD20. C. At low-power magnification, this immunostain highlights the nodular pattern and shows numerous B cells in the nodules. D. At high-power magnification, large LH cells and small reactive B cells are positive for CD20. E. Immunohistochemical stain for CD3. Scattered small reactive T cells are present and focally surround the LH cells (so-called rosetting).**

NLPHL are characterized as having a more indolent course with delayed relapse compared with those with cHL, analogous to low-grade non-HLs.[7] Patients with NLPHL are at a 5% to 6% risk of developing diffuse large B-cell lymphomas (DLBCLs) or T-cell/histiocyte-rich large B-cell lymphomas.[1]

The German Hodgkin Lymphoma Study Group (GHSG) has reported a large retrospective study of 394 patients with NLPHL. Patients were predominantly men (75%), only 9% had B symptoms, and 79% had early-stage disease.[8] With a median follow-up of period 50 months, tumor control (freedom from treatment failure [FFTF]) and overall survival (OS) were 88% and 96%, respectively, slightly better than in cHL (82% and 92%, respectively).

Histologic Features

NLPHL is characterized by effacement of nodal architecture by variably sized, vague nodules composed of numerous small lymphocytes, histiocytes, and characteristic neoplastic LP cells (see Fig. 13–1A).[1,9] These cells are typically large, with pale cytoplasms and polyploid vesicular nuclei containing inconspicuous

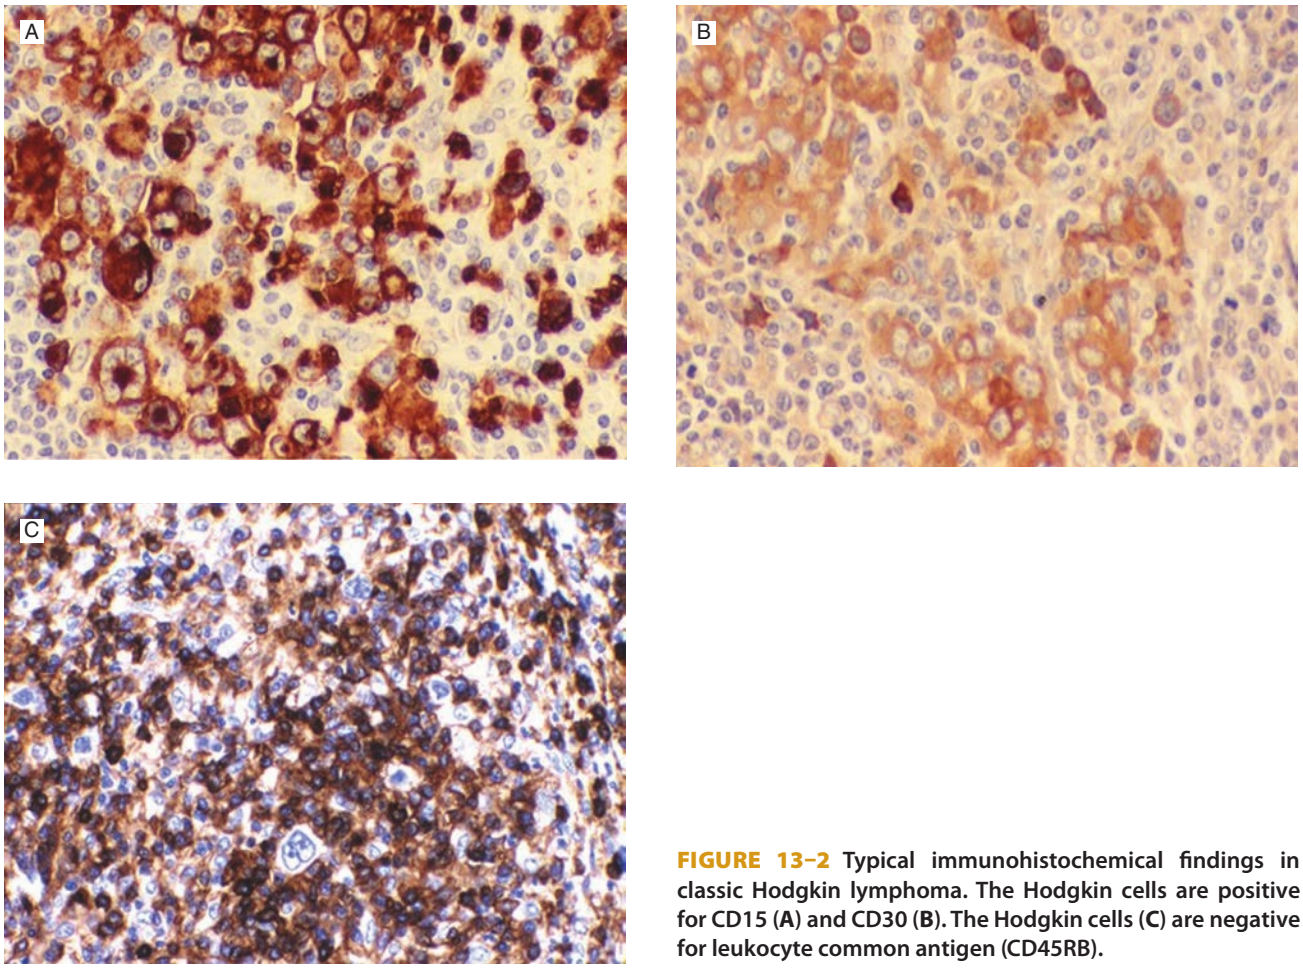

FIGURE 13–2 Typical immunohistochemical findings in classic Hodgkin lymphoma. The Hodgkin cells are positive for CD15 (**A**) and CD30 (**B**). The Hodgkin cells (**C**) are negative for leukocyte common antigen (CD45RB).

nucleoli resembling kernels of popped corn—hence the nickname popcorn cells (see Fig. 13–1B). However, LP cells can exhibit a range of cytologic appearances. These cells can be round or have relatively prominent nucleoli. Eosinophils, neutrophils, and plasma cells are usually absent in NLPHL, and there is no associated necrosis or fibrosis.

Cases of NLPHL can also have diffuse areas. When diffuse areas are large, their presence often correlates with more aggressive disease. To reflect this change in clinical behavior, many pathologists

TABLE 13–2 Comparison of Clinical Features of Nodular Lymphocyte–Predominant (NLPHL) and Classical Hodgkin Lymphoma (HL)

Clinical Feature	NLPHL	Classical HL
Frequency	5%	95%
Age distribution	Unimodal: equal in children and adults	Bimodal: peak in second and third decades of life
Male (%)	70	50
Sites involved	Lymph nodes with sparing mediastinum	Mediastinum, cervical lymph nodes
Stage at diagnosis[a]	I	II or III
B symptoms (%)	<20	40
Clinical course	Indolent, late relapses	Aggressive, curable

[a]Most common stage at time of diagnosis.

diagnose such cases as NLPHL with progression to T-cell/histiocyte-rich large B-cell lymphoma, also described as T-cell–rich B-cell lymphoma (TCRBCL). Other pathologists use the term *NLPHL with large diffuse areas* and suggest that the diffuse areas may represent the beginning stages of progression to DLBCL. The boundary between NLPHL with diffuse areas and TCRBCL remains blurred. Most cases previously designated as diffuse LPHL, as defined previously, are now classified differently.[10] With appropriate workup, these cases are usually classified as NLPHL with large diffuse areas, lymphocyte-rich cHL, or TCRBCL.

Gene expression profiling of NLPHL to determine the origin and pathogenesis of LP cells found significant similarities between NLPHL, TCRBCL, and cHL.[11] Overall, LP cells are thought to derive from antigen-selected GC B cells.[5] LP cells also demonstrate deregulation of numerous apoptosis regulators and putative oncogenes and a partial loss of their B-cell phenotype. In addition, there is constitutive activation of nuclear factor-κB (NF-κB), the Janus kinases/signal transducers and activator of transcription (JAK/STAT) pathway, and aberrant extracellular-regulated kinase signaling.

Lymphocyte-Rich Classical Hodgkin Lymphoma

Lymphocyte-rich cHLs (LRHLs) have been recognized that resemble NLPHL histologically but are cHL immunophenotypically.[1,7] In a study of NLPHL by the European Task Force on Lymphoma, a large number of tumors that had been classified as NLPHL were reviewed; the diagnosis was confirmed in only half of these cases. Most of those excluded were reclassified as LRHL.[9] The frequency of this type of HL is not well known but is most likely low (<5%). Clinically, patients with LRHL have disease that is similar to that seen in patients with other subtypes of cHL or have clinical findings intermediate between NLPHL and cHL. Unlike patients with NLPHL, late relapse is uncommon in patients with LRHL.

Histologically, these tumors are rich in small lymphocytes and histiocytes. Granulocytes and plasma cells are usually infrequent. Necrosis is usually not present. Lymphocyte-rich cHL may be either nodular or diffuse. The nodular type closely resembles NLPHL. Vague nodules of numerous small lymphocytes are present, and the nodules may have a small, compressed GC (Figs. 13–3A and B). The neoplastic cells are present in the mantle zones of the nodules. These neoplastic cells usually resemble Reed-Sternberg and typical mononuclear variant cells (so-called Hodgkin cells) rather than LP cells. The cell composition is similar in diffuse cases of LRHL, but nodularity is minimal or absent. Immunohistochemical studies of LRHL show that the large neoplastic cells have an immunophenotype similar to that of all cHL cases, positive for CD15 and CD30 and negative for LCA (CD45) (Figs. 13–3C–E).

Nodular Sclerosis Hodgkin Lymphoma

Clinical Features

NS is the most common form of cHL, representing 60% to 70% of all cases in Western countries; it is also the most common type of cHL in patients younger than 50 years of age. Whites are affected more often than others, and nodular sclerosis HL (NSHL) is much less frequent in Asian countries.[2,3] The age-adjusted incidence rate of NSHL has been stable since 1993 to 2008 in the United States according to the National Cancer Institute (NCI) Surveillance, Epidemiology, and End Results (SEER) data.[2] The male-to-female ratio is approximately equal. NSHL has a marked predilection for involving mediastinal, supraclavicular, and cervical lymph nodes. A mediastinal mass is very common, and the thymus may be involved.

Histologic Features

NSHL is characterized by a triad of findings: (1) a nodular pattern, (2) broad bands of fibrosis that outline the nodules, and (3) characteristic mononuclear cell variants known as lacunar cells (Fig. 13–4). A lacunar cell has abundant clear cytoplasm with a sharply demarcated cell membrane. In formalin-fixed tissue, a characteristic artifact occurs. The cell cytoplasm retracts, leaving a clear space or lacuna surrounding the cell, hence the origin of the name. The typical lacunar cell has a polylobate nucleus with one or multiple small nucleoli. However, lacunar cells can show great morphologic variability and can be round with prominent nucleoli, or they may resemble large noncleaved cells. A heterogeneous mixture of reactive cells may be seen in HL, including small lymphocytes, histiocytes, eosinophils, neutrophils, and plasma cells in variable numbers.

NSHL has been graded as 1 or 2 by the British National Lymphoma Investigation (BNLI) group according to numbers of neoplastic cells and reactive cells present; this grading system has been adopted in the WHO classification.[1,12] Grade 2 cases of NSHL show numerous neoplastic (lacunar) cells and depletion of reactive lymphocytes. Lymphocyte-depleted and syncytial variants (Fig. 13–5) of NSHL have been described; these cases are the outermost examples of grade 2 NSHL. This syncytial variant of NSHL is composed of sheets of neoplastic cells and necrosis.

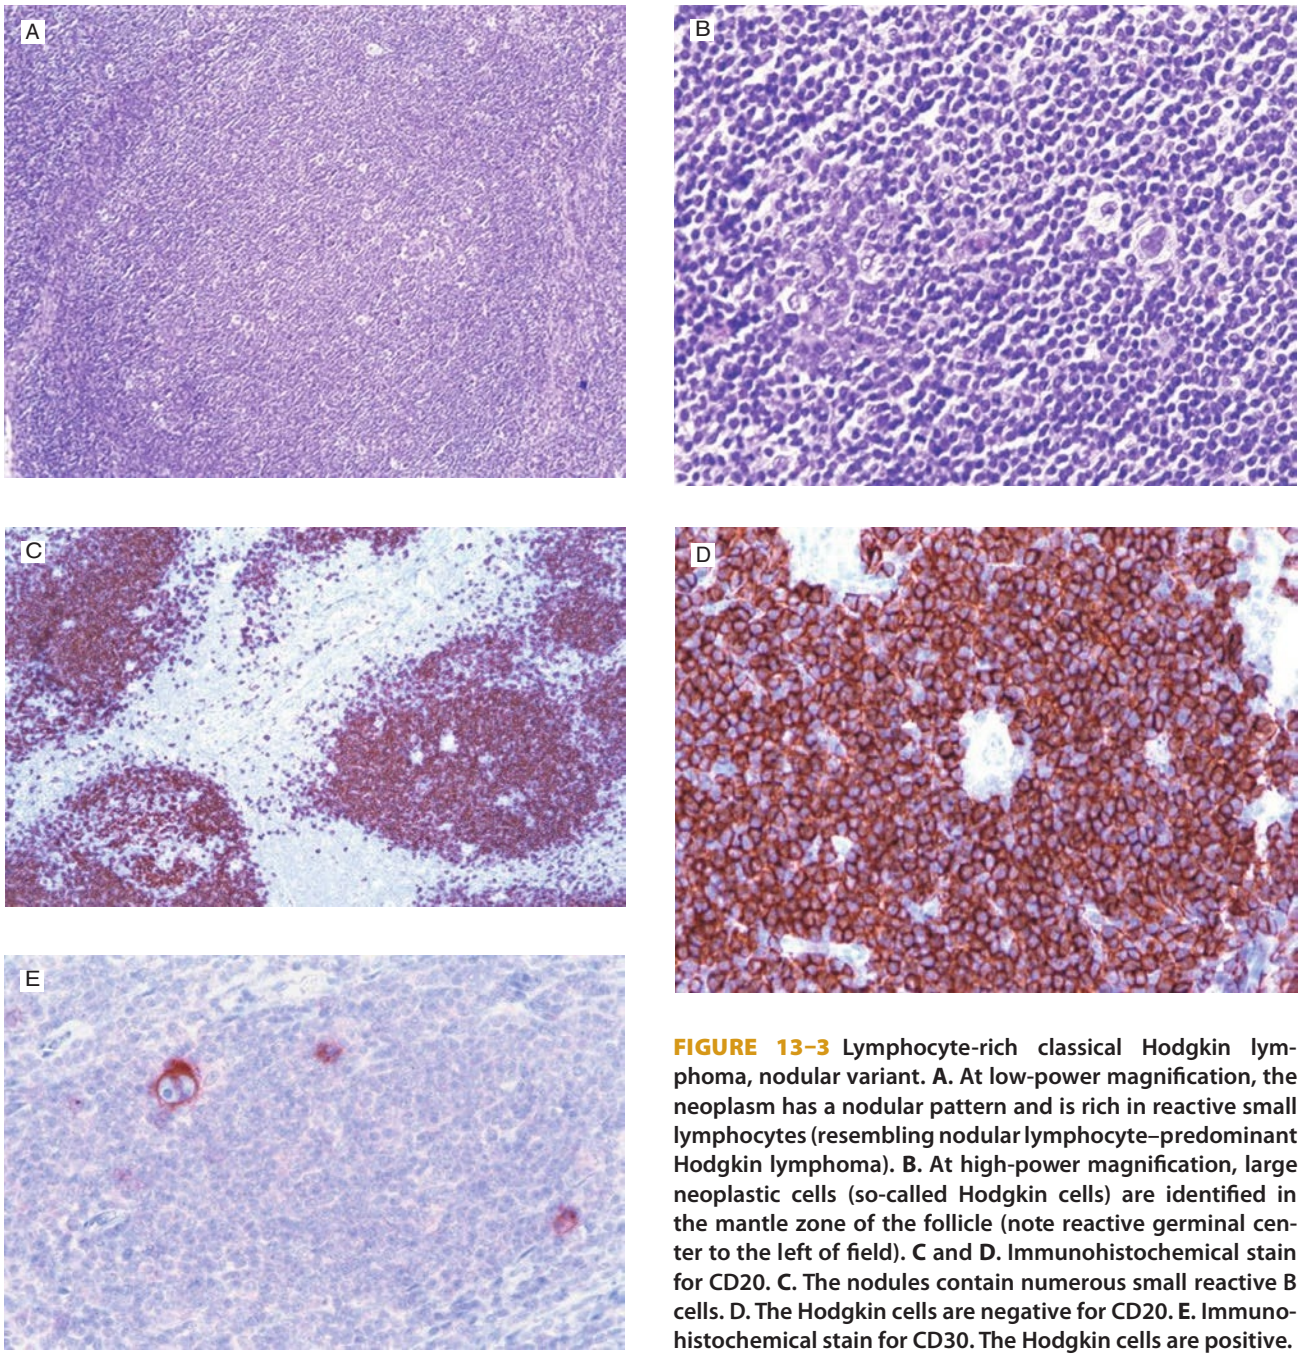

FIGURE 13–3 **Lymphocyte-rich classical Hodgkin lymphoma, nodular variant. A. At low-power magnification, the neoplasm has a nodular pattern and is rich in reactive small lymphocytes (resembling nodular lymphocyte–predominant Hodgkin lymphoma). B. At high-power magnification, large neoplastic cells (so-called Hodgkin cells) are identified in the mantle zone of the follicle (note reactive germinal center to the left of field). C and D. Immunohistochemical stain for CD20. C. The nodules contain numerous small reactive B cells. D. The Hodgkin cells are negative for CD20. E. Immunohistochemical stain for CD30. The Hodgkin cells are positive.**

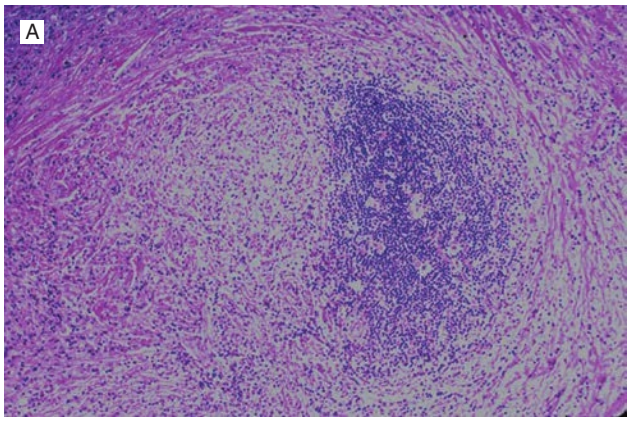


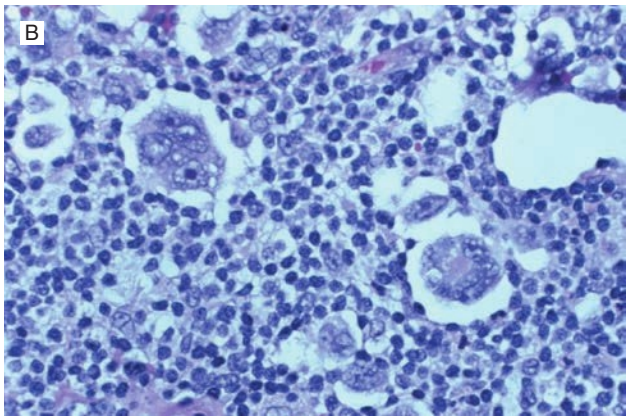
Mixed-Cellularity Hodgkin Lymphoma

Clinical Features

The mixed-cellularity variant of HL (MCHL), the second most common type, affects 15% to 25% of all patients with the disease and is the most common form in patients older than 50 years of age.[1,13] Men are affected more often than women. According to NCI SEER data, MCHL is relatively more common in African Americans and Hispanic Americans than in whites in the United States. A substantial percentage of patients with MCHL have clinical stage III or stage IV disease and B symptoms.

Histologic Features

Mixed-cellularity HL is characterized by a large number of Reed-Sternberg cells and Hodgkin cells in a background of numerous eosinophils, plasma cells, histiocytes, and granulocytes in varying proportions (Fig. 13–6).[1] The lymph node architecture is usually diffusely replaced. Partially involved lymph nodes show



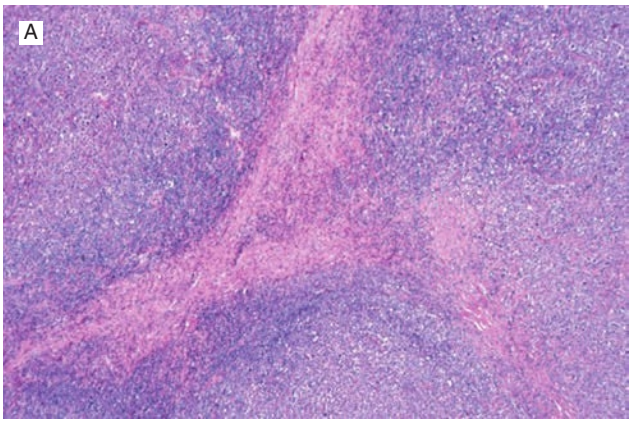


FIGURE 13–4 Nodular sclerosis Hodgkin lymphoma. **A.** The neoplasm is nodular, and the nodules are surrounded by dense fibrous bands. **B.** The large neoplastic cells (lacunar cells) lie within lacunar spaces, and many are multinucleated in this field. Reactive cells are present in the background.

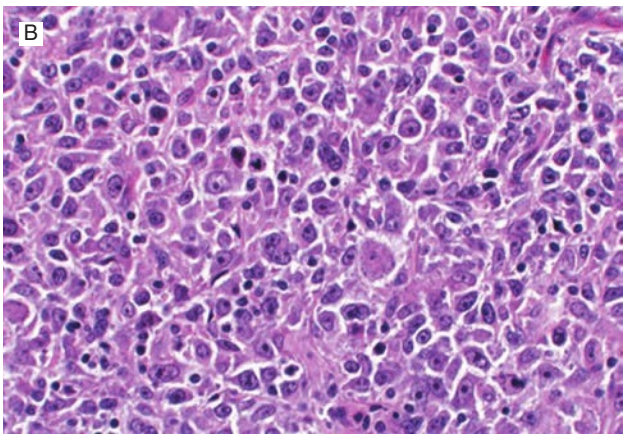

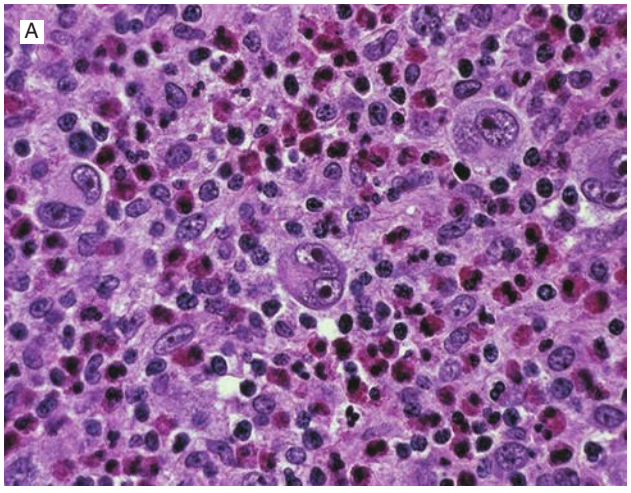

FIGURE 13–5 Syncytial variant of nodular sclerosis Hodgkin lymphoma. **A.** Nodularity and a fibrous bond can be appreciated in this field. B. The nodules are composed of many neoplastic cells with depletion of small lymphocytes.

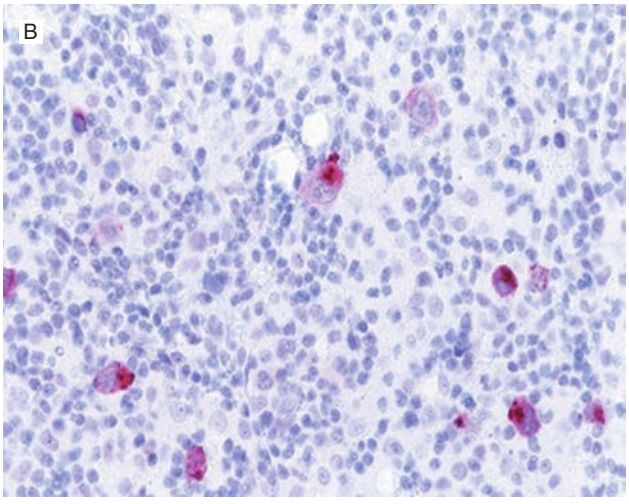

FIGURE 13–6 Mixed-cellularity Hodgkin lymphoma. **A.** Classic Reed-Sternberg cell (center of field) and mononuclear Hodgkin cells can be appreciated in a background of reactive lymphocytes, histiocytes, and eosinophils. **B.** Immunostain for Epstein-Barr virus latent membrane protein type 1. The neoplastic cells are positive.

selective paracortical infiltration. Disorderly fibrosis may be seen, but the broad fibrous bands and capsular fibrosis characteristic of NSHL are absent.

Two variants of MCHL can be relatively more difficult to diagnose. In the interfollicular variant, which most likely represents partial involvement of lymph nodes by HL, the tumor is located in the interfollicular region and is often associated with reactive follicular hyperplasia and marked plasmacytosis. In the epithelioid histiocyte-rich variant, numerous epithelioid histiocytes and granulomas are present; these can be so numerous as to obscure the neoplastic cells. The importance of these variants of MCHL lies in their unusual histologic findings.

Lymphocyte-Depleted Hodgkin Lymphoma

Clinical Features

Lymphocyte-depleted HL (LDHL) is the least common type, representing 1% of all cases.[13] In the NCI SEER study, it was shown that the age-adjusted incidence rate for LDHL has decreased. This decrease is most likely explained by the recognition by pathologists that many tumors previously classified as LDHL are, in fact, non-HLs (eg, anaplastic large-cell lymphoma). Improved classification is the result of application of immunohistochemical and molecular methods to the study of these tumors.

Patients with LDHL are usually older, and LDHL is rare in individuals younger than 40 years of age. There is a slight male predominance. Whites and African Americans are equally affected. Most patients have advanced clinical stage and B symptoms. Patients commonly have a large contiguous mass of matted lymph nodes or diffuse visceral involvement. The diffuse fibrosis type of LDHL commonly has a subdiaphragmatic distribution. Lymphocyte-depleted HL has the poorest prognosis of all types of HL.

Histologic Features

The LDHL category includes two variants originally recognized by Lukes and Butler: diffuse fibrosis and reticular (Fig. 13–7). The diffuse fibrosis variant of LDHL is characterized by an extensive proliferation of disordered, hypocellular fibrosis. Diagnostic HRS cells can be difficult to find and may be spindled within dense collagen. Reactive inflammatory cells are relatively few. The reticular variant of LDHL has numerous HRS cells and bizarre variants that have been termed *pleomorphic variants*. These cells may exhibit marked variations in nuclear number and shape, often with giant nucleoli. Normal small lymphocytes are infrequent compared with the other subtypes of HL. Necrosis is common and may be extensive. The HRS cells and pleomorphic variants may be found in sheets. Mitotic figures are usually numerous.

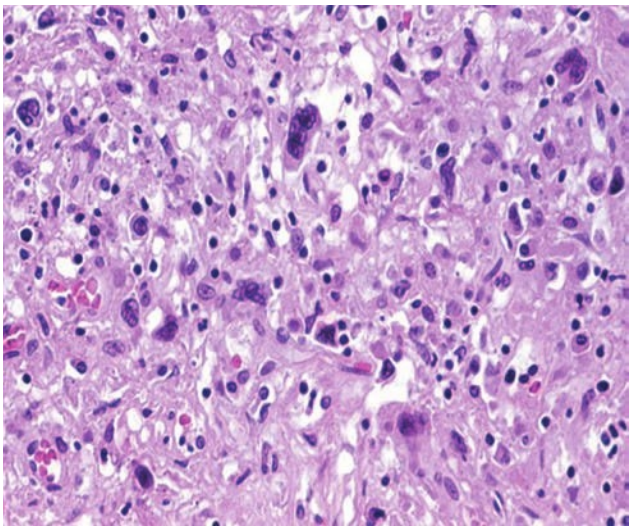

FIGURE 13–7 Lymphocyte-depleted Hodgkin lymphoma. Large neoplastic cells in the background of loose, nonpolarized fibrosis and lymphocyte depletion.

CLINICAL EVALUATION

Staging of Patients

The Ann Arbor system for staging patients with HL at the time of initial presentation forms the basis for the treatment of disease and has allowed comparison of results achieved by different investigations for more than two decades. Important modifications of the Ann Arbor system were developed at the Cotswold Conference in 1989 (Table 13–3).[14] Since then, the staging evaluation has been in evolution. A recent recommendation for the staging procedure in lymphoma described the importance of positron emission tomography (PET)–computed tomography (CT) scan for fluorodeoxyglucose (FDG)-avid lymphomas, of which HL is one example.[15] For HL and other FDG-avid lymphomas, PET-CT improves the accuracy of staging compared with CT scans for nodal and extranodal sites.[16] PET-CT leads to change in stage in 10% to 30% of patients, more often upstaging, although alteration in treatment occurs in fewer patients with no demonstrated impact on overall outcome. However, PET-CT is critical as a baseline measurement before therapy to increase the accuracy of subsequent response assessment.[17] In addition, contrast-enhanced CT should be included for a more accurate measurement of nodal size if required for clinical trials. The University of Texas MD Anderson Cancer Center (MDACC) diagnostic and treatment algorithms for HL are shown in Figure 13–8.

TABLE 13–3 Ann Arbor Staging System with Cotswold Modifications for Hodgkin Lymphoma

Stage I	Involvement of a single lymph node region or lymphoid structure (eg, spleen, thymus, Waldeyer ring) or a single extralymphatic site
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm; localized contiguous involvement of only one extralymphatic organ or site and lymph node region on the same side of the diaphragm (IIE); the number of anatomic regions involved should be indicated by a subscript (eg, II_3)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by spleen involvement (IIIS) or by localized contiguous involvement of only one extralymphatic organ or site (IIIE) or both (IIISE)
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement
Modifying Features	
A	No symptoms
B	Fever (>38°C), drenching night sweats, unexplained weight loss of >10% body weight within the preceding 6 months
X	Bulky disease: greater than one third widening of the mediastinum, >10 cm maximum diameter of a nodal mass
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site
CS	Clinical stage
PS	Pathologic stage (as determined by laparotomy)

A + AVD, brentuximab vedotin, Adriamycin, vinblastine, and dacarbazine; ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; ASCT, autologous stem cell transplantation; AVD, Adriamycin, vinblastine, and dacarbazine; BV, brentuximab vedotin; DHAP, high-dose cytarabine, cisplatin, and dexamethasone; DS, Deauville score; ESR, erythrocyte sedimentation rate; GND, gemcitabine, Navelbine, and Doxil; ICE, ifosfamide, carboplatin, and etoposide; IPS, International Prognostic Score; IFRT, involved-field radiotherapy; IGEV, ifosfamide, gemcitabine, vinorelbine, and prednisone; PD-1, programmed death-1; PET-2, positron emission tomography assessment after two cycles of therapy; R-ABVD, rituximab, doxorubicin, bleomycin, vinblastine, and dacarbazine; R-CHOP, rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone; RT, radiation therapy.

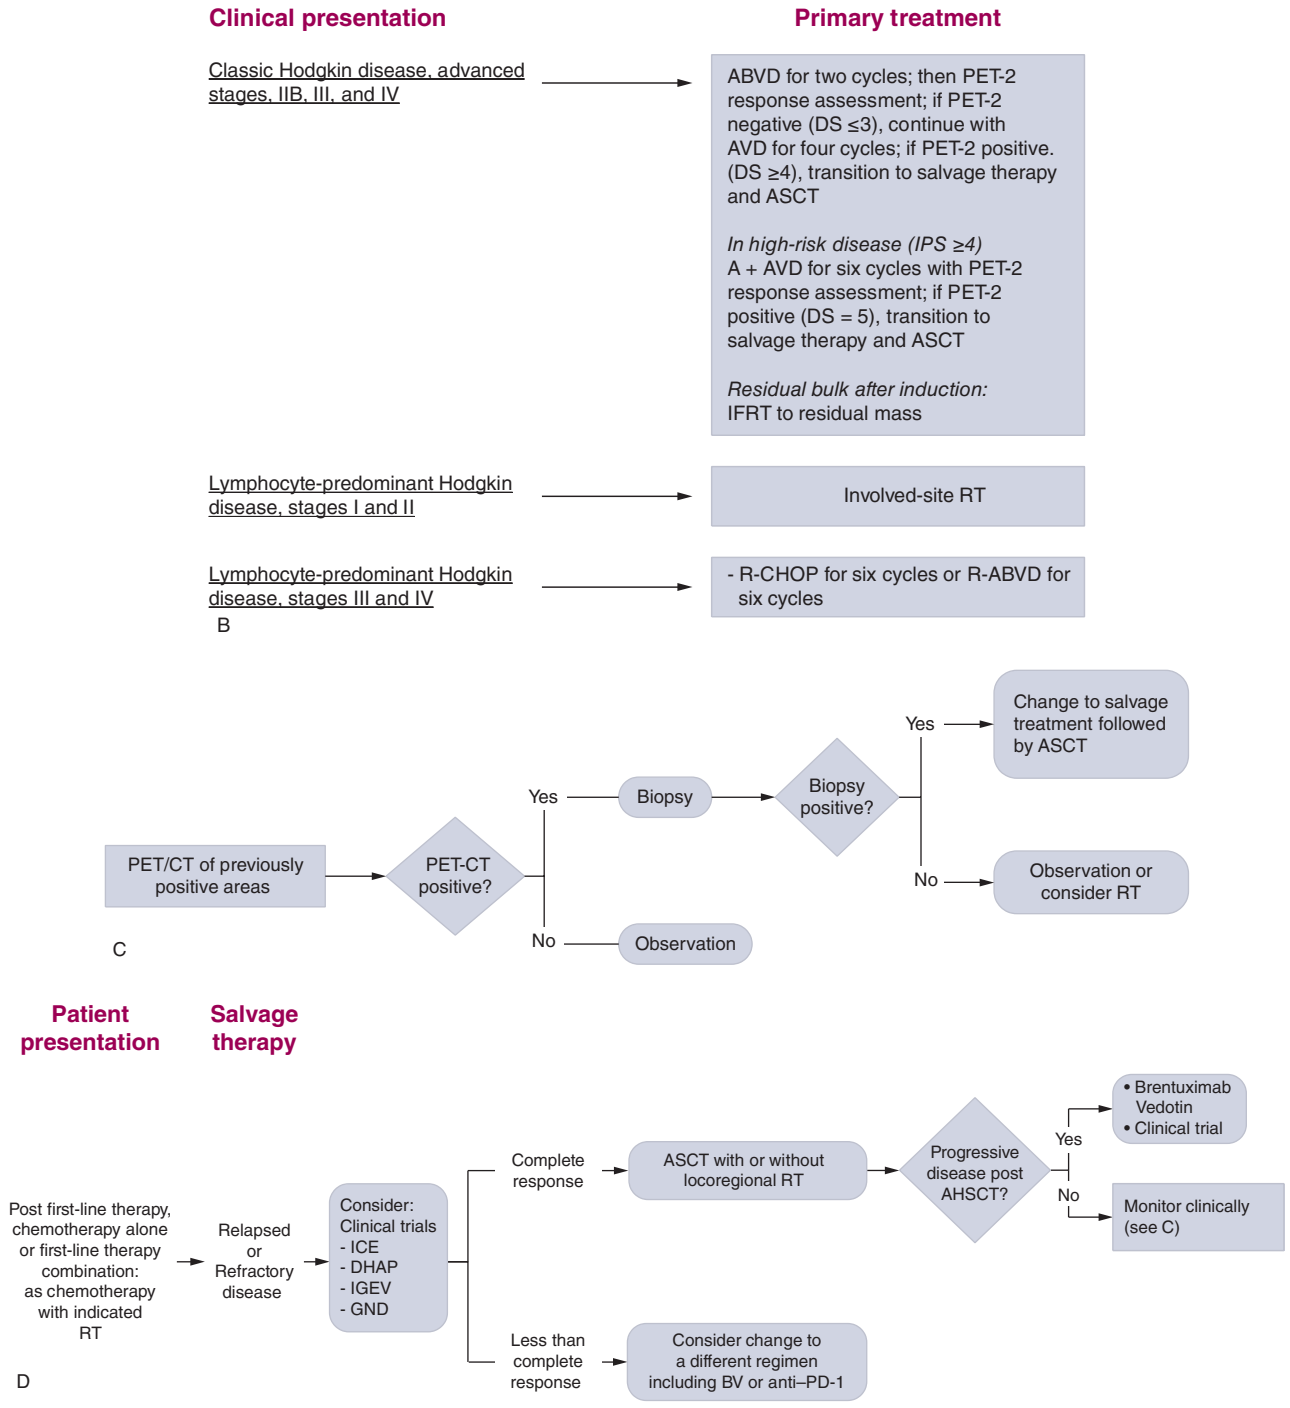

FIGURE 13–8 (Continued)

Patient Evaluation

The initial evaluation of patients with HL has both prognostic and therapeutic significance (see Figure 13–8). Routine studies that should be performed include a complete blood cell count with differential; electrolytes; blood urea nitrogen; creatinine; liver function tests; lactate dehydrogenase; albumin; pregnancy tests in women of childbearing age; erythrocyte sedimentation rate (ESR); pulmonary function testing with carbon monoxide diffusing capacity; evaluation of cardiac ejection fraction; chest radiography; CT of the neck, chest, abdomen, and pelvis; and PET-CT (Table 13–4).

Bone-marrow biopsy has been a standard test for lymphoma staging. However, the high sensitivity of PET-CT for bone-marrow involvement has recently led to questioning the use of bone-marrow biopsy as

TABLE 13–4 Recommended Procedures for Staging of Hodgkin Lymphoma

History and Examination	Identification of B Symptoms
Radiologic and other assessments	- Chest radiograph - CT scans, including the neck, chest, abdomen, and pelvis whole-body PET scan - Echocardiogram or MUGA scan - Pulmonary function tests - HIV serology - Pregnancy test in women of childbearing age
Hematologic procedures	- CBC with differential - ESR
Biochemical procedures	- Liver function tests - Serum albumin - Lactate dehydrogenase
Procedures for use under special circumstances	- Ultrasound scanning - MRI

CBC, complete blood count; CT, computed tomography; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging; MUGA, multigated acquisition; PET, positron emission tomography.

a staging procedure in several common histologies, including HL.[15] In one study of patients with HL, 18% had focal skeletal lesion on PET-CT, but only 6% had positive bone-marrow biopsies, all with advanced-stage disease on PET-CT.[18] Patients with early-stage disease rarely have marrow involvement in the absence of a suggestive PET finding, and those with advanced-stage disease rarely have marrow involvement in the absence of disease-related symptoms. Although the issue is controversial and some institutions perform bone-marrow biopsy for initial staging evaluation of HL, almost all patients would not have been allocated to another treatment based on bone-marrow biopsy results. Thus, bone-marrow biopsy is no longer indicated for the routine staging of patients with cHL. Magnetic resonance imaging has also not superseded CT scanning of the chest and abdomen in the evaluation of HL. It is largely restricted to the assessment of specific situations such as bony involvement and spinal cord compression and in lieu of CT scans in pregnant patients.

Prognostic Factors

For clinically early-stage (CS) disease (CS I or CS II), several prognostic factors have been identified through retrospective studies of patients with HLs, largely based on patients treated with radiotherapy alone. Adverse features include (1) advanced age, which correlates with the presence of occult abdominal disease and with poor results of salvage therapy; (2) male gender; (3) MC histologic type, which is associated with the presence of occult abdominal disease; (4) B symptoms, also associated with the presence of occult abdominal disease; (5) large mediastinal mass, defined as a mass measuring greater than one-third of the chest diameter on a standard chest radiograph; (6) a larger number of involved nodal regions; (7) elevated ESR; (8) anemia; and (9) low serum albumin level.[19,20]

International organizations have defined various systems that calculate the risk of recurrence of disease or, in some cases, death, after treatment for HL. The European Organization for the Research and Treatment of Cancer (EORTC) has defined CS I and CS II patients as having an unfavorable risk of development of recurrence if any of the following factors apply: (1) age older than 50 years, (2) no B symptoms present with an ESR greater than 50 mm/hr or B symptoms with ESR greater than 30 mm/hr, (3) a large mediastinal mass, (4) stage II, or (5) at least four nodal regions involved.[21] The GHSG has assigned CS I and CS II patients to the category of unfavorable disease with any of the following adverse factors: (1) large mediastinal mass, (2) at least three nodal regions involved, (3) no symptoms present with ESR greater than 50 mm/hr or B symptoms with ESR greater than 30 mm/hr, or (4) localized extranodal infiltration (so-called E lesions) (Table 13–5).[22] In advanced disease, the International Prognostic Score (IPS) was developed on the basis of an analysis of 5141 patients, most of whom were initially treated with an anthracycline-containing chemotherapy regimen. Seven factors were identified, as shown in Table 13–6.[23]

Response Assessment

Before 1999, the criteria used to assess response to therapy were not routinely standardized. The International Working Group formulated guidelines for the assessment of response to therapy in 1999.[24] The criteria were based on CT scan and gained international recognition. However, with the introduction of the PET scan, the guideline has been updated twice, in 2007 and

TABLE 13–5 Prognostic Classification of the European Organization for the Research and Treatment of Cancer (EORTC) and German Hodgkin Lymphoma Study Group (GHSG) Groups for Clinical Stage I/II Hodgkin Lymphoma

	Unfavorable (presence of *any* of the following)
EORTC	- Age 50 years or younger - ESR >50 mm/hr without B symptoms; ESR >30mm/hr with B symptoms - Four or fewer nodal sites of involvement - Bulky mediastinal mass
	Unfavorable (presence of *any* of the following)
GHSG	- ESR >50 mm/hr without B symptoms; ESR >30 mm/hr with B symptoms - Three or fewer nodal sites of involvement - Bulky mediastinal mass - Extranodal involvement

ESR, erythrocyte sedimentation rate.

TABLE 13–6 International Prognostic Score for Hodgkin Lymphoma

Hemoglobin <10.5 g/dL
Age 45 years or younger
Male sex
Lymphocyte count <600/mL or <8% of WBC count
Serum albumin <4g/dL
WBC count ≤ 15,000/mL
Stage IV disease (Ann Arbor system)

WBC, white blood cell.
Data from Moccia AA, Donaldson J, Chhanabhai M, et al: International Prognostic Score in advanced-stage Hodgkin's lymphoma: altered utility in the modern era, *J Clin Oncol*. 2012 Sep 20;30(27):3383-3388.

TABLE 13–7 Five-Point Deauville Criteria

Score 1: no uptake
Score 2: uptake ≤ mediastinum
Score 3: uptake > mediastinum but ≤ liver
Score 4: moderately increased uptake > liver
Score 5: markedly increased uptake > liver or new lesions related to lymphoma
Score X: new areas of uptake unlikely to be related to lymphoma

in 2014.[15,25] Based on the high negative predictive value (95%–100%) and positive predictive value (>90%) of PET scan in the response evaluation for HL, current recommendations for response evaluation clearly state that PET-CT is more accurate than CT for end-of-treatment (EOT) assessment.[26] Previous guidelines for reviewing PET scans were based on somewhat imprecise visual interpretation as to whether a scan was positive or negative and whether it was intended for EOT evaluation using mediastinal blood pool as the comparator.[27] More recent guidelines recommend using a 5-point scale assessment (Deauville criteria; Table 13–7) for clinical trials including interim analysis and EOT assessment. A score of 1 or 2 is considered to represent complete metabolic response (CMR). A score of 4 or 5 is considered to be treatment failure at the EOT evaluation. Inherent are difficulties in the interpretation of a score of 3, in which the uptake is higher than mediastinal but less than or equivalent to liver uptake. Recent data suggest that patients with a score of 3 at the EOT have a good prognosis and should be considered as having CMRs.[28,29] However, in response-adapted trials exploring treatment deescalation, a more cautious approach may be preferred.

TREATMENT

Nodular Lymphocyte–Predominant Hodgkin Lymphoma

Because of the rarity of this disease, it is difficult to perform randomized prospective clinical trials. However, several well-designed single-arm phase II trials and large retrospective analyses have been recently reported.

Early-Stage Disease

Although radiation as a single modality for treatment would be considered inferior treatment for patients with early-stage cHL, multiple studies have observed excellent outcomes using RT for early-stage NLPHL. In a retrospective review of results for early-staged NLPHL from the HD-4 and HD-7 trials performed by the GHSG, the 2-year FFTF and OS rates after treatment with IFRT were 92% and 100%, respectively, compared with 100% and 94%, respectively, for EFRT.[30] Investigators from our center (MDACC) also reported excellent outcomes with RT alone for stage IA and IIA

patients.[31] With a median follow-up of 8.8 years, only one of 20 patients who received limited-field RT experienced relapse. The best outcome was noted in stage IA patients, who had a 5-year relapse-free survival rate of 95%. The Harvard study group reported a retrospective analysis of long-term outcomes of 113 patients with early-stage NLPHL.[32] Ten-year progression-free survival (PFS) and OS rates were 64% and 100%, respectively, with limited-field RT, and 81% and 95%, respectively, with EFRT. Of note, 86% of patients who received chemotherapy alone had relapse of disease.

These observations suggest that (1) chemotherapy alone is not indicated for patients with NLPHL, (2) RT alone should be the standard of care for patients with early-stage NLPHL without bulky disease or B symptoms, and (3) limited-field RT is appropriate to reduce toxicity and mortality after more extensive RT. In these retrospective analyses, no improvement was seen with combined-modality treatment (chemotherapy and RT) compared with RT alone. However, review of data from therapy of early-stage NLPHL at the British Columbia Cancer Agency (BCCA) have suggested a potential improvement in the outcomes by adding a brief course of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) before RT.[33] Ten-year PFS and OS rates were 65% and 84%, respectively, after RT alone, and 91% and 93%, respectively, for combined-modality treatment. As with retrospective studies, cautious interpretation is needed because of possible selection bias, variable staging procedures, availability of supportive care, and differences in duration of follow-up for these different treatments.

Because of high CD20 expression in NLPHL, rituximab monotherapy was evaluated for the treatment of patients with early-stage NLPHL. The GHSG and Stanford groups have reported analyses of prospective studies of therapy of patients with NLPHL with this drug.[34,35] Overall response rates (ORRs) were high (100% in both studies); however, responses were not durable. Currently, National Comprehensive Cancer Network (NCCN) guidelines recommend IFRT alone for early-stage NLPHL without B symptoms. B symptoms and bulky disease are uncommon presentations for NLPHL and should be treated with combined-modality treatment as for cHL.

Advanced-Stage Disease

Because at least 70% to 80% of patients with NLPHL are diagnosed with early-stage disease, defining the optimal treatment regimen for advanced-stage disease is challenging. However, chemotherapy is the mainstay of treatment for those with stage II or IV disease.

The GHSG recently compared the outcomes of patients with NLPHL and cHL enrolled in prospective trials.[7] There was no significant difference in FFTF results between those with NLPHL and cHL, with 50-month FFTF rates of 77% and 75%, respectively. Chemotherapy regimens used in the GHSG trials were COPP (cyclophosphamide, vincristine, procarbazine, and prednisone), COPP/ABVD, and BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), combinations that contain higher doses of alkylating agents than ABVD. The BCCA also reported a matched-control analysis of patients with NLPHL and cHL treated with ABVD or ABVD-like chemotherapy.[36] Although not statistically significant, there was a trend toward an inferior PFS for patients with NLPHL compared with that for cHL (44% and 77% at 15 years, respectively; $P = .096$). These studies have suggested that alkylating agents may provide some therapeutic advantage for this disease. We have reported the results of R-CHOP (rituximab plus cyclophosphamide, doxorubicin, vincristine, and prednisone) in therapy of patients with advanced-stage NLPHL.[37] Five- and 10-year PFS rates for patients treated with R-CHOP were 88% and 59%, respectively. With a median follow-up period of 6.7 years, no transformation to DLBCL or TCRBL has been observed. Currently, NCCN guidelines list therapeutic options including CVP (cyclophosphamide, vincristine, and prednisone), CHOP, and ABVD with or without rituximab for patients with advanced disease.

Relapsed and Transformed Disease

Patients with NLPHL may have late relapse or develop transformation to B-cell lymphoma, for which standard treatment has to be yet defined. However, rituximab has been evaluated for treatment of patients with relapsed NLPHL. In a study of 14 patients reported by the GHSG, rituximab therapy induced an ORR of 100%, a complete response (CR) rate of 57% and a median time to progression of 33 months.[38] The Stanford group examined the benefit of limited versus extended rituximab therapy in frontline and relapsed settings.[34] Eighteen patients with relapsed NLPHL were enrolled in this study; the ORR with rituximab monotherapy was 100%, and the 5-year PFS was 71.4% with rituximab maintenance therapy, consisting of four weekly infusions every 6 months for 2 years. These results suggest that rituximab monotherapy is effective in relapsed NLPHL.

Transformation at time of relapse can be a challenging disorder. In a retrospective study by the BCCA, 95 patients with NLPHL were seen over a 40-year time period.[39] Median time of follow-up was 6.5 years, and 14% of patients experienced transformation. The median time to transformation was 8.1 years, with a 4:1 ratio of DLBCL to TCRBCL. In the 10 patients with transformed lymphoma, the 10-year PFS and OS rates were 52% and 62%, respectively.

The rarity of the disease makes it difficult to prospectively evaluate the role of autologous stem cell transplantation (ASCT) for patients with relapsed or refractory NLPHL. However, patients who relapse with transformation should be managed according to algorithms for DLBCL. An MDACC retrospective study reviewed the outcomes for 26 patients who underwent ASCT. At the time of transplantation, many had transformation to TCRBCL. At the time of ASCT, 85% were in remission, with 25% in CR. At a median follow-up period of 50 months, the event-free survival (EFS) rate was 69%.[40]

MD Anderson Approach to Therapy for NLPHL: Summary

We treat patients with stage IA and IIA NLPHL with IFRT. It is rare for stage I or II patients to present with B symptoms, but if a patient does, we administer combined-modality therapy with an anthracycline-containing chemotherapy regimen followed by IFRT, particularly for stage IIB. Our preferred regimen is R-CHOP, and patients with advanced-stage disease receive six cycles of this regimen. Patients who experience relapse are considered for extended rituximab therapy. For patients with evidence of transformation to DLBCL or TCRBCL, if anthracycline-containing chemotherapy was already given, we use salvage chemotherapy with regimens such as rituximab plus ICE (ifosfamide, carboplatin, and etoposide) followed by ASCT.

Classical Hodgkin Lymphoma

The common practice for treatment and participation in clinical trials is to divide patients with cHL into three treatment groups: early-stage favorable, early-stage unfavorable, and advanced stage.

Favorable Early-Stage Classical Hodgkin Lymphoma

Treatment of patients with early-stage HL is evolving. Historically, wide-field RT or EFRT without chemotherapy was the standard of care.[41] Extended-field RT produced superior disease-free survival (DFS) results compared with IFRT.[42] More than 90% of patients achieved CR with this approach; however, the relapse rate was unacceptably high (≥30%). In addition, EFRT had considerable long-term side effects. In a large prospective analysis of over 15,000 HL patients, the actuarial risk of developing a solid tumor was 21.9% at 25 years after HL diagnosis, with the absolute risk being nearly 50%. Female breast and lung cancers were common secondary malignancies.[43]

In an attempt to improve these results, the GHSG and EORTC conducted key studies comparing RT alone with combined-modality strategies. In the GHSG HD-7 trial, patients were randomly assigned to receive either 30 Gy of EFRT alone or two cycles of ABVD followed by the same RT.[44] Although response rates did not differ between the two treatment arms, the 7-year FFTF rate was significantly better in the combined-modality arm (88% vs 67%). The results of the randomized EORTC H8F trial were similar. In this trial, treatment arms consisted of three cycles of MOPP (mechlorethamine, vincristine, procarbazine, prednisone)/ABV (doxorubicin, bleomycin, vinblastine) followed by IFRT or subtotal nodal irradiation (STNI) alone.[45] Patients receiving combined-modality treatment had a significantly superior 5-year EFS (98% vs 74%) and better 1-year OS estimates (97% vs 92%). As a result of these two large randomized controlled trials and the recognition of notable long-term side effects and high relapse rates, EFRT monotherapy has now been abandoned in favor of combined-modality therapy, which is now the standard treatment for early-stage HL.

Combined-modality therapy has evolved based on the finding that this approach results in high freedom from recurrence in early-stage HL and that efficacy can be maintained using less toxic chemotherapy and RT regimens. At MDACC, investigators performed a retrospective analysis of 286 patients with early-stage HL treated with chemotherapy followed by IFRT or EFRT with a median dose of 40 Gy.[46] Five-year relapse-free survival (RFS) and OS rates were 88% and 93%, respectively. The type and number of chemotherapy cycles used did not significantly affect RFS and OS. However, the 5-, 10-, and 15-year cumulative risks of developing solid tumors in patients treated with chemotherapy and IFRT were 0%, 6.9% and 11.4%, respectively. These results were strikingly more favorable than those of chemotherapy plus EFRT (2.7%, 11.1%, and 28.7%, respectively).

There are many completed and ongoing trials addressing issues of the best modality, best RT field, optimal dose of RT, optimal combination of drugs, number of cycles, and optimal timing of chemotherapy, with the goals being to maintain efficacy and minimize toxicities (Table 13–8).[22,47–51] The key study in combined-modality therapy for the current standard treatment is the HD-10 trial by the GHSG.[22] This study had four arms testing two versus four cycles of ABVD followed by 20 versus 30 Gy of IFRT in patients with favorable early-stage HL. This trial addressed both the optimal dose of RT and the optimal number of cycles of chemotherapy. The ABVD two- and four-cycle arms both had CR rates of 97%. The 20- and 30-Gy IFRT groups had CR rates of 97% and 98%, respectively. With a median follow-up period of 7.5 years, there were no differences among the four groups with respect to PFS, FFTF, and OS. However, the four-cycle

ABVD and 30-Gy IFRT treatment groups induced more toxicity than the less intensive treatment groups. Based on these data, the least toxic regimen, two cycles of ABVD and 20 Gy of IFRT, is the current preferred approach for patients with favorable early-stage HL.

In an attempt to further reduce toxicity, the GHSG conducted the HD-13 trial, a study that was designed to determine whether bleomycin or dacarbazine can be omitted from the ABVD regimen.[48] This four-arm trial investigated ABVD, AVD (doxorubicin, vinblastine, dacarbazine), ABV, and AV (doxorubicin, vinblastine) plus 30 Gy of IFRT. In this trial, the ABV and AV plus IFRT arms were closed because of concern for higher relapse rates. Five-year FFTF rates were 93%, 81%, 89%, and 77% with ABVD, ABV, AVD, and AV, respectively. Based on results from this trial, both dacarbazine and bleomycin cannot be omitted from this regimen for favorable early-stage disease without a substantial loss of efficacy, and the standard treatment remains ABVD followed by IFRT.

TABLE 13–8 Key Trials for Patients with Favorable Early-Stage Hodgkin Lymphoma

Trial	Trial Design
Milan 1990 to 1997	ABVD × 4 → STLI ABVD × 4 → IFRT
Stanford	Stanford V × 8 weeks → IFRT
EORTC/GELA H9F	EBVP × 6 → IFRT 20 Gy EBVP × 6 → IFRT 30 Gy EBVP × 6 → alone
GHSG HD-10	ABVD × 2 → IFRT 2 Gy ABVD × 4 → IFRT 20Gy ABVD × 2 → IFRT 30 Gy ABVD × 4 → IFRT 30 Gy

EORTC/LYSA/FIL H10F	ABVD × 3 → INRT 30 Gy (+6 Gy) ABVD × 2 → then PET scan – If PET negative → ABVD × 2 – If PET positive → BEACOPP escalated × 2 → INRT 30 Gy (+ 6 Gy)
GHSG HD-16	ABVD x 2 → IFRT 20 Gy ABVD x 2 → then PET scan – If PET negative → stop treatment – If PET positive → IFRT 20 Gy
UK RAPID	ABVD × 3 → then PET scan – If PET negative (DS ≤4) → stop treatment – If PET positive → ABVD × 1 + 30 Gy IFRT

ABV, doxorubicin, bleomycin, vinblastine; ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; AV, doxorubicin, vinblastine; AVD, doxorubicin, vinblastine, dacarbazine; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; EBVP, epirubicin, bleomycin, vinblastine, prednisone; EORTC, European Organization for Research and Treatment of Cancer; FIL, Fondazione Italiana Linfomi; GELA, Groupe d'Etude des Lymphomes de l'Adulte; GHSG, German Hodgkin Lymphoma Study Group; IFRT, involved-field radiotherapy; INRT, involved-node radiotherapy; LYSA, Lymphoma Study Association; PET, positron emission tomography; Stanford V, mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisolone; STLI, subtotal lymphoid irradiation.

Several studies have evaluated the utility of interim PET imaging for treatment stratification. The EORTC/Lymphoma Study Association (LYSA)/Fondazione Italiana Linfomi (FIL) H10 trial was conducted to assess whether involved-node radiotherapy (INRT) could be omitted without compromising PFS in patients attaining a negative early PET scan after two cycles (PET-2) of ABVD as compared with standard combined-modality treatment.[47] Patients were randomized to receive standard therapy with INRT or an experimental arm that omitted RT if the PET was interpreted as negative (Deauville score [DS] 1 or 2) after two cycles of ABVD. Patients with a positive interim PET (DS ≥3) continued treatment with two cycles of escalated BEACOPP. The chemotherapy-only arm was closed because of an increased number of events, and all patients with a negative PET findings received additional RT. Five-year PFS was significantly lower in the experimental arm than the standard arm (87% and 99%, respectively).[52] In contrast, the UK RAPID trial showed noninferior outcomes for patients who omitted RT after negative PET scan (DS 1 or 2).[53] Patients were randomized to IFRT or no further treatment if the PET result was negative after three cycles of ABVD. Three-year PFS rates were 93.8% and 90.7%, and 3-year OS rates in an intent-to-treat analysis were 97.0% and 99.5% in patients who received IFRT and no further treatment, respectively. Thus, there was a nonsignificant trend toward improved PFS for patients who received IFRT. In a post-hoc analysis of this trial, investigators reported that only patients with a PET DS score of 5 had inferior PFS compared with patients with a DS score of 4 or less, thereby warranting treatment escalation only for patients with a DS score of 5.[28]

In a similar study, the GHSG HD-16 trial randomized patients with favorable early-stage cHL to two cycles of ABVD and 20 Gy IFRT or to an experimental arm of two cycles of ABVD with PET-guided treatment, omitting IFRT if the PET-2 was negative (DS <3). With a median follow-up period of 45 months, the 5-year PFS rates were 93.4% in the standard therapy arm and 86.1% in the experimental arm. Of the patients who received IFRT, 5-year PFS rates were significantly different in the PET-2–negative and PET-2–positive patients (93.2% and 88.4%, respectively; $P = .047$), which was more pronounced when using the more common liver cut-off for PET scoring, DS less than 4 (5-year PFS rates 93.1% and 80.9%, respectively; $P = .0011$), suggesting that IFRT cannot be safely omitted

in PET-2–negative patients without significant loss of local tumor control.[54] The question of whether treatment can be further reduced based on the results of the PET scan is the subject of ongoing clinical trials. The GHSG HD-17 trial is investigating the potential equivalence of IFRT and INRT. Small phase II studies are investigating the option of using novel agents such as nivolumab or brentuximab vedotin (BV) to replace RT and bleomycin with favorable early results.[55,56]

The MD Anderson Approach for Favorable Early-Stage Classical Hodgkin Lymphoma

The treatment for favorable early-stage HL is still evolving. Patients are screened for clinical protocol options if available. As standard therapy, we use two cycles of ABVD plus 20 Gy of IFRT for this group of patients. In patients in whom the radiotherapy field crosses vital tissues, including breast tissue and coronary arteries, we use three cycles of ABVD followed by interim PET imaging. If PET negative (DS ≤4), no further treatment is given; if PET positive (DS = 5), one additional cycle of ABVD is given with 30 Gy of IFRT.

Unfavorable Early-Stage Hodgkin Lymphoma

Combined-modality approaches consisting of four cycles of chemotherapy followed by IFRT represent the standard of care for patients with unfavorable early-stage HL. Multiple trials have shown that reduction of radiation field does not lead to inferior clinical outcomes. In a retrospective analysis conducted at MDACC, 286 patients (1980–1995) with early-stage HL received chemotherapy followed by IFRT or EFRT. The type and number of chemotherapy regimens used did not significantly affect RFS and OS. There was a trend toward a higher risk of secondary tumors in the EFRT group.[46] Given the relapse rates with ABVD, there is interest in evaluating alternative more intensive regimens (Table 13–9).[47,57–60]

To address whether ABVD or the Stanford V regimen (mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisone) would be the best approach for patients with bulky unfavorable early-stage HL, the SWOG and Eastern Cooperative Oncology Group (ECOG) conducted the intergroup 2496 trial.[57] In this study, patients with bulky unfavorable early-stage disease (patients with advanced-stage disease were also enrolled in this trial) received six cycles of ABVD followed by IFRT, 36 Gy to bulky disease greater than 5 cm, or 12 weeks of Stanford V followed by the same IFRT plan of care. In this study, there were no differences between ABVD and Stanford V with respect to ORR and FFS.

In another study of therapy more intensive than ABVD for unfavorable early-stage cHL, the GHSG HD-11 trial randomized patients to four arms of therapy: four cycles of ABVD followed by 30 versus 20 Gy of IFRT or four cycles of BEACOPP baseline followed by 30 versus 20 Gy of IFRT. FFTF results were better with BEACOPP than with ABVD for patients who received 20 Gy of IFRT, whereas there were no differences between the BEACOPP and ABVD arms for patients who received 30 Gy of IFRT. OS did not differ significantly between the four treatment arms. BEACOPP also induced more toxicity in comparison with ABVD; therefore, four cycles of ABVD remained the standard for these patients with unfavorable early-stage HL.[59] However, in a follow-up study, in an attempt to reduce the toxicity observed with BEACOPP, the

TABLE 13–9 Key Trials for Patients with Unfavorable Early-Stage Hodgkin Lymphoma

	ABVD × 6 → IFRT 36 Gy to >5 cm disease
	Stanford V × 12 weeks → IFRT 36 Gy to >5 cm disease
EORTC/GELA H9U	ABVD × 6 → IFRT (36–40 Gy)
	ABVD × 4 → IFRT (36–40 Gy)
	BEACOPP × 4 → IFRT (36–40 Gy)
GHSG HD11	ABVD × 4 → IFRT 30 Gy
	ABVD × 4 → IFRT 20 Gy
	BEACOPP baseline × 4 → IFRT 30 Gy
	BEACOPP baseline × 4 → IFRT 20 Gy
GHSG HD-14	ABVD × 4 → IFRT 30 Gy
	BEACOPP escalated + ABVD × 2 → IFRT 30 Gy
EORTC/LYSA/FIL H10U	ABVD × 4 → INRT 30Gy (+ 6 Gy)
	ABVD × 2 → then PET scan
	If PET negative → ABVD × 4
	If PET positive → BEACOPP escalated × 2 → INRT 30 Gy (+ 6 Gy)
GHSG HD-17	BEACOPP escalated + ABVD × 2 → IFRT 30 Gy
	BEACOPP escalated + ABVD × 2 → then PET scan
	If PET negative → stop treatment
	If PET positive → INRT 30 Gy

ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; ECOG, Eastern Cooperative Oncology Group; EORTC, European Organization for Research and Treatment of Cancer; FIL, Fondazione Italiana Linfomi; GELA, Groupe d'Etude des Lymphomes de l'Adulte; GHSG, German Hodgkin Lymphoma Study Group; IFRT, involved-field radiotherapy; INRT, involved-node radiotherapy; LYSA, Lymphoma Study Association; PET, positron emission tomography; Stanford V, mechlorethamine, doxorubicin, vinblastine, vincristine, bleomycin, etoposide, prednisone; SWOG, Southwest Oncology Group.

GHSG HD-14 trial evaluated four cycles of ABVD followed by 30 Gy of IFRT versus two cycles of BEACOPP escalated followed by two cycles of ABVD (2 + 2) followed by 30-Gy IFRT for this same group of patients.[58] At a median follow-up period of 43 months, there was better tumor control (5-year FFTF estimate of 94.8%) with the 2 + 2 protocol compared with the ABVD arm (5-year FFTF of 87.7%), although there was no significant difference in OS between the two arms because of more toxic deaths in the 2 + 2 arm.

Using a similar rationale, the EORTC designed the H9U trial, comparing three different less versus more intensive therapies.[60] Patients received either four or six cycles of ABVD followed by IFRT or four cycles of BEACOPP followed by IFRT. Patients in CR/Cru (CR unconfirmed) after chemotherapy received 30 Gy of IFRT with those in partial remission (PR) receiving 36 Gy in total. Four cycles of ABVD followed by IFRT was noninferior to six cycles of ABVD or four cycles of BEACOPP with IFRT (5-year EFS, 86%, 89%, and 90%, respectively) with no differences in 5-year OS rates and fewer toxic events compared with BEACOPP. Based on these two trials, four cycles of ABVD chemotherapy remains the standard comparator for patients with unfavorable early-stage HL.

Similar to favorable early-stage HL, current trials for patients with unfavorable early-stage HL, such as the EORTC/Groupe d'Etude des Lymphomes de l'Adulte H10U and GHSG HD-17, are evaluating treatment stratification according to the result of an interim PET scan. The standard arm in the EORTC/LYSA/FIL H10U trial consisted of four cycles of ABVD followed by 30 Gy of INRT irrespective of the result of an interim PET scan performed after the second cycle of ABVD. In the experimental arm, patients with negative PET results received a total of six cycles of ABVD without consolidation RT, whereas patients with positive PET results continued treatment with two cycles of escalated BEACOPP before receiving INRT. However, as for patients with early-stage favorable HL, the chemotherapy-only arm (six cycles of ABVD) was closed because of an increased number of events, so that all patients with negative PET results received additional RT. There was no difference in the 1-year PFS between the standard and experimental arms (97.3% and 94.7%, respectively). In the GHSG HD-17 trial, all patients received chemotherapy according to the 2 + 2 regimen before a PET scan was performed. In the standard arm, patients received an additional 30 Gy of IFRT irrespective of the results of the PET scan. In the experimental arm, patients with negative PET scan results stopped treatment, whereas patients with positive PET scan results received 30 Gy of INRT. This ongoing trial plans to evaluate whether it is possible to spare RT in patients with a negative PET scan after intensive escalated BEACOPP.

A trial conducted by the National Cancer Institute of Canada and the ECOG indicated that chemotherapy-only approaches appear possible in patients with unfavorable early-stage cHL, at least in patients with nonbulky disease.[61] The trial randomized patients with unfavorable early-stage disease to receive either four to six cycles of ABVD or two cycles of ABVD followed by STNI. At a median follow-up period of 11.3 years, freedom from disease progression was better in patients who received combined-modality treatment; however, OS was better for patients treated with chemotherapy alone. This was mainly caused by the increased number of deaths from secondary neoplasia among patients who had received combined-modality treatment. Because of results of this study and others previously mentioned, STNI fields have been abandoned in favor of limited fields after ABVD or variants. Chemotherapy alone may still be an option for selected patients with nonbulky unfavorable early-stage HL, given similar excellent OS results with and without RT, but the combined-modality therapy approach remains a standard of care.

The MD Anderson Approach to Unfavorable Early-Stage Classical Hodgkin Lymphoma

Treatment with four cycles of ABVD plus 30 Gy of IFRT is our standard-of-care option for unfavorable early-stage HL. We screen patients for any available clinical protocols. If patients have elevated short- or long-term risks associated with RT, such as young female patients who might need significant breast tissue irradiation because of bulky masses at diagnosis, six cycles of ABVD without RT is an acceptable alternative, especially if the PET-2 result is interpreted as negative for active disease.

Advanced-Stage Hodgkin Lymphoma

Treatment of patients with advanced-stage HL usually consists of six to eight cycles of chemotherapy. The ABVD regimen was shown to be effective and less toxic than MOPP and MOPP/ABVD in a randomized clinical trial by the Cancer and Leukemia Group B (CALGB).[62] With ABVD, MOPP, and MOPP/ABVD, 5-year failure-free survival rates were 61%, 50%, and 65%, and 5-year OS rates were 73%, 66%, and 75%, respectively. Based on this trial, the chemotherapy regimen most often used in the United States became ABVD. However, the GHSG subsequently reported that escalated BEACOPP induced better PFS results would ABVD for advanced-stage HL. Many trials are addressing whether one regimen may be more suitable for the treatment of advanced HL than another, and the issue has been the subject of ongoing debate for more than decade (Table 13–10).[26,62–66]

TABLE 13–10 Key Trials for Advanced-Stage Hodgkin Lymphoma

Trials	Design
CALGB	ABVD × 6 to 8
	ABVD/MOPP × 12
	MOPP × 6 to 8
GHSG HD-9	COPP/ABVD × 8
	BEACOPP baseline × 8
	BEACOPP escalated × 8
GHSG HD-12	BEACOPP escalated × 8 → IFRT to bulk/residual mass
	BEACOPP escalated × 8
	BEACOPP escalated × 4 + BEACOPP baseline × 4 → IFRT to bulk or residual mass
	BEACOPP escalated × 4 + BEACOPP baseline × 4
GHSG HD-15	BEACOPP escalated × 8 → IFRT to PET-positive residual masses ≤2.5 cm
	BEACOPP escalated × 6 → IFRT to PET-positive residual masses ≤2.5 cm
	BEACOPP-14 × 8 → IFRT to PET-positive residual masses ≤2.5 cm
LYSA H34	ABVD × 8
	BEACOPP escalated × 4 + BEACOPP baseline × 4
GITIL	ABVD × 6 to 8 depends on the response after four cycles
	BEACOPP escalated × 4 + BEACOPP baseline × 4
	HDCT is planned by protocol at the time of progression or relapse
GHSG HD-18	BEACOPP escalated × 2 → then PET scan
	If PET negative
	Additional BEACOPP escalated × 4
	Additional BEACOPP escalated × 2
	If PET positive
	Additional BEACOPP escalated × 4
	Additional BEACOPP escalated × 4 + rituximab
CALGB	ABVD × 6 to 8
	ABVD/MOPP × 12
SWOG S0816	ABVD × 2 → then PET scan - If PET negative (DS≤3), then ABVD × 4 - If PET positive (DS≥4), then BEACOPP × 6
RATHL	ABVD × 2 → then PET scan - If PET negative (DS≤3), then ABVD × 4 or AVD × 4 - If PET positive (DS ≥4), then BEACOPP × 4 or eBEACOPP × 4
ECHELON-1	A+AVD × 2 → then PET scan - If PET negative (DS ≤4), then A+AVD × 4 - If PET positive (DS = 5), then alternative frontline therapy

A + AVD, brentuximab vedotin, doxorubicin, vinblastine, dacarbazine; ABVD, doxorubicin, bleomycin, vinblastine, dacarbazine; AVD, doxorubicin, vinblastine, dacarbazine; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; CALGB, Cancer and Leukemia Group B; COPP, cyclophosphamide, vincristine, procarbazine, prednisone; GHSG, German Hodgkin Lymphoma Study Group; GITIL, Gruppo Italiano Terapie Innovative nei Linfomie; HDCT, high-dose chemotherapy; IFRT, involved-field radiotherapy; LYSA, Lymphoma Study Association; MOPP, mechlorethamine, vincristine, procarbazine, prednisone; PET, positron emission tomography; SWOG, South West Oncology Group; RATHL, Response adapted therapy for Hodgkin Lymphoma.

In the original BEACOPP study for advanced cHL, the GHSG HD-9 trial, a three-arm randomized trial evaluated four cycles of COPP/ABVD versus eight cycles of BEACOPP baseline versus eight cycles of BEACOPP escalated.[66,67] The BEACOPP escalated arm provided significantly a better survival rate than the other two arms. With BEACOPP escalated, COPP/ABVD, and BEACOPP baseline, 5-year FFTF rates were 87%, 69%, and 76%, respectively. Five-year OS rates were 91%, 83%, and 88%, respectively. Because of concerns of toxicity with escalated BEACOPP, the GHSG HD-12 trial investigated whether the number of cycles of

BEACOPP escalated could be deescalated by evaluating eight cycles of BEACOPP escalated versus four cycles of BEACOPP escalated plus four cycles of BEACOPP baseline (4 + 4), along with the effect of consolidation RT for sites of initial bulk or residual disease.[65] Severe toxicity and therapy-related death rates were similar in both arms, and the survival outcome was slightly inferior in the 4 + 4 regimen. Thus, the trial could not address how to decrease the toxicity while maintaining the efficacy of eight cycles of BEACOPP escalated. Their next trial (HD15) also aimed to reduce treatment toxicity without compromising efficacy.[26] The trial evaluated the role of response evaluation based on PET scan in assessing the need for IFRT. Chemotherapy consisted of eight cycles of BEACOPP escalated, six cycles of BEACOPP escalated, or eight cycles of BEACOPP-14, a time-dense variant of the BEACOPP baseline protocol. Additional localized RT was only applied to patients who had PET-positive residual lymphoma larger than 2.5 cm at the end of chemotherapy. With eight cycles of BEACOPP escalated, six cycles of BEACOPP escalated, and eight cycles of BEACOPP-14, the 5-year FFTF rates were 85%, 89%, and 85%, respectively, and the 5-year OS rates were 92%, 95%, and 95%, respectively. The negative predictive value of the post chemotherapy PET scan was very high (94.1% at 12 months), allowing omission of PET negative residua. The superiority of six cycles of BEACOPP escalated was mainly attributed to the lower rate of treatment-related adverse events (AEs) and fewer deaths caused by secondary neoplasia compared with those observed with the more intensive regimens.

The GHSG HD-18 trial further evaluated the utility of the interim PET scan after two cycles of eBEACOPP to adapt treatment intensity.[68] Patients with a positive PET after two cycles of eBEACOPP were randomized to six additional cycles of eBEACOPP or eBEACOPP with rituximab (this was amended to four additional cycles in June 2011 based on the GHSG HD-15 results). Patients with negative PET-2 results were randomized to six additional cycles of eBEACOPP or two additional cycles. RT was recommended for lesions of 2.5 cm or larger in the largest diameter with residual FDG uptake after chemotherapy. Of the PET-2–positive patients, there was no survival benefit with the addition of rituximab. However, survival was similar in the PET-2–negative patients who received six additional cycles of eBEACOPP compared with two additional cycles (5-year PFS 90.8% and 92.2%, respectively) with fewer severe infections and organ toxicities in patients only receiving two additional cycles of eBEACOPP. Therefore, for patients with a negative PET-2 results, the standard of care became four cycles of eBEACOPP.

Using a different approach that escalated therapy for PET-2–positive disease, investigators of the SWOG S0816 trial studied results of therapy for patients with stage III or IV disease.[69] All patients underwent staging by PET followed by two cycles of ABVD and a repeat PET scan (PET-2). If the PET-2 result was negative, the patient received four additional cycles of ABVD. If the PET-2 scan result was positive, treatment was changed and intensified to BEACOPP escalated for six cycles for patients who were seronegative for human immunodeficiency virus (HIV); BEACOPP standard for six cycles was given to those who were seropositive). This trial was also the first American study to use centralized real-time intergroup review (SWOG, ECOG, CALGB) of the PET scan results for treatment decisions. The 5-year PFS of PET-2–positive patients with PET-2–positive disease was still lower than that reported for those who had PET-2–negative disease (66% and 76% respectively) even though they received six more cycles of BEACOPP escalated after PET-2.[70]

The Gruppo Italiano Terapie Innovative nei Linfomi (GITIL) conducted a similar trial.[71] In the GITIL HD0607, all patients received two cycles of ABVD and then underwent PET-2. If the results were negative, they received another four cycles of ABVD with or without RT. If the PET-2 results were positive, the patient received four cycles of BEACOPP escalated and two cycles of BEACOPP baseline. The 3-year PFS rates of patients with positive and negative PET-2 scans were 60% and 87%, respectively.[72] In patients with both interim and post-ABVD-negative PET who had a large nodal mass 5 cm or larger at diagnosis, the addition of radiotherapy did not improve PFS (3 year PFS 97% and 93%, respectively, $P = .29$), adding to earlier suggestions that PET negativity at PET-2 and the end of therapy (PET-EOT) may allow deletion of RT altogether. However, those with PET-2 positivity after two cycles of ABVD had inferior results, and further improvements are needed with this approach.

The Response-Adapted Therapy for Advanced Hodgkin Lymphoma (RATHL) trial also used a PET-2 adapted strategy to assess the impact of treatment deescalation in the PET-2–negative population by omitting bleomycin. All patients received two cycles of ABVD followed by PET imaging. Patients with negative PET-2 results were randomized to either four further cycles of ABVD or AVD. Patients with positive PET-2 results proceeded with either BEACOPP-14 or eBEACOPP in a nonrandomized fashion. In the PET-2–negative patients, the regimen without bleomycin just fell short of the specified noninferiority margin (3-year PFS, 85.7% and 84.4%, respectively) with higher rates of respiratory AEs in the ABVD group than the AVD group.[73] The 3-year PFS rates for patients with PET-2–positive and PET-2–negative scans were 67% and 85%, respectively. Although not strictly meeting the specified noninferiority margin, many clinicians in the United States have adopted the practice of dropping

bleomycin in patients with negative PET-2 results after two cycles of ABVD with minimal impact on PFS. The relatively poor results with escalation to BEACOPP after a positive PET-2 result in this trial were similar to those previously reported in other studies.

Even with the results of the GHSG HD-9 trial, initial chemotherapy for advanced-stage HL is still a matter of debate. The standard arm used in the HD-9 trial was COPP/ABVD, not ABVD alone. Three randomized trials have been conducted to address this issue. An Italian group conducted the HD2000 trial and LYSA conducted the H34 trial to compare the outcomes of randomized therapy with BEACOPP and ABVD.[63,74,75] In the HD2000 trial, patients were randomly assigned to receive six cycles of ABVD, four cycles of BEACOPP escalated plus two cycles of BEACOPP baseline, or six courses of CEC (cyclophosphamide, lomustine, vindesine, melphalan, prednisone, epidoxorubicin, vincristine, procarbazine, vinblastine, and bleomycin). Patients who received BEACOPP had higher PFS and OS rates than patients who received ABVD (5-year PFS, 81% and 68%; 5-year OS, 92% and 84%, respectively). In the H34 trial, patients were randomly assigned to receive eight cycles of ABVD or four cycles of BEACOPP escalated plus four cycles of BEACOPP baseline. Both PFS and OS were higher in the BEACOPP arm than the ABVD arm (5-year PFS, 93% and 75%; 5-year OS, 99% and 92%, respectively), results similar to those reported from the HD2000 study. Therefore, in GHSG trials, BEACOPP has been a standard of care for younger patients with advanced-stage cHL. Unfortunately, for patients older than 65 years of age, standard-dose BEACOPP was toxic in the HD9 study, a randomized study of the regimen versus COPP–ABVD, causing 21% early deaths in this older population.[76]

Regardless of these excellent results in younger patients by the GHSG, the GITIL has reported that ABVD has a similar efficacy to BEACOPP if high-dose chemotherapy (HDCT) is planned at the time of relapse or refractory disease.[64] In the GITIL trial, patients were randomly assigned to either four cycles of BEACOPP escalated plus four cycles of BEACOPP baseline or to six to eight cycles of ABVD, each followed by local RT when indicated. Patients with residual or progressive disease after the initial therapy were to be treated with high-dose salvage therapy with ASCT. The 7-year FFTF was significantly better with BEACOPP than ABVD (85% vs 73%); however, there was no significant difference in the 7-year OS between arms after completion of the overall planned treatment (89% vs 84%). Although two of these three randomized trials showed some benefit in survival with BEACOPP, longer follow-up periods are essential to confirm the conclusion because toxicities, including secondary malignancies, are issues for long-term survival in these young patients. Most of the institutes in the United States are still using ABVD as the first-line chemotherapy backbone of treatment for patients with HL, mostly because of its high efficacy, high tolerability, and lower toxicity rates compared with BEACOPP escalated.[75]

After the introduction of BV for patients with relapsed or refractory cHL, investigators conducted a phase III randomized study (ECHELON-1) to incorporate this novel agent into initial therapy of advanced-stage cHL.[77] Because of significant pulmonary toxicity associated with concomitant administration of this agent and bleomycin, this anti-CD30 antibody–drug conjugate was substituted for bleomycin in the ABVD regimen (A + AVD); patients with advanced cHL received six cycles of A+AVD or six cycles of ABVD. All patients underwent PET-2 restaging, and those with a DS score of 5 had the option of switching to alternative frontline therapy. At a median follow-up period of 2 years, modified PFS rates were superior in the A +AVD group compared with the ABVD group (82% vs 77%) with lower rates of pulmonary toxicity. However, higher rates of neutropenia and peripheral neuropathy (all grades) were reported in the A + AVD group. At a 3-year update, results remained superior for those receiving A + AVD.[78] In the North American subgroup, patients with a high-risk IPS (≥4) appeared to have a statistically significant PFS benefit with A + AVD compared with ABVD, with a hazard ratio (HR) of 0.396.[79] Two-year PFS and OS results for this NA subgroup overall were 88% and 76.4%, and 97% and 93.2%, respectively ($P = .094$). Based on these differences at 2 years between the A + AVD and ABVD groups, a number of US centers now administer A + AVD as initial therapy for advanced-stage cHL, especially for patients with high IPS or preexisting lung disease; granulocyte colony-stimulating factor support and careful monitoring of peripheral neuropathy and hepatic function are mandatory with this regimen.

In one phase 2 study, BV was given as initial therapy to patients with cHL 60 years of age or older who were considered ineligible for standard chemotherapy.[80] Ninety-one percent of the patients responded, with a 73% CR rate. Unfortunately, the median PFS result with BV alone was only 10.5 months. Brentuximab has also been studied in combination with other drugs (nivolumab, dacarbazine, bendamustine) in another small study of older patients with cHL who were not considered eligible to receive chemotherapy.[81] Responses were good for all of the regimens in this trial; unfortunately, results with BV appeared inferior compared with results after the combination of this drug with either nivolumab or DTIC. The combination of brentuximab with bendamustine was considered more toxic than the other combinations. Another

small phase II trial has shown early promising activity of the anti-PD1 antibody, nivolumab, as an alternative to bleomycin in combination with AVD, and results of the randomized phase III SWOG S1826 trial comparing N-AVD and A-AVD are awaited.[82]

Predictors of Outcomes for Advanced-Stage Classical Hodgkin Lymphoma

The Value of Positron Emission Tomography in Hodgkin Lymphoma

Staging by PET scan is proven as a standard of care, but PET is also a valuable tool for evaluation of response and prediction of outcomes in patients with HL. In one study, an interim PET scan obtained after two cycles of therapy (PET-2) was a stronger prediction of outcome than the IPS, with 2-year PFS results for patients with positive PET-2 results of 13% compared with 95% for those with negative PET-2 results.[83] The PET-2 also strongly predicts treatment failure.[84] In a meta-analysis, a positive PET-2 result in low-intermediate–risk advanced HL patients was a reliable predictor of poor response.[85] Interim PET scans are now routinely incorporated into clinical trial designs, can stratify high and low risk patients, and guide treatment escalation or deescalation strategies. However, the role of interim PET imaging after two cycles of either ABVD or escalated BEACOPP remains controversial in practice for the individual patient despite integration in numerous upfront studies in advanced cHL. Historical studies that demonstrated that positive PET imaging following two cycles of ABVD were associated with poor outcomes were inherently flawed because treatment failure was determined by imaging with histologic confirmation of relapse rarely performed.[86–88] Given a historically high false-positive rate for FDG-PET imaging in patients with cHL, this may have overestimated the positive predictive value of PET-2 imaging after ABVD therapy. In addition, there are no large studies documenting concordance of PET positivity and histologic findings for cHL. Given the disease biology of cHL, comprising a minority of Reed-Sternberg cells surrounded by an inflammatory infiltrate, a false-positive PET-2 result may be possible. Therefore, other markers are needed as alternative methods to identify poor responders with truly chemorefractory disease.[88]

Other Predictors of Response and Outcomes for Classical Hodgkin Lymphoma

Investigators have demonstrated that tumor burden, as assessed with biochemical markers or by CT imaging, is prognostic for outcomes. A retrospective analysis of patients with early-stage cHL from the HD10 and HD11 trials showed that elevated ESR and large tumor burden (assessed by CT) were predictive of inferior outcomes.[89] With PET imaging, the total metabolic tumor volume (TMTV) measures both tumor size and activity of the tumor and the microenvironment. A prospective analysis of 294 patients with early-stage cHL from the H10 trial found high initial TMTV (>147 cm^3) to be highly prognostic for inferior PFS (5-year rates of 71% and 92%, respectively; P <.0001) and OS (83% and 98%, respectively; P = .0001).[90] However, TMTV was not predictive of PFS or OS results for advanced HL in the PET-adapted HD18 trial cohort, possibly because of a low number of progression events with eBEACOPP.[91]

Investigators have reported that circulating tumor DNA (ctDNA) can predict outcomes of therapy for cHL. A study of 112 patients with newly diagnosed and refractory cHL identified nonsynonymous somatic mutations in ctDNA samples, evaluating previously described *TNFAIP3, ITPKB, GNA13,* and *B2M* genes. *STAT6* was the most frequently mutated gene in 40% of cases.[92] Genotyping of the tumor from HRS cell–enriched samples identified 96 somatic mutations compared with no mutations from the tumor sample from areas devoid of HRS cells. Genotyping of plasma ctDNA identified 106 somatic mutations with a sensitivity of 87.5%, with the additional mutations in the plasma ctDNA thought to be caused by subclonal or anatomic heterogeneity of the tumor. A 2-log-fold drop of ctDNA was associated with superior PFS despite interim PET positivity likely because of the notion that FDG avidity reflects the metabolic activity of the inflammatory component of the mass, whereas ctDNA more accurately reflects tumor burden. Further studies incorporating ctDNA monitoring and PET imaging are needed to establish the role of ctDNA in predicting clinical outcomes.

The MD Anderson Approach to Management of Advanced-Stage Classical Hodgkin Lymphoma

We screen patients for available protocols for initial treatment of advanced-stage disease. As a standard of care, we treat these patients a PET-2–adapted approach. For patients with high-risk disease (IPS ≥4), we use six cycles of A + AVD with interim response assessment using PET-2 imaging. If the PET-2 is interpreted as DS 4 or less, we recommend completing six cycles in total of A + AVD. If the disease is PET-2–positive (DS 5), we transition to non–BEACOPP-based salvage therapy such as ICE or clinical trials using anti-PD1 agents followed by ASCT. In patients with non-high-risk disease (IPS <4) or with contraindications to BV such as preexisting neuropathy or liver disease, we use a RATHL-style approach with two cycles of ABVD followed by interim PET-2 imaging. If PET-2 negative in this situation (DS ≤3), we delete bleomycin and complete four

additional cycles of AVD. If PET-2–positive (DS 4 or 5), we transition to non–BEACOPP-based salvage therapy followed by ASCT if the patient is transplant eligible. We reserve IFRT for patients who have presented with an initial bulky mass with residual bulk at the end of therapy. Based on phase II data, we favor the following regimens in specific patient cohorts. Older patients (older than 65 years) receive two lead-in doses of single-agent BV (1.8 mg/kg once every 3 weeks), then six cycles of AVD, then four consolidative doses of single-agent BV in responding patients.[93] HIV-positive patients receive six cycles of A + AVD with careful medication review to avoid interactions with strong CYP3A4 inhibitors to minimize toxicity.[94]

REFRACTORY OR RELAPSED HODGKIN LYMPHOMA

Although many patients with HL are cured with frontline therapy, 10% to 15% of patients with early-stage disease with unfavorable risk factors and 40% of patients with advanced-stage disease with high-risk factors can develop relapse or refractory disease. Relapsed HL can be divided into three subgroups: early relapse within 12 months of CR after first-line chemotherapy, late relapse after CR more than 12 months after first-line chemotherapy, and primary refractory HL (patients who never achieve a CR). Moskowitz and colleagues[95] identified the following three prognostic factors associated with EFS in patients receiving ICE followed by HDCT and ASCT: CR less than 1 year, extranodal disease, and presence of B symptoms. The 5-year EFS rate was 83% in patients with zero to one factor compared with 10% if all three factors were present.[95]

Standard Therapy for Relapsed or Refractory Classical Hodgkin Lymphoma

For patients with relapsed or refractory disease after standard frontline management, additional salvage chemotherapy followed by HDCT plus ASCT is the standard approach. One of the key goals of salvage chemotherapy is to achieve CR before ASCT. The response rates of multiple salvage regimens are listed in Table 13–11. It is difficult to directly compare these regimens because they have not been evaluated in randomized clinical trials.

Although all patients at relapse should undergo screening for protocol therapy, the most common salvage chemotherapies outside clinical trials are the platinum-containing regimens such as ICE or DHAP (cisplatin, cytarabine, dexamethasone). With ICE, the ORR was 88%, and the CR rate was 26%.[95] Using variations of this this regimen, patients with PET negativity before ASCT had an EFS of greater than 80%.[96] The DHAP regimen provided similar results, with ORR of 89% and CR rate of 21%.[97] Gemcitabine-containing regimens are also effective in therapy of patients with relapsed or refractory cHL. A phase II study of single-agent gemcitabine, 200 mg/m^2 given on days 1, 8, and 15 of a 28-day schedule, produced an ORR of 43% with a CR rate of 14%.[98] The GVD regimen (gemcitabine, vinorelbine, and pegylated liposomal doxorubicin) was evaluated by the CALGB in 91 patients with relapsed or refractory HL. The ORR was 70%, with a CR rate of 19%.[99] The 4-year PFS and OS rates for transplant-naïve patients treated with GVD followed by ASCT were 52% and 70%, respectively. In patients in whom prior transplant had failed, the 4-year DFS and OS rates were 10% and 34%, respectively. The GDP regimen produced similar results, with an ORR of 62% and a CR rate of 10%.[100] A combination regimen named IGEV (ifosfamide, gemcitabine, vinorelbine) was evaluated in 91 patients and produced an ORR of 81% with a high CR rate of 54%; 60% of patients with primary refractory disease responded to IGEV.[101]

TABLE 13-11 Salvage Chemotherapy Regimens for Hodgkin Lymphoma

Regimen	ORR (%)	CR (%)
DHAP	88	21
ASHAP	70	34
ESHAP	73	41
MINE	73	34
ICE	85	26
IGEV	81	54
GND	70	19
GDP	62	10
Nivolumab (+/- ICE if not in CR)[90]	94	91

ASHAP, doxorubicin, methylprednisolone, cytarabine, cisplatin; CR, complete response; DHAP, dexamethasone, cytarabine, cisplatin; ESHAP, etoposide, methylprednisolone, cytarabine, cisplatin; GDP, gemcitabine, dexamethasone, cisplatin; GND, gemcitabine, vinorelbine, pegylated liposomal doxorubicin; ICE, ifosfamide, carboplatin, etoposide; IGEV, ifosfamide, gemcitabine, vinorelbine; MINE, mitoguazone, ifosfamide, vinorelbine, etoposide; ORR, overall response rate.

High-Dose Chemotherapy with Autologous Stem Cell Transplantation for Relapsed Hodgkin Lymphoma

For patients with chemotherapy-sensitive disease, the treatment of choice after relapse is HDCT followed by ASCT. This recommendation is based on reports from two historically important, randomized clinical trials.[102,103] In the BNLI study, patients with relapsed or refractory HL received BEAM (carmustine, etoposide,

Table 13-12 Initial Management of the Patient with HL Establishing the Diagnosis

Diagnosis	Workup

- FNA alone is insufficient
- Hematopathology review of all slides with at least one tumor paraffin block; rebiopsy if consult material is nondiagnostic
- Core-needle biopsy may be adequate if diagnostic, but an excisional or nodal biopsy is recommended
- Recommend staining for CD15, CD30, T and B panels, CD20, PAX5
- Adequate immunophenotype to confirm diagnosis
  ○ Paraffin panel for HL including NLPHL:
  ○ CD20, PAX-5, CD30, CD3, CD15 and CD45 (LCA)
  ○ EBER
- EBV proteins (ie, LMP1) recommended for NS grade 2 or anaplastic variants
Of use in certain circumstances:
- Immunohistochemical studies:
  ○ LMP1
  ○ BOB1, OCT2, and CD79a (differential diagnosis with B-cell lymphoma, unclassifiable with features intermediate between classical HL and DLBCL and primary mediastinal large B-cell lymphoma).
  ○ CD21, CD23, or CD35 (follicular dendritic cell markers), CD57, BCL6, and IgD in cases of NLPHL (may help with T-cell/histiocyte-rich large B-cell lymphoma)
  ○ CD2, CD43, ALK, and EMA (differential diagnosis with anaplastic large-cell lymphoma)
Strongly recommend:
- Core biopsy for tissue banking by protocol
	- History and physical examination, including:
	  ○ B symptoms (fever, sweats, weight loss)
	  ○ ETOH intolerance
	  ○ Pruritus
	  ○ Fatigue
	  ○ Performance status
	  ○ Examination of nodes
	  ○ Spleen, liver
	- CBC, differential, platelets
	- LDH; LFTs, including alkaline phosphatase, AST, ALT, and albumin, BUN, creatinine
	- ESR
	- Screening for HIV-1, HIV-2, hepatitis B and C (HBcAb, HBsAg, HCVAb)
	- Chest radiography
	- CT of the neck, chest, abdomen, and pelvis
	- PET-CT
	- MUGA or ECG
	- Counseling: fertility, psychosocial if clinically indicated
	Useful in selected cases:
	- Pregnancy test: women of childbearing potential
	- Discuss fertility issues and sperm banking for patients of childbearing potential
	- Semen cryopreservation if chemotherapy or pelvic RT is contemplated

ALK, anaplastic lymphoma kinase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; DLBCL, diffuse large B-cell lymphoma; EBER, Epstein-Barr virus-encoded small RNA; ECG, echocardiography; EBV, Epstein-Barr virus; EMA, epithelial membrane antigen; ESR, erythrocyte sedimentation rate; ETOH, alcohol; HBcAb, hepatitis B core antibody; HBsAg, hepatitis B surface antigen; HCVAb, hepatitis C virus antibody; HIV, human immunodeficiency syndrome; HL, Hodgkin lymphoma; LDH, lactated dehydrogenase; LFT, liver function test; MUGA, multigated acquisition; NLPHL, nodular lymphocyte–predominant Hodgkin lymphoma; NS, nodular sclerosis; PET, positron emission tomography; RT, radiation therapy.

cytarabine, and melphalan) at high doses followed by an ASCT or at lower doses (mini-BEAM) without an ASCT. The 3-year freedom from second treatment failure was significantly better for patients who received HDCT (53% and 10%, respectively). The GHSG/European Group for Blood and Marrow Transplantation (EBMT) randomized trial compared four cycles of Dexa-BEAM (dexamethasone plus BEAM) versus two cycles of Dexa-BEAM followed by ASCT for patients with relapsed cHL. At 3 years, the FFTF in the high-dose therapy group was 55% compared with 34% after four cycles of chemotherapy. These studies were performed before development of the PET and anti-CD30 therapy.

Multiple investigators have reported that response to salvage chemotherapy is a strong predictor of long-term outcome after ASCT. In one study, the 5-year OS for patients who were in CR at the time of ASCT was 79% compared with 59% for those in PR and 17% for those with resistant disease at the time of ASCT.[104] Studies have shown the impact of pre-ASCT PET scan results on EFS; those with negative pre-ASCT PET scan results have significantly higher EFS and failure-free survival rates compared to patients with positive pre-ASCT PET scan results.[105–107] In another trial, a European intergroup study evaluated a dose-intensified regimen before ASCT.[108] Patients were randomly assigned after two cycles of DHAP to ASCT or sequential cyclophosphamide, methotrexate, and etoposide before ASCT. There were no significant differences between the two treatment arms in terms of mortality, FFTF, and OS. Thus, the less toxic approach consisting of two cycles of DHAP (or other salvage regimen such as ICE) followed by HDCT and ASCT remained the standard of care for patients with relapsed HL. Achievement of PET negativity is also an established goal for these patients before ASCT, but the role of anti-CD30 antibody therapy remained unclear before the development of BV.

Patients with disease progression after ASCT uniformly have a poor outcome. In a study of patients with HL who failed ASCT, the median time to progression after the next therapy was only 3.8 months, and the median survival after ASCT failure was 26

months.[9] An international multicenter retrospective study showed that the survival of patients who relapsed after an ASCT did not improve from 1981 to 2007.[109,110] However, there has been a major advance in the treatment of relapsed or refractory cHL in the past 10 years: development of novel agents for the disease.

Immunotherapeutic Agents for Relapsed or Refractory Classical Hodgkin Lymphoma

Brentuximab Vedotin

CD30 was considered an ideal target for monoclonal antibody therapy for HL because its expression is highly restricted to HRS cells. BV (SGN-35) is an intravenously administered antibody–drug conjugate that consists of the CD30-specific monoclonal antibody conjugated with monomethyl auristatin E (MMAE) by linker peptide. Binding of the antibody–drug conjugate to CD30 on the cell surface causes internalization of the drug by endocytosis, and the drug subsequently travels to the lysosome, where proteases cleave the linker and release MMAE to the cytosol.[111] Released MMAE binds to tubulin and disrupts the microtubule polymerization, resulting in cell cycle arrest and apoptotic death of CD30-expressing cells. After reports of efficacy in a phase I trial in 45 patients with relapsed or refractory CD30-positive hematologic malignancies, investigators conducted a pivotal phase II trial of 102 patients with HL with relapse using this drug alone following HDCT and ASCT.[112,113] Patients received BV 1.8 mg/kg every 3 weeks up to a maximum of 16 cycles. The ORR was 75%, with a CR rate of 34%. These data led to the first drug approval by the US Food and Drug Administration (FDA) for the treatment of patients with HL in more than 30 years. Durable remission was reported with a longer follow-up period, and the median OS and PFS were 40.5 months and 9.3 months, respectively.[114] The 3-year PFS rate of patients who achieved CR with BV was 58%. This survival outcome is notable considering that the patients enrolled in this trial had disease progression after ASCT.

Achieving CR before ASCT is the key to better outcomes in patients with relapsed or refractory HL. Therefore, BV is often used as a third-line therapy in patients who have not achieved CR after second-line salvage chemotherapy such as ICE. The Seattle group retrospectively evaluated the efficacy of BV in patients who had disease refractory to platinum-based salvage chemotherapy.[6] Fifteen patients who had PET-positive disease after platinum-based salvage therapy received a median of four cycles of BV. PET scan negativity occurred in eight (53%) of 15 patients but was only observed in patients who had achieved partial remission or stable disease after salvage therapy. This suggests that BV can achieve CR by PET in a considerable subset of patients with platinum-refractory HL before ASCT.

Maintenance therapy with BV after ASCT was evaluated in a placebo-controlled randomized phase III study (AETHERA).[115,116] Patients were enrolled in this study if they had (1) disease considered refractory to frontline therapy, (2) relapse less than 12 months after frontline therapy, or (3) relapse 12 months or more after frontline therapy with extranodal disease. At 5 years of follow-up, PFS rates were superior in the BV compared with placebo cohorts (59% and 41%, respectively) with 90% of patients who received BV reporting significant improvement or resolution of associated peripheral neuropathy.[117] Patients with high-risk disease, defined as the presence of two or more risk factors (relapse <12 months or refractory to frontline therapy, best response of PR or stable disease to most recent salvage therapy, extranodal disease at pretransplant relapse, B symptoms at pretransplant relapse, two or more prior salvage therapies) demonstrated more pronounced benefit (5-year PFS HR, 0.42) with BV maintenance therapy. Therefore, BV consolidation should be offered to high-risk patients who develop relapse after first-line chemotherapy.

In an attempt to improve responses before ASCT, investigators performed a phase II study of BV in combination with ICE chemotherapy as salvage therapy before ASCT. Patients received two cycles of BV-ICE before evaluation, and patients in CMR received an additional dose of BV only rather than a third cycle of BV-ICE. Of the 39 patients in the efficacy analysis, 69% achieved a CMR, and 26% achieved a partial (P) MR, with a 1-year PFS of 69% post ASCT.[118] In another phase II study of 66 patients who received BV in combination with ESHAP chemotherapy before ASCT, the pretransplant CMR was 80%, with a PMR of 7%, and a projected 1-year PFS of 87% after ASCT.[119] BV was also studied in a phase II trial that combined this drug with bendamustine before ASCT; the pretransplant CMR and PMR rates were 79% and 5%, respectively, with projected 3-year PFS and OS rates of 67% and 88%, respectively.[120] No significant excess in toxicity was reported in the trials evaluating BV in combination with chemotherapy before ASCT; however, a longer follow-up period is required to evaluate whether improved pretransplant responses translate to improved survival outcomes.

Bendamustine is a bifunctional alkylating agent derived from 2-chloroethylamine that had been a standard chemotherapy for patients with indolent lymphoma (follicular lymphoma and mantle cell lymphoma).[121,122] The Memorial Sloan-Kettering Cancer Center conducted a phase II trial of bendamustine in patients with HL who had relapse after ASCT or were

not eligible for ASCT.[123] Patients received bendamustine 120 mg/m^2 on days 1 and 2 of a 28-day cycle for six planned cycles. The ORR was 53%, with a 33% CR rate; the median PFS was 5.2 months. Preliminary data of a phase I/II study for the combination of bendamustine and BV for relapsed or refractory transplant-naïve patients produced an ORR of 94%, with a CR rate of 82%.[124] At the time of report, 20 of 34 patients who had a response to this combination had undergone ASCT.

BV also appears effective in therapy of patients with relapse after allogeneic stem cell transplantation (allo-SCT). In one retrospective analysis of 184 patients with relapsed cHL after allo-SCT, 88 had received BV salvage therapy, and 104 did not. Of the patients who received BV, 29% achieved a CR and 45% PR with significantly more patients alive at last follow-up compared with patients who did not (34% and 18%, respectively; $P = .003$).[125] However, salvage BV did not affect the incidence of chronic graft-versus-host disease, and 1-year OS rates post recurrence after allo-SCT were similar (76% and 67%, respectively).

Programmed Death-1 Inhibitors

PD-1 ligand is overexpressed on malignant Reed-Sternberg cells in HL, facilitating immune evasion from antitumor cells. Nivolumab is a PD-1 immune checkpoint inhibitor antibody that selectively blocks the interaction between PD-1 and its ligands PD-L1 and PD-L2. By inhibiting PD-1 interaction, nivolumab can enhance T-cell function, which results in antitumor activity. Nivolumab has been evaluated in a multicenter phase II trial for patients with relapsed or refractory cHL with or without prior exposure to BV or prior ASCT. Of 243 treated patients, the ORR was 69% with a median PFS of 14.7 months.[126] Based on promising single-agent activity, nivolumab has gained FDA approval for relapsed or refractory HL after ASCT.

PD-1 inhibition with nivolumab has been explored in a phase II study as salvage therapy at first relapse in relapsed or refractory cHL.[127] Thirty-nine patients with relapsed or refractory cHL received 3 mg/kg of nivolumab every 2 weeks for six cycles followed by interim PET imaging. If patients were in CR, they proceeded to ASCT, whereas seven patients with PR or stable disease proceeded to receive nivolumab in combination with ICE chemotherapy for two cycles. After six cycles of nivolumab, the ORR was 90%, and CR was 77%; if the patients who were treated with nivolumab and ICE were included, the ORR was 94%, and CR was 91%. PD-1 inhibition was well tolerated, with mainly grade 1 to 2 AEs (fatigue, rash, fever, and thrombocytopenia). The impressive response rates to PD-1 inhibition at first relapse compared with historical data with salvage chemotherapy indicate that alternative salvage strategies may be effective for chemotherapy-refractory disease. However, the durability of response after ASCT is still to be determined, with reported 1-year PFS and OS rates of 79% and 97%, respectively.

Nivolumab has also been evaluated in combination with other novel agents. In a phase I/II study, nivolumab in combination with BV was evaluated as initial salvage therapy for 62 patients with relapsed or refractory HL, resulting in an ORR of 82% with a CR rate of 61%.[128] Grade 3 or higher AEs occurred in 31% of patients with no patients discontinuing therapy because of immune-related AEs. In a separate phase II study, a risk-adapted approach was applied in patients ages 5 to 30 years with relapsed or refractory HL. Four cycles of nivolumab in combination with BV were administered, and patients achieving less than CMR after induction received additional cycles of BV plus bendamustine for intensification. Of the 44 patients who have been treated, only 11 (25%) received BV plus bendamustine intensification. The ORR, CR rate, and 1-year PFS rate were 82%, 59%, and 91%, respectively.[129] Nivolumab has also been investigated as part of a triplet combination with ipilimumab and BV in a phase I study of 64 patients with relapsed or refractory HL. Across all dose levels, the triplet combination demonstrated impressive outcomes with an ORR of 95%, CR rate of 84%, and 1-year PFS of 72%.[130] This study also compared doublet combinations of nivolumab plus BV and BV plus ipilimumab in separate arms; nivolumab-containing cohorts appeared to have superior outcomes.

Another PD-1 inhibitor, pembrolizumab, has also received FDA approval for the treatment of patients with relapsed or refractory HL based on pivotal single-agent phase II data. A total of 210 patients with relapsed or refractory HL were enrolled in three separate cohorts to receive pembrolizumab 200 mg once every 3 weeks based on prior exposure to BV or ASCT. Across all cohorts, the ORR was 72%, the CR rate was 28%, and the median duration of response 16.5 months.[131] Pembrolizumab was well tolerated with grade 3 or 4 AEs occurring in 12% of patients. Avelumab, a human IgG-1 monoclonal antibody that selectively binds to PD-L1 has been evaluated in a phase 1 study of 31 patients with relapsed or refractory HL and has promising activity with an ORR of 55% and CR rate of 6% across all dose levels.[132]

Allogeneic Stem-Cell Transplantation

The main advantage of an allo-SCT is its graft-versus-HL effect. Retrospective studies have suggested this effect because of lower relapse rates in allo-SCT patients with chronic graft-versus-host disease (GVHD) and responses after donor lymphocyte infusion.[133] Initial studies of allo-SCT in HL patients described high

rates of nonrelapse mortality (NRM), up to 61%. More recent studies evaluated therapy with reduced-intensity conditioning (RIC), treatment associated decreased treatment-related mortality (TRM); in these studies, RIC allo-SCT induced long-term remissions in about 30% of patients.[134,135]

The EBMT reviewed 168 patients who had undergone allo-SCT.[135] Seventy-nine patients received myeloablative conditioning, and 89 patients received RIC. Fifty-two percent of patients had undergone a prior ASCT, and 45% had chemotherapy-sensitive disease. The NRM was significantly lower, and OS was significantly better with RIC versus myeloablative conditioning. One-year NRM was 23%, and 5-year PFS and OS were 18% and 28%, respectively, in patients who received RIC.

At MDACC, we reviewed the outcomes of 58 patients who received RIC with fludarabine–melphalan in preparation for allo-SCT.[136] Overall, 83% of patients had undergone a prior ASCT and 52% had chemotherapy-sensitive disease at the time of allo-SCT. The TRM at 2 years was 15%, with nearly half of the TRM occurring within the first 100 days after allo-SCT. The incidence of chronic GVHD was 73%. The 2-year PFS and OS rates were 32% and 64%, respectively. There was a trend toward improvement in PFS for those with chemotherapy-sensitive disease but not for OS. Allo-SCT is still an important option for eligible patients who develop relapse after ASCT.

Chimeric Antigen Receptor T-Cell Therapy

Anti-CD30 chimeric antigen receptor (CAR) T-cell therapy attempts to overcome the limited bioavailability and short half-lives of anti-CD30 monoclonal antibodies such as BV. A phase I study evaluated an anti-CD30 CAR T product with dual CD28 and 4-1BB co-stimulatory domains in nine patients with relapsed or refractory CD30-positive lymphomas. Of the nine patients, six (67%) had HL with a CR rate of 78% and a median PFS of 13 months among all patients.[137] In a separate phase 1 study of 14 patients with relapsed or refractory HL who received an anti-CD30 CAR T product, the ORR was 67%, and the CR rate was 58% for the evaluable patients.[138] In an update, incorporating two different phase I/II studies, these latter investigators evaluated results for 41 patients with relapsed or refractory cHL who received anti-CD30 CAR-Ts.[139] The median number of prior therapies was seven (range, 2–23), and 32 of these patients received fludarabine-based T-cell depletion. Of these 31, 72% had a response, and 59% had CR. The 1-year PFS was 36%, and the OS was 94%. CAR T–related cytokine release syndrome in this study occurred in 10 patients and was grade 1; significant neurotoxicity did not occur. A longer follow-up period is required to establish whether durable remissions are observed following this promising approach.

Bispecific Antibodies and Antibody–Drug Conjugates

Bispecific antibodies are immunoglobulin molecules containing two different antigen binding sites, one directed against specific tumor antigens and the other toward native immune effector cells. A phase Ib study of a CD30 bispecific antibody targeting CD16A on natural killer cells in combination with pembrolizumab demonstrated promising clinical activity in patients with relapsed or refractory HL. Of 30 patients, the ORR and CR rates were 88% and 46%, respectively, with an estimated 6-month PFS rate of 77% at the highest dose level.[140] The treatment was well tolerated, with grade 3 or higher toxicity occurring in only 13% of patients. A separate phase 1 study investigated an anti-CD25 antibody conjugated to a pyrrolobenzodiazepine dimer toxin was investigated in a phase 1 trial in adult patients with relapsed or refractory HL. Of the 37 patients treated at the highest dose cohort, the ORR was 86% and CR rate of 43% in a heavily pretreated population without excess toxicity.[141] However, durability of responses have not been reported because of limited follow-up. Therefore, despite promising activity with bispecific antibodies and antibody–drug conjugates, longer follow-up is needed to determine durability of responses.

The MD Anderson Approach to Relapsed or Refractory Classical Hodgkin Lymphoma

Patients with relapsed or refractory HL are planned for second-line or salvage chemotherapy followed by an ASCT. We screen patients who have relapsed or refractory HL for current clinical trial options. Patients who respond to salvage chemotherapy are planned to undergo ASCT. We offer BV maintenance therapy after ASCT for patients deemed high risk based on (1) relapsed or progressive HL occurring less than 12 months from end of frontline therapy; (2) a history of refractory HL, defined as progression during or failure to achieve CR after frontline therapy; or (3) extranodal involvement at the time of pre-ASCT relapse. For patients who fail to achieve a CMR before ASCT, we use either BV in combination with salvage chemotherapy (ICE or bendamustine) or a PD-1 inhibitor (pembrolizumab or nivolumab single agent, or nivolumab in combination with BV) to deepen the response before ASCT. In patients who have refractory disease or relapse after ASCT, we consider BV (if not previously refractory to BV) as single agent or in combination with bendamustine or nivolumab. In BV-refractory patients, we consider nivolumab or pembrolizumab

as single-agent therapy. Given the benefits versus risks of allo-SCT, a subset of patients can be potentially considered for this approach, particularly otherwise healthy patients who achieve complete remission with addition therapies.

CONCLUSION

Although standard frontline chemotherapy with or without RT offers a high cure rate for patients with cHL, approximately 20% of patients develop refractory or relapsed disease. Thus, the challenge that remains is how to best develop strategies of therapy that increase the cure rates for the refractory and relapsed group of patients while decreasing both short- and long-term toxicities, including secondary malignancies, for patients who are cured of their disease with current standard approaches. Huge recent achievements have occurred on both fronts, including a decrease of both the number of cycles of chemotherapy and the doses of RT for patients with early-stage disease and introduction of BV into frontline regimens paired with chemotherapy. The advent of PD-1 inhibitors has demonstrated the ability to have significant efficacy even in patients with BV-resistant disease. Future directions are anticipated to increase the focus on evaluating the efficacy of combinations of targeted agents, with likely future trials exploring the potential activity of chemotherapy-free targeted treatment combinations in the frontline setting. Better understanding of the molecular biology of both cHL and NLPHL will also lead to more rationally designed novel agent trials and allow us to best select treatment strategies. The future of HL treatment has evolved significantly over the past decade, and these successes will only be significantly multiplied over the next decade to follow.

MD ANDERSON PRACTICE TIPS

- For favorable early-stage classical HL, omitting radiation consolidation after two cycles of ABVD based on PET negativity is associated with a risk of treatment failure based on the GHSG HD16 study.
- For unfavorable early-stage classical HL, omitting RT based on a PET-adapted strategy provides results that are noninferior to those achieved with chemotherapy plus RT based on the GHSG HD17 trial. However, therapy must be escalated BEACOPP $\times 2$, followed by ABVD $\times 2$.
- In advanced-stage classical HL, if treating with ABVD, interim PET scan should be performed after two cycles, and bleomycin may be safely omitted with a negative PET scan result based on the RATHL study.
- The A (BV)-AVD regimen is recommended for classical HL patients who are young (younger than 60 years), with stage IV disease, and with high IPS (score 4–7) because patients with these features benefited the most in the ECHELON-1 trial by the substitution of BV for bleomycin in ABVD.
- The A-AVD regimen is associated with a high risk of neutropenia, and growth factor support is required to minimize the risk of neutropenic fever.
- Before beginning salvage chemotherapy and ASCT based on PET positivity, one must confirm histopathologic relapsed or refractory classical HL.

KEY CONCEPTS

- Systemic light chain (AL) amyloidosis is a rare protein deposition disease typically found accompanied by an indolent plasma cell dyscrasia, although it can also be found concomitantly with multiple myeloma.
- In the systemic presentation (some cases are localized), commonly affected organs may include the heart, kidneys, liver, gastrointestinal tract, and peripheral nervous system.
- Diagnosis requires histologic evidence of amyloid deposition in tissues either by aspiration of abdominal subcutaneous fat or biopsy of the organs involved, with the demonstration of clonal plasma cell disorder and abnormal free light chain in serum or urine.
- Historical cohorts of patients with severe cardiac involvement have a poor prognosis of 4 to 6 months, though recent studies show this can be greatly improved with successful treatment.
- Plasma cell–directed therapy with or without high-dose melphalan and autologous stem cell rescue is the treatment of choice for patients with confirmed systemic AL.
- Multidisciplinary care is beneficial because these patients have distinct clinical presentations, symptoms, and risks compared with patients with other plasma cell dyscrasias.

Systemic light chain (AL) amyloidosis is a rare plasma cell proliferative disorder. It results from organ deposition of amyloid fibrils that consist of the NH_2-terminal amino acid residues of the variable portion of the light chain immunoglobulin molecule. The estimated age-adjusted incidence is nine to 14 cases per million person-years, and around 4000 new cases are estimated annually in the United States. About 75% of cases are derived from lambda light chain. AL amyloidosis typically results primarily from a small plasma cell clone in the bone marrow or may rarely be associated with another B-cell malignancy. Coexisting AL amyloid deposits are identified in 10% to 15% of patients with multiple myeloma (MM).

The commonly affected organs include the heart, kidneys, liver, gastrointestinal tract, and peripheral nervous system. This leads to clinical symptomatology of nephrotic syndrome, cardiomyopathy, hepatomegaly, neuropathy, macroglossia, anemia, carpal tunnel syndrome, and periorbital purpura. Prognosis is driven primarily by the extent and severity of cardiac involvement with patients having severe cardiac involvement being at high risk for early death, although this risk is somewhat abrogated with successful plasma cell–directed treatment. However, beyond overall survival (OS), patients with AL often have chronic symptoms relating to the morbidity of amyloid organ involvement and decreased quality of life. The exact pathophysiology of organ or tissue damage in AL amyloidosis is not completely understood, but the reduction of serum free light chain concentration after chemotherapy treatment results in improved cardiac function and suggests that both circulating amyloidogenic free light chains in addition to those deposited play an important role in organ dysfunction. New therapies targeting the underlying plasma cell clone are improving hematologic response rates and potentially patient survival with the disease, and therapies that directly target the already deposited light chain amyloid continue in development at this time.

EPIDEMIOLOGY AND RISK FACTORS

Light chain amyloidosis is typically found with an underlying low-grade or indolent plasma cell population in the bone marrow, though is also found concomitantly with MM and less commonly with other hematolymphoid neoplasms. Estimates of the incidence and prevalence of AL have been drawn from population-based studies in the United States and European countries ranging from three to 14 cases per million-person years.[1–4] There are an estimated 12,000 people living in the United States with AL.

Less is known about specific risk factors for developing AL amyloidosis. Studies have identified male gender and age as risk factors, though these are also risk factors for the development of plasma cell neoplasms and monoclonal gammopathy of undetermined significance (MGUS) as well.[5,6]

PATHOPHYSIOLOGY AND GENETICS AND MOLECULAR CLASSIFICATION

The nature of the fundamental events relating to protein misfolding and amyloid fibril formation and deposition are not fully understood, though factors relating to the underlying light chain sequence and posttranslational modification, co-deposition of other proteins, and microenvironment factors in the tissue are all thought to have impact. The underlying light chain variable region gene usage (IGVL) is thought to play a role in amyloidogenesis and pattern of organ tropism. In one study of 821 AL patients, specific IGVL patterns assessed by mass spectrometry was associated with localized versus systemic AL, and specific patterns associated with organ involvement such as LV6-57 patients being more likely to have renal involvement and LV1-44 patients being more likely to have cardiac involvement.[7] Posttranslational modification including N-glycosylation has been associated with light chain amyloidosis, and its mechanism in amyloid fibrillogenesis is supported by the finding that isoelectric points of AL polypeptides spread heterogeneously and may form by electrostatic interaction of oppositely charged particles.[8] N-glycosylation of light chains in systemic AL is more prevalent compared with light chains found in non-amyloid plasma cell dyscrasias and contributes to mass or charge heterogeneity and potentially amyloidogenesis.[9,10] Co-deposition of other proteins with amyloid fibrils including serum amyloid P component and apolipoproteins is thought to play a role in fibril development and tissue deposition, though the exact mechanism is debated.[11] In addition to the deposition of amyloid fibrils, circulating amyloid light chains are thought to also play a significant role in mediating organ dysfunction, particularly cardiac dysfunction in AL. This is evidenced by studies in model organisms demonstrating worsened cardiac dysfunction after infusion of amyloid light chains, though not normal control light chains in the absence of amyloid fibril deposition, and clinical evidence showing early concordance in improvement in cardiac function with reduction of circulating involved amyloid light chains.[12–14]

In comparison with MM, plasma cells of AL amyloidosis are generally of lower clonal burden and have lower rates of proliferation.[15] The amyloid clone is often enriched for the $t^{11;14}$ structural abnormality detected by fluorescence in situ hybridization, found in up to 50% of patients with AL,[16] and genome-wide association studies show cyclin D1 playing a prominent role in AL.[17]

CLINICAL PRESENTATION AND DIAGNOSTIC WORK-UP

The clinical presentation of AL amyloidosis depends on the spectrum and severity of organ involvement. The common clinical features at diagnosis include cardiomyopathy typically presenting as heart failure with preserved ejection fraction (up to 80% of patients), nephrotic syndrome with or without renal insufficiency (up to 60% of patients), sensory axonal neuropathy, autonomic neuropathy, and hepatosplenomegaly.[18] Symptoms of systemic AL are often vague initially, and this leads frequently to delay in diagnosis of this rare condition.[19] Many patients have multisystem involvement at diagnosis (Table 14–1).

The diagnosis of AL requires histologic evidence of amyloid deposition in tissues either by aspiration of abdominal subcutaneous fat or biopsy of the organs involved, with the demonstration of clonal plasma cell disorder and abnormal free light chain in serum or urine (Table 14–2). The pathognomonic diagnostic feature of amyloid deposition is a positive tissue stain with Congo red to demonstrate apple-green birefringence under polarized light. Standard pathological tests, such as the use of antibodies for serum κ or λ light chains in immunohistochemistry, have low sensitivity for the diagnosis.[20] Mass spectrometry–based proteomic analysis of amyloid tissue should be pursued when available.[21] This helps confirm the type of amyloid protein because more than 10 forms of systemic amyloidosis are currently known, and correct typing is imperative for appropriate treatment, particularly with targeted therapies available for distinct amyloid subtypes such as transthyretin (TTR) amyloidosis.

Table 14–1 Clinical Presentations of Immunoglobulin Light Chain Amyloidosis

Organ Involvement	Clinical Presentation
Kidney	**Nephrotic syndrome Renal failure**
Heart	Abnormal electrocardiogram: low voltages in the standard leads Nondilated cardiomyopathy Arrhythmia
Peripheral and autonomic nervous system	Numbness Muscle weakness Carpal tunnel syndrome Postural hypotension Erectile dysfunction Altered bowel habit Anhidrosis
Gastrointestinal tract	Macroglossia Early satiety Diarrhea Malabsorption Gastrointestinal bleeding Hepatomegaly
Coagulation system	Periorbital purpura (raccoon eyes) Abnormal clotting tests Life-threatening bleeding

Assessment of amyloid organ involvement is performed at diagnosis with the use of serum biomarkers such as troponin-T or I, NT-proBNP (N-terminal pro b-type natriuretic peptide) levels, electrocardiography, echocardiography, cardiac magnetic resonance imaging (MRI) studies, 24-hour urine studies for albuminuria, and other studies as deemed clinically appropriate.

Table 14–2 Laboratory and Pathologic Evaluation of Immunoglobulin Light Chain Amyloidosis

Laboratory Evaluation
CBC with differential Serum creatinine Liver enzyme and bilirubin Coagulation tests: prothrombin time, partial thromboplastin time, factor X SPEP and immunofixation UPEP and immunofixation Serum free light chains 24-hour urine protein Cardiac troponin, BNP, or NT-proBNP Cardiac testing: ECG, echocardiogram, cardiac MRI, chest radiography Peripheral nervous system: EMG, nerve conduction test Pulmonary function tests
Pathologic Evaluation
Bone marrow aspiration and biopsy with immunohistochemistry staining for κ and λ light chain Abdominal fat pad aspiration or organ biopsy with Congo red staining for amyloid Mass spectrometry for amyloid protein identification

BNP, brain natriuretic peptide; ECG, electrocardiography; EMG, electromyography; MRI, magnetic resonance imaging; NT-proBNP, N-terminal pro b-type natriuretic peptide; SPEP, serum protein electrophoresis; UPEP, urine protein electrophoresis.

PROGNOSIS AND STAGING

Even though patients commonly have a low burden of clonal plasma cells, long-term survival outcome is poor in those presenting with advanced cardiac involvement. However, depending on the particular pattern and severity of organ involvement, survival outcomes are very broad. We do note additionally that beyond lifespan, the patient's quality of life can be severely impacted by his or her amyloid burden even without cardiac involvement. Although patients with severe cardiac involvement at diagnosis have been reported to have a median survival period of 4 to 6 months versus 16 months in those without it, data have shown that successfully treated patients who have obtained deep hematologic responses have improved survival.[5]

Cardiac dysfunction is best assessed by the elevation of cardiac biomarkers such as brain natriuretic peptide (BNP) and NT-proBNP, as well as cardiac troponin-T (cTnT) and troponin I (cTnI). Many studies have confirmed the prognostic significance of markers of cardiac injury and dysfunction in patients with AL amyloidosis, and they been incorporated in the staging system for AL amyloidosis[22,23] (Table 14–3). The first of the two main staging systems in AL, both originating with the Mayo Clinic group, is the European modification of the Mayo 2004 staging system, which assigns points for NT-proBNP greater than 332 ng/L and cTnT greater than 0.035 ng/mL; patients with both markers elevated are then stratified by NT-proBNP levels greater than or less than 8500 ng/L to differentiate stage IIIA and IIIB. Likewise, in the Revised Prognostic Scoring System from the Mayo Clinic group, patients are assigned a score of 1 for each of the difference between involved and uninvolved light chain (FLC-diff) 18 mg/dL or greater, cTnT 0.025 ng/mL or greater, and NT-proBNP 1800 pg/mL or greater. The median OS times of patients with Mayo stage I, II, III, and IV (score 0, 1, 2, and 3, respectively) are 94, 40, 14, and 5.8 months, respectively.[24]

RESPONSE CRITERIA

The overall aims of therapy for patients with AL are to improve and stabilize organ function and improve patient quality of life and survival. Because therapy has centered on the targeting of the underlying plasma cell clone to reduce circulating light chain burden, response criteria have included both hematologic and organ-based response categories (Table 14–4). Notably, historical response criteria were validated in patients presenting with dFLC levels greater than 50 mg/L, which is denoted as measurable disease; about 90% of patients at diagnosis meet this threshold of differential free light chains (dFLC). A minority of patients present at diagnosis with low dFLC levels, and a separate hematologic response category has been validated for this population defined as achieving a dFLC below 10 mg/L.[25] More recently, analysis of achieving this less than 10 mg/L dFLC threshold has been validated in a broader cohort of patients with AL presenting with measurable disease (dFLC >50 mg/L) and termed *stringent dFLC response*, with support for superior outcomes among this population compared with historical hematologic Very Good Partial Response (VGPR) or Complete Response (CR) outcomes.[26] However, for practical purposes, a hematologic VGPR or deeper response is the goal of upfront plasma cell–directed therapy. Organ responses strongly correlate with improved patient survival and outcomes and remain a central goal of therapy. Organ response definitions are typically based on biomarker reductions and other markers of cardiac or renal function. A cardiac response requires a 30% or greater reduction in NT-proBNP levels with absolute reduction of greater than 300 ng/L, and a renal response requires a 50% reduction of at least 0.5 g/day of proteinuria on 24-hour urine collection without increase in creatinine clearance of 25% over baseline.[27] Obtaining

TABLE 14–3 Staging of Immunoglobulin Light Chain Amyloidosis

Stage	Biomarkers	Stage	Survival Period (months)
Mayo 2004 with European modification[23]	NT-proBNP >332 ng/L cTnT >0.035 ng/mL	I: 0 points II: 1 point IIIA: 2 points and NT-proBNP <8500 ng/L IIIB: 2 points and NT-proBNP >8500	86 43 17 3–5
Revised Mayo Clinic staging[24]	NT-proBNP >1800 ng/L cTnT >0.025 ng/mL dFLC >180 mg/L	I: 0 points II: 1 point III: 2 points IV: 3 points	93 62 13 6

cTnT, cardiac troponin-T; dFLC, difference between the involved and uninvolved light chains; NT-proBNP, N-terminal pro b-type natriuretic peptide.

TABLE 14–4 Immunoglobulin Light Chain Amyloidosis Response Criteria

Category	Criteria
Complete response	Normal free light chain ratio and levels; negative serum and urine immunofixation
Very good partial response	dFLC <40 mg/L
Partial response	>50% reduction in dFLC
No response	Less than partial response

dFLC, difference between the involved and uninvolved light chains.

a deep hematologic response is intrinsically linked to later obtaining an organ response and improved survival.[28] More recently, deeper biomarker-graded organ responses have been shown superior to standard definitions of binary organ response; although prognostic, the ramifications on treatment are not fully understood, and the aim of plasma cell–directed therapies continues to be deep hematologic response.[29] Still, there remains a population of need who have persistent organ morbidity because of deposited amyloid despite achieving hematologic response to upfront therapy.

TREATMENT

Treatment for patients with AL amyloidosis shares similar drug classes targeted to malignant plasma cells as that for MM, consisting mainly of various chemotherapy combinations or high-dose therapy with autologous stem cell transplantation (HDT-ASCT). The choice of treatment should be based on risk stratification. Patients with good performance status and normal cardiac markers should be considered for HDT-ASCT or induction chemotherapy followed by HDT-ASCT.

High-Dose Therapy with Autologous Stem Cell Transplantation

HDT-ASCT has been used since the early 1990s, and it is an effective treatment modality associated with hematologic and organ responses as well as long-term survival.[30,31] It is associated with high treatment-related mortality rate ranging from 13% to 43%, especially in patients with cardiac involvement. Careful patient selection based on comorbidity index and cardiac staging is the key to successful outcome of high-dose therapy in AL amyloidosis. A randomized trial comparing HDT-ASCT with standard-dose melphalan plus high-dose dexamethasone showed no differences in hematologic or organ response. Landmark analysis examining only patients surviving more than 6 months after transplant also showed no survival benefit for HDT-ASCT.[32] However, almost 25% of the patients in this study received reduced-dose melphalan conditioning, which has been associated with poor transplant outcomes. Moreover, the 24% treatment-related mortality rate in the HDT-ASCT arm was unusually high, and the lack of careful patient selection and use of tertiary transplant centers may have biased results against HDT-ASCT. A meta-analysis of 12 studies of HDT-ASCT showed no superiority of HDT-ASCT over conventional chemotherapy.[33] However, in the MD Anderson Cancer Center experience, improved 10-year survival outcomes were reported in patients undergoing HDT-ASCT compared with conventional chemotherapy.[31] At centers with extensive experience in treating patients with AL amyloidosis, HDT-ASCT provides promising outcomes with careful patient selection. Patients with organ involvement of two or fewer organs and AL amyloidosis with renal involvement show the best overall outcome with HDT-ASCT.

Induction Therapy Before High-Dose Therapy with Autologous Stem Cell Transplantation

Induction chemotherapy is frequently administered for cytoreduction before HDT-ASCT, particularly in patients with concurrent asymptomatic or symptomatic myeloma. Hematologic and organ responses with the inclusion of novel agents in induction therapy can also lead to improvement in performance status and result in transplant eligibility for newly diagnosed patients.[34] A randomized trial evaluating the role of induction therapy containing bortezomib and dexamethasone followed by HDT-ASCT versus HDT-ASCT in patients with newly diagnosed AL amyloidosis showed better responses and survival outcomes with induction therapy.[35] In our experience, incorporation of novel agent induction therapy before transplant is associated with improved survival.[36] Based on retrospective studies and clinical experience, the combination of bortezomib, cyclophosphamide, and dexamethasone (CyBorD) has evolved to become a standard-of-care chemotherapy regimen for newly diagnosed AL amyloidosis.[34,37] Whereas conventional lenalidomide-based myeloma induction regimens such as bortezomib, lenalidomide, and dexamethasone (VRD) can lead to deep hematologic

responses, lenalidomide-related toxicity even at significant dose reductions has tempered their use in AL amyloidosis patients..[38] Deep and rapid hematologic responses with the incorporation of the anti-CD38 monoclonal antibody daratumumab to CyBorD have also been reported..[39] An ongoing randomized study comparing this regimen with CyBorD alone has shown significantly improved rates of VGPR or deeper responses (79 vs 49%), leading to improved rates of cardiac organ responses at 6 months (42 vs 22%) for patients with newly diagnosed AL amyloidosis (NCT03201965).[40]

Maintenance Therapy After High-Dose Therapy with Autologous Stem-Cell Transplantation

There are minimal data to support maintenance treatment in AL amyloidosis after HDT-ASCT, and it is not routinely administered. However, decisions are individualized to a given patient and can be considered in patients with AL amyloidosis with concurrent myeloma. Moreover, consolidation or maintenance therapy (or both) can also be considered in patients achieving less than VGPR after HDT-ASCT given the prognostic significance of achieving at least a hematologic VGPR in patients with AL amyloidosis.[41]

Induction Therapy for Transplant-Ineligible Patients

The combination of melphalan and dexamethasone (MDex) has long been considered a standard of care for first-line treatment of transplant-ineligible patients and is associated with a good hematologic response (67%) and low toxicity (4%).[42] More recently, results from the EMN-03 study were reported, which evaluated the combination of MDex versus bortezomib, melphalan, and dexamethasone (BMDex) in patients not undergoing HDT-ASCT.[43] Overall response (81%) and ≥ VGPR or deeper response (64%) significantly higher with BMDex versus MDex (56% and 38%, respectively). Cardiac progression rates also favored BMDex, although at a median follow-up time of 25 months, no OS difference had yet been observed between the two regimens. CyBorD also remains an excellent option for transplant-ineligible patients with AL amyloidosis.

Relapsed or Refractory Immunoglobulin Light Chain Amyloidosis

There is no standard of care for relapsed or refractory AL amyloidosis, although a number of small studies have investigated the use of novel agents approved for the treatment of patients with MM in this setting. Lenalidomide has been evaluated in two phase 2 studies in relapsed or refractory AL amyloidosis with an overall response rate (ORR) of 67% and 39%.[44,45] However, treatment was also associated with significant toxicities such as fatigue and myelosuppression, requiring frequent lenalidomide dose reductions and treatment discontinuations. Pomalidomide has shown a similar ORR of 48% to 68%,[46–48] and its use generally favored over lenalidomide because of better tolerance in patients with AL amyloidosis. The proteasome inhibitors (PIs) carfilzomib[49] and ixazomib[50] have demonstrated ORRs of 63% and 52%, respectively, including in patients who were previously PI refractory. Given the known cardiopulmonary adverse events associated with carfilzomib, it should be used with caution in carefully selected patients and –generally avoided in patients with cardiac amyloid involvement. Finally, the safety, tolerability, and promising efficacy of daratumumab in relapsed or refractory AL amyloidosis have been reported in two recent prospective studies showing deep hematologic responses with ≥ VGPR or deeper response rates of 86% and 48%.[51,52]

CONCLUSIONS

Systemic AL remains a rare disease in which patients benefit from multidisciplinary care beyond that provided solely by the treating hematologist. Medical management of patients with cardiac amyloidosis often differs from standard heart failure treatment, and cardiologists and other specialists experienced in the management of AL such as nephrologists, hepatologists, and neurologists, often at specialized tertiary centers, do make a difference in the care of patients. With the incorporation of additional novel agents, including monoclonal antibodies, obtaining deeper hematologic responses and organ responses, patient outcomes are expected to continue to improve, though ultimately these patients require long-term follow-up with their amyloid teams because each patient's constellation of organ involvement and symptoms is unique.

MD ANDERSON PRACTICE TIPS

- Confirmation of the diagnosis with tissue mass spectrometry is beneficial when feasible.
- Be cautious of the possibility of patients presenting with concomitant MGUS and other forms of cardiac amyloidosis such as TTR (this is not as rare as one may think).
- Organ biopsies are not always required if another surrogate site can provide the diagnosis, but consider cardiac imaging ,including cardiac MRI, to carefully rule out or rule in cardiac AL involvement when in doubt.
- Quick initiation of plasma cell–directed therapy is warranted for patients with severe organ involvement; starting chemotherapy before consideration for stem cell transplantation is appropriate.
- Patients with worsening organ function because of increasing amyloid burden often require reinitiating or a change in therapy even before involved serum free light chains may formally meet criteria for hematologic relapse.
- Anti–amyloid fibril–directed antibodies continue in development and may provide a future avenue for expanding how we are able to directly treat the disease.

KEY CONCEPTS

- Waldenström macroglobulinemia (WM) is synonymous with lymphoplasmacytic lymphoma as well as the presence of a monoclonal immunoglobulin (Ig) M gammopathy.
- Most cases are associated with a mutation in MYD88, which offers a better prognosis than MYD88 wild-type cases.
- CXCR4 mutations are associated with increased IgM levels and a higher risk of hyperviscosity.
- Patients with WM are at risk for symptomatic hyperviscosity syndrome, which may present with visual disturbances, dizziness, cardiopulmonary symptoms, decreased consciousness, and a bleeding diathesis. Therapy for hyperviscosity consists of prompt initiation of plasma exchange followed by systemic therapy.
- As with other low-grade lymphoid malignancies, asymptomatic patients and those without significant cytopenias or other end-organ manifestations can be observed with close follow-up.
- Therapy should be initiated for symptomatic hyperviscosity, hemoglobin less than 10 g/dL, platelet count 100,000 K/uL or less, bulky adenopathy, symptomatic organomegaly, symptomatic cryoglobulinemia, or significant peripheral neuropathy

BACKGROUND

Waldenström macroglobulinemia (WM) is an uncommon, low-grade malignancy characterized by the presence of lymphoplasmacytic cells together with the presence of a monoclonal immunoglobulin (Ig) M paraproteinemia.[1] The median age at diagnosis is between 63 and 68 years of age, men are more commonly affected than women, and the disease is more common among whites than those of other populations.[2] Approximately, 90% of WM cases are associated with a mutation of the myeloid differentiation primary response 88 (*MYD88*) gene located on chromosome 3p22. WM cases having wild-type *MYD88* are associated with worse outcomes and a higher propensity to transform into an aggressive lymphoma compared with cases having the *MYD88* mutation.[3–11] Of WM cases having the *MYD88* mutation, approximately one third also have a mutation of chemokine receptor 4 (CXCR4); CXCR4 mutations are often associated with higher IgM levels and therefore increased risk of hyperviscosity.[11,12]

CLINICAL PRESENTATION AND DIAGNOSTIC WORK-UP

Many patients with WM are asymptomatic at the time of diagnosis. When symptoms develop, they are caused by tumor infiltration (cytopenias, hepatomegaly, splenomegaly), circulating IgM (hyperviscosity, cryoglobulinemia, cold agglutinin anemia), or tissue deposition of IgM (neuropathy, glomerular disease, amyloidosis). Patients with symptomatic hyperviscosity syndrome may present with visual disturbances, dizziness, cardiopulmonary symptoms, decreased consciousness, and a bleeding diathesis. Polyneuropathies are common. Some are associated with antigenic targets of the monoclonal serum IgM, including myelin-associated glycoprotein (MAG) and sulfatide. Others are caused

by direct tumor infiltration, tissue deposition of IgM, the amount and properties of the circulating monoclonal IgM, binding of unidentified antigens, or associated amyloidosis.[2] Patients may also present with cold or warm autoimmune hemolytic anemia, iron-deficiency anemia, or dilutional anemia.[2]

Initial evaluation (Table 15–1) of patients with suspected WM should include a complete blood count with differential, serum chemistries, liver function tests, viral hepatitis serologies, serum protein electrophoresis (SPEP) and immunofixation, quantitative immunoglobulin levels, and a β_2-microglobulin. In patients suspected of having cryoglobulinemia, a cryocrit should be drawn and together with SPEP and quantitative immunoglobulin specimens should immediately be placed in a 37°C water bath to facilitate accurate assessment.[13] A serum viscosity level and a cold agglutinin titer or Coombs test should be drawn if hyperviscosity or hemolytic anemia is suspected. Iron-deficiency studies should be considered for patients with a microcytic anemia.[13] Bone marrow biopsy should be performed to demonstrate infiltration by lymphoplasmacytic cells; determine the cause of anemia; and when indicated, evaluate for systemic light chain (AL) amyloidosis. Flow cytometry typically demonstrates a pattern of sIgM$^+$, CD19$^+$, CD20$^+$, CD22$^+$, CD79$^+$.[14] Testing for the MYD88 L265P gene mutation in the marrow or peripheral blood can help distinguish WM from marginal zone lymphoma and multiple myeloma, in which the incidence of this mutation is low.[3–10] Patients should have baseline computed tomography (CT) scans (neck, chest, abdomen, and pelvis) or positron emission tomography (PET)–CT scans to evaluate for extramedullary disease. An ophthalmologic examination should be performed to look for retinal changes (hemorrhages or "sausage vessels") in patients with suspected hyperviscosity syndrome.[15,16] In patients with neuropathy, standard evaluation for endocrinopathies and vitamin deficiencies should be accompanied by evaluation with nerve conduction studies, electromyography, and serum studies for antimyelin associated glycoprotein (MAG) and antiganglioside 1 (GM1) antibodies.[11,16] Abdominal fat pad biopsy with Congo red staining should also be performed to evaluate for associated amyloidosis.

PROGNOSTIC STRATIFICATION

Patients with symptomatic WM may be risk stratified according to the International Prognostic Scoring System for WM (ISSWM). This system considers five covariates, namely, advanced age (older than 65 years), hemoglobin 11.5 g/dL or less, platelet count 100 × 10^9/L or less, β_2-microglobulingreater than 3 mg/L, and serum monoclonal protein concentration greater than 7.0 g/dL. Low risk is defined as having one or no adverse characteristics except for advanced age, intermediate-risk as two adverse characteristics or only advanced age, and high risk as more than two adverse characteristics. In a series, of 587 patients, 5-year survival rates were 87%, 68%, and 36%, for these respective subgroups (P <.001).[17] Among those

Table 15–1 Initial Work-up for Waldenström Macroglobulinemia

Essential Testing	Useful Under Certain Circumstances
History and physical examination	Fundoscopic examination[c]
CBC with differential, BUN, creatinine, electrolytes, liver function tests, uric acid, LDH, β_2-microglobulin	Coombs test
Peripheral blood smear	Anti-MAG) antibody and anti-GM1 antibody
Quantitative immunoglobulins (IgG, IgM, IgA)	EMG and NCS
Serum light chain assay (kappa and lambda)	Congo red staining of abdominal fat pad biopsy and/or bone marrow biopsy
SPEP and immunofixation	Coagulation testing and vWD testing if there is bleeding or bruising
24-hour UPEP and immunofixation	
Serum viscosity[a]	
Hepatitis B and C serology	
Cryocrit[b]	
Cold agglutinin titer	
Unilateral bone marrow aspirate and biopsy with immunohistochemistry and/or flow cytometry and CXCR4 and MYD88 L265P AS-PCR testing	
PET-CT or CT of the neck, chest, abdomen, and pelvis	

[a]Most patients with serum viscosity of <4 cP will not have symptoms of hyperviscosity.
[b]If cryocrit result is positive, then initial and follow-up cryocrit and serum protein electrophoresis (SPEP) samples should be measured under warm conditions.
[c]When hyperviscosity is suspected or immunoglobulin (Ig)M >/-3g/dL.
AS-PCR, Allele-specific polymerase chain reaction; BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; EMG, electromyography; LDH, lactate dehydrogenase; NCS, nerve conduction study; PET, positron emission tomography; UPEP, urine protein electrophoresis; vWD, von Willebrand disease.

deemed to be high risk, elevated lactate dehydrogenase increases the likelihood of death from WM (90% vs 60%).[18]

MANAGEMENT

Asymptomatic patients and those without significant cytopenias or other end-organ manifestations can be followed every 3 months during the first year (with longer follow-up intervals thereafter in the setting of disease stability).[19] In such patients, lifelong follow-up is necessary because the risk of developing symptomatic disease is approximately 6% in the first year, 39% at 3 years, and 55% at 5 years.[19] Higher M protein and marrow infiltration have been associated with increased risk of progression to symptomatic disease.[19]

Therapy should be initiated for symptomatic hyperviscosity, hemoglobin less than 10 g/dL, platelet count 100,000 K/uL or less, bulky adenopathy, symptomatic organomegaly, symptomatic cryoglobulinemia, or significant peripheral neuropathy (Table 15–2).[20] Therapy for hyperviscosity consists of prompt initiation of plasma exchange followed by systemic therapy.[21] Given the risk of precipitating symptomatic hyperviscosity in patients with high levels of circulating IgM, packed red cell transfusions should be used conservatively and preferably administered after plasma exchange in high-risk patients.

Frontline Therapy

When autologous stem cell transplant (ASCT) may be considered at relapse, nucleoside analogs should be avoided before stem cell harvest, and primary therapy with a proteasome inhibitor or alkylator, together with rituximab with or without dexamethasone should be considered.[21–26] Combinations of bortezomib-rituximab with or without dexamethasone result in an overall response rate (ORR) of 57% to 83%. Carfilzomib–rituximab–dexamethasone showed an ORR of 68%.[25,26] Comparable ORRs (77%–96%) have been seen with alkylating agent-based regimens (R-CHOP [rituximab, cyclophosphamide, doxorubicin hydrochloride, = Oncovin, and prednisone], Rituximab, cyclophosphamide, vincristine, prednisone, R-cyclophosphamide–dexamethasone, and rituximab-bendamustine); however, of these, R-bendamustine is the preferred regimen given improved progression-free survival (PFS) and fewer adverse effects.[11,27–30] The use of single-agent rituximab should be reserved for patients unable to tolerate combination chemotherapy because ORRs and PFS are low (20%–50% and 12–24 months, respectively).[11,31,32] Rituximab must be used with caution in patients with highly elevated IgM levels because of the potential for an associated IgM flare. In these cases, it is prudent to delay administration of rituximab until after the patient has received cytoreductive therapy.[33] In 2015, the Bruton tyrosine kinase (BTK) inhibitor ibrutinib was approved by the Food and Drug Administration for patients with symptomatic WM. In a phase II trial of 63 patients, ibrutinib was associated with a single-agent partial response rate of 57% and an ORR of 90% in previously treated patients.[11,34] In subset analysis, patients with MYD88 L265P mutations responded better (major response rate, 80%) to ibrutinib than did those without the mutation. However, patients with CXCR4 mutations in addition to MYD88 mutations had a less favorable response (major response rate, 60%).[11] Of note, ibrutinib is not cytotoxic and therefore must be continued until evidence of progression or unacceptable toxicity. A phase 3 trial comparing ibrutinib–rituximab versus rituximab in both newly diagnosed and relapsed or refractory patients with WM noted an ORR of 95% in the combination group compared with 48% in the rituximab arm.[35,36]

When future ASCT is not a consideration, nucleoside analog–based combinations with either fludarabine or cladribine could be considered as alternatives to previously detailed regimens.[37–40] In a trial by the Waldenström's Macroglobulinemia Clinical Trials Group, fludarabine–rituximab demonstrated an ORR of 96% and median PFS of 51.2 months.[40] Cladribine has also been studied alone and in combination with cyclophosphamide and/or rituximab. In 18 previously untreated patients with WM who received two cycles of cladribine, cyclophosphamide, and rituximab, the ORR was 94%, and the median time to response was 2.4 months; at 5 years, 83% of patients remained alive.[39] However, the use of nucleoside analogs must be weighed against the risk (~6%–12%) of second malignancies and transformation to large-cell lymphoma.[41]

Table 15–2 Treatment Indications for Waldenström Macroglobulinemia

- Symptomatic hyperviscosity (eye grounds, neurologic changes)
- Hemoglobin <10 g/dL (caused by marrow involvement, hypersplenism, or cold agglutinin hemolytic anemia)
- Platelet count ≤100,000/μL
- Bulky adenopathy
- Symptomatic organomegaly
- Symptomatic cryoglobulinemia
- Amyloidosis
- Neuropathy
- Cryoglobulinemia
- Pseudo von Willebrand disease

Regimen Selection

Choice of therapy should take into consideration both disease- and patient-related factors, including genomic information, comorbidities, and presenting signs and symptoms. In patients with both MYD88 and CXCR4 mutations who need rapid therapeutic benefit, the preferred regimen is rituximab with either and bendamustine or bortezomib and dexamethasone. However, if a rapid response is not needed, treatment with ibrutinib with or without rituximab could also be considered. In patients with MYD88 mutations but wild-type CXCR4, all of these regimens are likely to be effective, so the choice of regimen is primarily based on the side effect profile. In patients with neither mutation, a chemotherapy-based regimen as described earlier is the preferred first-line agent.[12]

With respect to patient-related factors, providers should consider the patient's age, functional status, and comorbidities when selecting a regimen. Bortezomib can be associated with a significant risk of neuropathy; therefore, in patients with baseline neuropathy, this agent ideally should be avoided as frontline therapy. Carfilzomib can be used in lieu of bortezomib in patients with neuropathy, but caution should be used in older adult patients and in those with cardiopulmonary disease, given the risk for toxicity. In patients with cardiac disease, ibrutinib should also be used cautiously, given the risk of atrial fibrillation. For patients with a history of atrial fibrillation or who develop treatment-emergent atrial fibrillation, careful co-management with a cardiologist is essential. Additionally, because antithrombotic therapy with aspirin or anticoagulation is needed in most patients with atrial fibrillation, further caution is needed with the use of ibrutinib given the increased risk for bleeding with this agent. Newer BTK inhibitors with less off-target effects of bleeding and arrhythmias are being evaluated as single agents and in combination therapy in various ongoing trials.

Maintenance

Although retrospective studies have shown improved PFS and overall survival (OS) in patients who received maintenance rituximab (the recommendation is for eight infusions over 2 years),[42] the prospective, randomized, multicenter MAINTAIN trial did not note any improvement in PFS or OS for the group that received 2 years of maintenance rituximab.[12,43] In light of this, the use of maintenance rituximab remains controversial and cannot be routinely recommended at this time.

TREATMENT AT DISEASE RELAPSE

At relapse, patients may be retreated with a previously successful regimen if their initial remission lasted at least 1 year. When the initial disease-free-interval is shorter, use of one of the other regimens (detailed earlier) should be considered.

For patients intolerant to rituximab, the fully human monoclonal anti-CD20 antibody ofatumumab may be useful. In patients who have previously received rituximab, two cycles of ofatumumab were associated with an ORR of 52%.[44]

The role of stem cell transplantation in patients with WM is still being defined. In a retrospective review of 158 patients (32% had at least three prior lines of therapy) the 5-year PFS and OS with ASCT were 39.7% and 68.5%, respectively.[45] Several groups have also studied allogeneic stem cell transplantation in patients with WM. The 5-year PFS was between 49% and 56% but with notable treatment-related mortality.[46]

FUTURE DIRECTIONS

Many new therapies are under study for patients with WM. These include next-generation proteasome inhibitors (eg, ixazomib), phosphoinositide 3-kinaseinhibitors, the histone deacetylase inhibitor panobinostat, immune checkpoint inhibitors, monoclonal antibodies such as the anti-CD38 antibody daratumumab, and chimeric antigen receptor T-cell therapies. Some of the most promising agents are the BCL2 inhibitor venetoclax and the CXCR4 inhibitor ulocuplumab.[47] In addition, second-generation Bruton tyrosine kinase inhibitors, such as zanubrutinib, and ERK pathway inhibitors are also being evaluated. The development of these and other agents together with emerging knowledge about the molecular drivers of this disease continues to propel the field forward and allow for more rational targeted therapies.[11,12,47]

MD ANDERSON PRACTICE TIPS

- Many patients present asymptomatically. The work-up should include laboratory studies (refer to the text for specifics), staging CT or PET-CT scans, bone marrow biopsy, and CXCR4 testing of the marrow or blood. Ophthalmology evaluation should be performed. Other testing should be guided by the patient's symptoms.
- In patients with WM and neuropathy, nerve conduction studies, electromyography, and serum studies for anti-MAG and anti-GM1 antibodies should be evaluated.
- Higher M protein and marrow infiltration have been associated with increased risk of progression to symptomatic disease. However, M protein levels alone should not be used to determine the timing of treatment.
- In patients with both MYD88 and CXCR4 mutations who need rapid therapeutic benefit, the preferred regimen is rituximab with either and bendamustine or bortezomib and dexamethasone. If a rapid response is not needed, ibrutinib with or without rituximab could also be considered. In patients with neither mutation, a chemotherapy-based regimen such as rituximab–bendamustine is the preferred frontline regimen given improved PFS and fewer adverse effects.
- Rituximab should be used with caution in patients with significantly high IgM levels because IgM flare can occur.
- At relapse, patients may be retreated with a previously successful regimen if their initial remission lasted at least 1 year.

KEY CONCEPTS

- The updated International Myeloma Working Group (IMWG) criteria for multiple myeloma includes patients with bone marrow plasmacytosis of at least 60%, an involved-to-uninvolved serum-free light-chain ratio of at least 100, or more than one focal lesion on magnetic resonance imaging (MRI) studies of at least 5 mm in size in addition to the criteria of hypercalcemia, renal disease, anemia, and bone disease (CRAB).
- The IMWG now recommends advanced imaging, such as whole-body low-dose computed tomography (CT), positron emission tomography–computed tomography (PET-CT), or MRI to evaluate for bone disease because it can detect up to 80% more lesions compared with plain film radiographs.
- Triplet therapies, such as with a proteasome inhibitor, immunomodulatory drugs, and steroids have shown significant improvement over doublet therapy. Ongoing trials are investigating quadruplet therapy, with promising initial results, and they could become standard of care in the future.
- As of 2020, autologous transplant after induction chemotherapy remains the standard of care and has shown significant improvement in progression-free survival. This might change in the future depending on disease risk status, and minimal residual disease testing.
- Maintenance therapy after autologous transplant is recommended because it has been shown to significantly improve progression-free survival.
- As of 2020, there is no indication to treat patients with smoldering myeloma. However, this could change in the future, because recent trials have shown that treatment of high-risk smoldering myeloma can potentially delay its progression to myeloma.

Plasma cell dyscrasias are heterogeneous disorders arising from the proliferation of a monoclonal population of plasma cells. Some of these disorders can present serendipitously as benign processes that can be observed; others are highly aggressive and require immediate intervention. The most common plasma cell dyscrasia is monoclonal gammopathy of undetermined significance (MGUS), a benign condition that can be observed. Related disorders include smoldering multiple myeloma (SMM), multiple myeloma (MM), solitary plasmacytoma of the bone, extramedullary plasmacytoma, Waldenström macroglobulinemia, primary amyloid light-chain amyloidosis, heavy-chain disease, POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome, and TEMPI (telangiectasias, elevated erythropoietin and erythrocytosis, monoclonal gammopathy, perinephric fluid collection, and intrapulmonary shunting) syndrome. The spectrum of MGUS, SMM, and MM represents a natural progression of the same disease. This chapter focuses on the etiology, genetics, biology, diagnosis, clinical features, and current therapy of MM.

Major recent discoveries have changed the way we understand, diagnose, and treat plasma cell dyscrasias. The initial sequencing of the myeloma genome and single-cell genetic analysis paved the way for the concept of intraclonal heterogeneity and Darwinian selection of clones. Increasingly sensitive diagnostic and monitoring techniques allow for more accurate diagnosis, minimal residual disease (MRD) monitoring, and detection of early relapse. New diagnostic criteria for MM have been implemented, and the introduction of novel classes of agents such as immunomodulatory

drugs and proteasome inhibitors has led to improved overall survival. In addition, immunotherapy using monoclonal antibodies against different myeloma targets including CD38 and SLAMF7 (CS1) has significantly improved outcomes for patients with relapsed and/or refractory disease.

MULTIPLE MYELOMA

MM is a malignant proliferation of plasma cells. In virtually all cases, myeloma cells (as well as their precursors MGUS and SMM) secrete immunoglobulins (Igs). Usually, myeloma cells secrete IgG (60%); other types are less common (IgA 20%, IgD 2%, IgE <0.1%, biclonal <1%). Light-chain-only secretion is noted in 18%; less than 5% of patients do not secrete a heavy- or light-chain immunoglobulin (nonsecretory MM).

Epidemiology and Risk Factors

In 2019, approximately 32,000 people were diagnosed with MM in the United States with, 12,960 deaths from the disease. The median age at diagnosis is 69 years. The incidence is highest in the age range of 65 to 74 years (27.7%), followed by the 75- to 84-year-old range (24.7%). The annual age-adjusted incidence of the disease per 100,000 population is 7.2 among white men and 4.3 among white women. Among Blacks, the frequency doubles to 14.8 in men and 10.5 in women. There is also a difference in mortality by racial group. The annual age-adjusted mortality rate per 100,000 is 4.0 and 2.5 in White men and women, respectively, and 7.7 and 5.3 in Black men and women, respectively. The incidence and mortality rates are lowest among Asians and Pacific Islanders.

Risk factors that predispose to MGUS and MM point toward common shared etiologic environmental and genetic factors. Age is a risk factor for MGUS, because its prevalence is four times higher among individuals at least 80 years old than among those 50 to 59 years old. Increased risk of MGUS has also been reported in first-degree family members of patients with MGUS and MM (risk ratio between 2 and 3). In a study of Black and White women of similar socioeconomic status, obesity, black race, and increasing age conferred an increased risk of MGUS. Personal and family history of autoimmune or inflammatory disorders as well as infections have been linked to an increased risk of MGUS and MM. Exposure to infections has been hypothesized to be involved in the malignant transformation of MM, or it could represent impaired immunity associated with MGUS and SMM, which often precedes a diagnosis of MM. Radiation exposure, pesticides, and cleaners are also associated with an increased risk of MGUS and MM.

Although MM is not an inherited disease, more than 100 familial cases have been reported in the literature. The largest series described 39 unique families with 79 cases of MM. Both dominant and recessive inherited traits may play a role in familial MM. Large genomic studies have identified low penetrant genetic variants that confer a modest increase in the risk of developing MM.[1,2] Based on epidemiologic and familial aggregation studies, most of the inherited risk of developing MM may result from different genetic polymorphisms, each of which has only a small effect on the predisposition to develop disease.[3]

Pathophysiology and Genetics/Molecular Classification

MM arises from terminally differentiated B cells or even early committed B cells (germinal-center B cells) that manifest clinically as more differentiated plasma cells. The major role of normal differentiated plasma cells is to produce Igs (antibodies) to fight infections. To become an effective part of the adaptive immune system, B cells must undergo Ig gene rearrangement and affinity maturation in response to antigens presented by antigen-presenting cells within the lymph node germinal center. For this to occur, hypervariable regions in the Ig heavy-chain locus (IGH in chromosome 14q32) undergo programmed mutations (somatic hypermutation) through which, among others, double DNA strand breaks and chromosomal translocations are generated. The primary etiology of MM has been linked to *IGH* translocations and increased copies of odd-numbered chromosomes (hyperdiploidy), which result in cyclin D dysregulation. These events can be observed early in the course of monoclonal gammopathies (such as in MGUS or SMM) as well as in MM, suggesting that they are primary genetic events. Initial whole-genome and exome sequencing in 38 patients with MM confirmed the complexity of genetic alterations seen in MM and uncovered secondary mechanisms of transformation to MM.[4] Secondary events included mutations in the oncogene *MYC* (most commonly observed in plasma cell leukemia or aggressive forms of MM), mutations in the nuclear factor-κβ (NF-κβ) pathway, including *BRAF* and *RAS*, and chromosome copy number abnormalities such as deletions, amplifications, or additions. Changes in DNA methylation patterns are also important secondary events leading to increased tumor diversity and more aggressive forms of plasma cell dyscrasias.

Different tests for gene expression profiling (GEP) are available for molecular classification of MM. As of this writing, molecular profiling of MM is mostly used for research purposes (eg, identification of high-risk MM for inclusion in clinical trials). These tests may

become increasingly important as we develop more personalized treatment for MM.

Serial genomic analysis during the disease course of patients with myeloma has identified different MM subclones within the same tumor. This has been termed *intraclonal heterogeneity*. In this model, different myeloma subclones compete for selection as they are exposed to the microenvironment and therapeutic pressures.[5] Single-cell genetic analysis at diagnosis confirmed that MM is highly heterogeneous and characterized by the accumulation of a diverse range of mutations at the subclonal level.[6] In this scenario, the acquisition of new mutations leads to new subclones with different clinical phenotypes and sensitivities to therapy. Intraclonal heterogeneity in myeloma has many potential implications for therapy, suggesting that subclonal targeting in combination therapies may be needed to eradicate the multiple subclones. Increasing genetic complexity is seen with progression from MGUS to MM and plasma cell leukemia, which may suggest that earlier treatment may result in improved clinical outcomes.

The bone marrow microenvironment also plays a role in the etiology of MM and its related disorders. Upregulation of cytokines that increase vascular permeability, proliferation, or cell homing (interleukin [IL]-6, vascular endothelial growth factor, and insulin-like growth factor) have been involved in the progression to MM. Gene expression profiling has revealed that modulation of certain genes can lead to a permissive microenvironment that promotes growth of myeloma subclones, leading to active disease.[7] Thus, targeting the microenvironment is an area of extensive research that, combined with therapeutic targeting of myeloma subclones, may lead to improved outcomes. New and effective antimyeloma combination therapies and well-designed clinical trials are needed to test these hypotheses.

Clinical Presentation

The clinical presentation of MM and its precursors is variable. Patients with MGUS or SMM are often incidentally diagnosed based on workup for a low albumin-to-globulin ratio, high serum protein, or other conditions such as autoimmune diseases, peripheral neuropathy, skin rashes, or hemolytic anemias.

In contrast, patients initially presenting with MM usually have at least one of the CRAB criteria (hyperCalcemia, Renal disease, Anemia, and Bone disease), classically used to define symptomatic MM. Anemia is the most common finding, occurring in 73% of patients, and is typically a normocytic, normochromic anemia. Anemia can be caused by a variety of factors, including marrow replacement or cytokine production by plasma cells, which lead to decreased erythropoiesis, or decreased erythropoietin levels as a result of renal disease.[8]

Bone pain is common, occurring in 60% of patients, and related to increased resorption of bone, leading to lytic bone lesions. Painful vertebral compression fractures can occur and may represent a medical emergency when associated with symptoms of cord compression. Increased bone resorption has been attributed to factors such as RANK ligand (RANKL), osteoprotegerin (OPG), macrophage inflammatory protein (MIP)-1α, IL-6, and IL-3, which stimulate osteoclast activity in areas infiltrated by plasma cells as a result of interactions between plasma cells and the microenvironment (Fig. 16–1).

An elevated creatinine is a presenting sign in 50% of patients. Renal disease is often attributed to light-chain cast nephropathy resulting from precipitation of light chains that bind to Tamm-Horsfall mucoproteins secreted by cells in the ascending loop of Henle. These precipitated complexes obstruct the distal convoluted tubules and collecting ducts, leading to tubular atrophy and interstitial fibrosis. Other causes of renal failure include hypercalcemia, leading to nephrocalcinosis, as well as amyloidosis, heavy-chain disease, and light-chain disease.

Hypercalcemia of higher than 11 mg/dL is present in 10% of patients and represents a medical emergency requiring hydration with isotonic saline and bisphosphonate therapy with zoledronic acid or pamidronate in moderate or severe cases. Calcitonin can also be used to rapidly reduce serum calcium levels.

Other common presenting symptoms include fatigue (32%) and weight loss (20%). As a result of immune dysfunction, patients are at risk for infections. About 7% to 18% of patients may present with extramedullary plasmacytomas. Less common symptoms include fever, splenomegaly, hepatomegaly, and lymphadenopathy.

FIGURE 16–1 Radiographic image of the skull showing "punched out" osteolytic lesions characteristic of multiple myeloma.

Diagnostic Workup

Once a plasma cell dyscrasia is suspected, a comprehensive diagnostic workup should be initiated to demonstrate the presence or absence of a clonal plasma cell disorder, to determine whether end-organ damage is present, and to evaluate laboratory markers related to prognosis. These should include the following components.

Laboratory Studies

- Complete blood count
- Serum chemistries including creatinine, calcium, albumin, lactate dehydrogenase (LDH), β_2-microglobulin, and immunoglobulin levels (IgG, IgA, IgM)
- Serum protein electrophoresis with immunofixation to quantify monoclonal protein (M-protein) and determine immunoglobulin isotype
- Serum-free light-chain assay to evaluate the ratio of serum κ to λ light chains
- Urinalysis with 24-hour urine collection with protein electrophoresis and immunofixation (Fig. 16–2)

Imaging Studies

- The International Myeloma Working Group (IMWG) now recommends that advanced imaging with either whole-body low-dose computed tomography (CT), positron emission tomography–computed tomography (PET-CT), or magnetic resonance imaging (MRI) be used because they can detect up to 80% more lesions compared with plain film radiographs.[9]
  - An advanced imaging modality is particularly recommended in the diagnosis of SMM to detect subtle bone lesions that would warrant the initiation of treatment. It is also helpful in assessing baseline disease burden as an adjunct to serum and urine markers before initiation of treatment in MM.
  - A CT scan can be helpful in the characterization of soft tissue masses in the case of extramedullary plasmacytomas and can direct to an area to be biopsied.
  - An MRI scan is useful for evaluating the axial skeleton in the presence of symptoms and assessing for spinal cord compression. It can also identify abnormal marrow uptake because T1-weighted images will show a diffuse decrease in marrow signal intensity but will enhance with the administration of contrast.
  - PET-CT can be prone to false-positive findings but has more specificity because of its increased metabolic uptake at the site of lytic lesions, and is the preferred initial baseline advanced imaging modality at the MDACC, in combination with skeletal surveys.
  - There is no role for nuclear bone imaging because bone scan isotopes are not taken up by lytic lesions.

Bone Marrow Aspiration and Biopsy

- Morphologic review and immunohistochemistry (Fig. 11–3)
- Flow cytometry for immunophenotyping of plasma cells:
  - Plasma cells are positive for CD38 and CD138.
  - Normal plasma cells have higher expression of CD19 and CD45; malignant plasma cells typically lack these surface antigens.
  - Malignant plasma cells have increased expression of CD56 and CD117; normal plasma cells have weak expression of these markers.
- Conventional cytogenetic karyotyping.

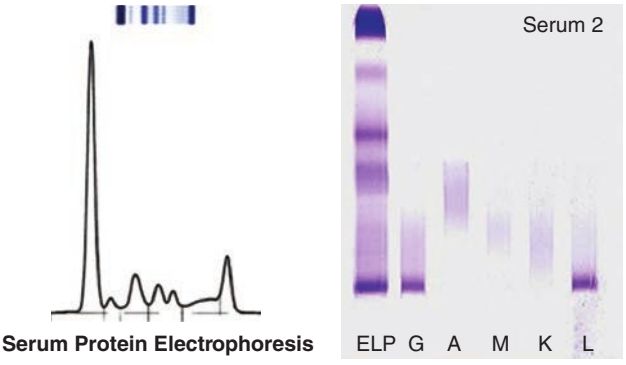

FIGURE 16–2 Serum protein electrophoresis demonstrates an M-protein peak *(left)*. Immunofixation confirms it to be monoclonal IgG lambda type.

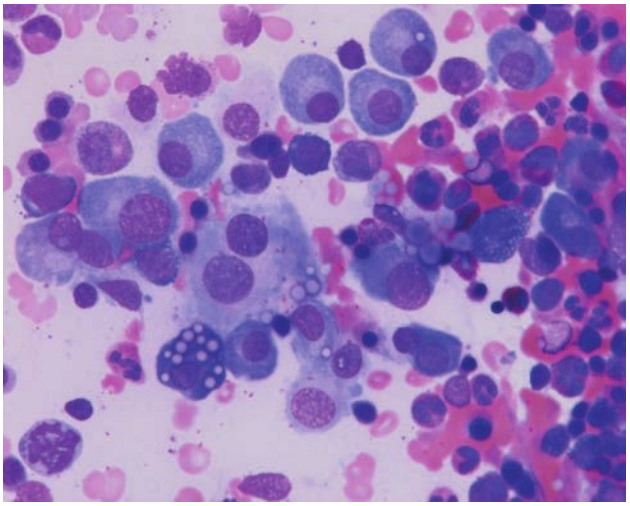

FIGURE 16–3 Multiple myeloma bone marrow aspirate. Some plasma cells have cytoplasmic immunoglobulin inclusions (Wright-Giemsa, 500×).

- Fluorescent in situ hybridization (FISH) for recurrent chromosomal deletions, amplifications, and translocations that have prognostic significance. These include:
  - Deletion 13q14, deletion 17p13 (*TP53*), and deletion of 1p32.
  - Amplification of 1q21.
  - Translocations involving the immunoglobulin heavy-chain locus on chromosome 14q32 and its common partners, including 11q13 (*CCND1*), 4p16 (*FGFR3* and *MMSET*), 16q23 (*c-MAF*), 6p21 (*CCND3*), and 20q12 (*MAFB*).
- GEP of the CD138+ bone marrow aspirate plasma cells to identify high-risk MM and to facilitate inclusion in clinical trials.

Other Tests

- Abdominal wall fat pad biopsy (warranted if there are signs and symptoms suggestive of amyloidosis; see separate chapter), which should be stained with Congo red. Amyloid fibrils show green birefringence under polarized light.
- Serum viscosity (if there are concerns for hyperviscosity usually caused by elevated IgM levels in Waldenström macroglobulinemia; see separate chapter). Hyperviscosity should be a clinical diagnosis, and therapeutic plasma exchange should not be delayed while waiting for the results of serum viscosity level.

Myeloma Diagnostic Criteria

Based on the above workup, a diagnosis of a plasma cell dyscrasia may be made, as summarized in Table 16–1.[10] Historically, SMM and MM have been distinguished by the presence of end-organ damage as defined by CRAB criteria. The 2014 updated IMWG criteria were revised to reclassify some SMM patients as having MM (even in the absence of symptoms) if the patient has clonal bone marrow plasmacytosis of at least 60%, an involved-to-uninvolved serum-free light-chain ratio of at least 100, or more than one focal lesion on MRI studies of at least 5 mm in size. Patients with SMM and at least one of these biomarkers have a 70% to 80% chance of progression to MM at 2 years compared with 20% (10% per year) in the absence of these high-risk features.

Staging and Risk Stratification

The course of MM is heterogeneous. Risk stratification using staging and prognostic tools can help stratify patients in clinical trials and may help guide therapy.

Table 16–1 Definitions of MGUS, SMM, and MM by 2014 IMWG Criteria

		Definition	Progression Rate
Premalignant	Monoclonal gammopathy of undetermined significance (MGUS)	• Monoclonal protein <3 g/dL • Clonal bone marrow plasma cells <10% • Absence of CRAB[a] criteria related to plasma cell clonal disorder • In light-chain MGUS[b], urinary monoclonal protein must be <500 mg/24 h	• 1% per year for MGUS • 0.3% per year for light-chain MGUS
	Smoldering multiple myeloma (SMM)	• Serum monoclonal protein ≥3 g/dL or urinary monoclonal protein ≥500 mg/24 h and/or bone marrow plasmacytosis 10%–60% • Absence of CRAB criteria[a] or amyloidosis	10% per year (see Table 16-4 for risk stratification in SMM)
	Multiple myeloma (MM)	• Clonal bone marrow plasma cells ≥10% or biopsy-proven bony or extramedullary plasmacytoma AND • Evidence of end-organ damage attributed to a plasma cell disorder as defined by CRAB[a] criteria OR ≥1 biomarker of malignancy, which includes bone marrow clonal plasmacytosis ≥60%, involved-to-uninvolved serum-free light chains ≥100, or >1 focal lesion on MRI studies that is at least 5 mm in size	Not applicable

[a]CRAB criteria:
1. HyperCalcemia: Serum calcium >1 mg/dL above the upper limit of normal or >11 mg/dL.
2. Renal insufficiency: creatinine clearance <40 mL/min or serum creatinine >2 mg/dL.
3. Anemia: hemoglobin <2 g/dL below the lower limit of normal or <10 g/dL.
4. Bone lesions: one or more osteolytic lesions on skeletal survey, CT scan, or PET-CT.

[b]Defined as abnormal free light-chain ratio (<0.26 or >1.65) in the absence of immunoglobulin heavy-chain expression on immunofixation.

Table 16–2 Risk Stratification of Newly Diagnosed Multiple Myeloma

Revised International Staging System	
Stage I	**Parameters:** Albumin ≥3.5 g/dL, β_2-microglobulin <3.5 mg/L, normal LDH, no high-risk chromosomal abnormalities **Median Overall Survival:** Not reached
Stage II	**Parameters:** Neither stage I nor stage III **Median Overall Survival:** 83 months
Stage III	**Parameters:** β_2-microglobulin ≥5.5 mg/L and either high LDH or high-risk chromosomal abnormalities **Median Overall Survival:** 43 months High-risk chromosomal abnormalities as determined by interphase FISH: del(17p), t(4;14), t(14;16)
Risk Stratification	
Standard risk	t(11;14) t(6;14) Hyperdiploid karyotype
Intermediate risk	t(4;14) Del 13q Hypodiploid karyotype
High risk	Del 17p13 Amplification of 1q21 t(14;20) t(14;16) Lactate dehydrogenase ≥2× institutional upper limit of normal Plasma cell leukemia High-risk gene expression profiling signature

International Staging System

The International Staging System (ISS) was established in 2005 by the IMWG after a retrospective analysis of the outcomes of more than 10,000 patients across 17 different centers. In this study, β_2-microglobulin and albumin were powerful correlates of median survival, and patients could be categorized into three stages based on serum levels at diagnosis. The staging system was subsequently revised to include LDH and high-risk chromosomal abnormalities (Table 16–2). Because β_2-microglobulin is excreted renally, high levels may be found in the presence of renal failure, which makes the interpretation of the ISS in this setting challenging. The ISS is the preferred staging method and has supplanted the previously used Durie-Salmon staging system, which was confounded by observer-dependent variables. It is important to note that the ISS has only been validated at the time of diagnosis in patients with MM and should not be extrapolated to patients with MGUS or SMM.

Risk Stratification

In addition to the ISS, patients can be stratified into standard-, intermediate-, and high-risk categories based on cytogenetic findings by both conventional karyotyping and FISH. The presence of del(17p), t(4;14), t(14;16), t(14;20) gain 1q, or p53 mutation is considered high-risk MM. Recently, high-risk myeloma was further defined as double-hit myeloma when two high-risk factors are present, and triple-hit myeloma when three or more high-risk factors are present. More risk factors portend worse outcomes. Risk stratification based on these criteria is summarized in Table 16–2.

Response Criteria

International Myeloma Working Group Uniform Response Criteria

The IMWG proposed new guidelines in 2006 to standardize response criteria in MM and to define disease progression to facilitate comparisons of outcomes between treatment centers and for reporting results in clinical trials. These International Uniform Response Criteria guidelines are summarized in Table 16–3. Assessment of response with M-protein measurements using serum protein electrophoresis, urine protein electrophoresis, and serum-free light-chain assay is recommended prior to each cycle of therapy. Bone marrow biopsy is necessary to monitor disease in the absence of a measurable M-protein in the serum or urine or to document a complete or stringent complete

Table 16–3 IMWG International Uniform Response Criteria

Response Category	Criteria
sCR	Meets criteria for CR PLUS Normal free light chain ratio AND No clonal cells in bone marrow by immunohistochemistry or immunofluorescence
CR	Negative serum and urine immunofixation AND Disappearance of any soft tissue plasmacytomas AND ≤5% plasma cells in bone marrow
VGPR	Serum and urine M-protein detectable by immunofixation but negative M-protein OR ≥90% reduction in serum M-protein plus urine M-protein level <100 mg per 24 h
PR	≥50% reduction of serum M-protein and reduction in 24-h urinary M-protein by ≥90% or to <200 mg per 24 h If unmeasurable serum and urine M-protein, ≥50% decrease in the difference between involved and uninvolved FLC levels If unmeasurable serum and urine M-protein serum FLC assay, ≥50% reduction in plasma cells is required in place of M-protein, as long as baseline bone marrow plasma cell percentage was ≥30% In addition to above criteria, a ≥50% reduction in the size of any baseline soft tissue plasmacytoma is required
SD	Not meeting criteria for CR, VGPR, PR, or progressive disease
PD	Increase of ≥25% from baseline in at least one of the following: • Serum M-component (the absolute increase must be ≥0.5 g/dL) • Urine M-component (the absolute increase must be ≥200 mg/24 h • Difference between involved and uninvolved FLC levels if serum and urine M-protein are unmeasurable (the absolute increase must be >10 mg/dL) • Bone marrow plasma cell percentage (the absolute % must be ≥10%) Development of new bone lesions or soft tissue plasmacytomas or definite increase in size of existing bone lesions or soft tissue plasmacytomas Development of hypercalcemia >11.5 mg/dL related to plasma cell dyscrasia

CR, complete response; FLC, free light chain; IMWG, International Myeloma Working Group; M-protein, monoclonal protein; PD, progressive disease; PR, partial response; sCR, stringent complete response; SD, stable disease; VGPR, very good partial response.
Adapted with permission from Durie BG, Harousseau JL, Miguel JS, et al. International uniform response criteria for multiple myeloma, *Leukemia* 2006 Sep;20(9):1467-1473.

response. Serial imaging assessments may be required if soft tissue plasmacytomas are present at baseline.

Minimal Residual Disease

In recent years, the fraction of patients achieving deep responses, including complete remission, after initial MM therapy has increased significantly. This correlates with improved progression-free survival (PFS) and overall survival (OS) in several studies[11] With a deepened level of remission, more sensitive methods to assess and monitor MRD have been investigated. These include flow cytometry, allele-specific polymerase chain reaction, and next-generation sequencing–based assays.[12] MRD may soon be used as a valid surrogate end point to compare treatment strategies and advise on consolidation and maintenance therapies. As of this writing, MRD assessment by multiparameter flow cytometry is the most reproducible method in MM. It has a sensitivity of 10^{-5} if at least 2×10^6 cells from bone marrow aspirates are analyzed. An international effort to adopt standardized or harmonized MRD detection assay and analysis by multiparameter flow cytometry in clinical practice and in clinical trials is ongoing.

Treatment of Newly Diagnosed Multiple Myeloma

After the diagnostic workup and risk stratification are complete, patients who meet the criteria for MM as defined by IMWG criteria should initiate therapy. The most important initial assessment is whether a patient is a candidate for high-dose chemotherapy and autologous stem cell transplantation (SCT), largely based on existing comorbidities and age. In the transplant-eligible population, current MM standard of care involves frontline chemotherapy, followed by consolidative high-dose melphalan and autologous SCT, followed by maintenance therapy. Some chemotherapy agents (eg, melphalan) may adversely affect stem cell collection and should be avoided in the initial therapy of transplant-eligible patients. Melphalan may be included in the frontline therapy of transplant-ineligible patients.

Frontline Therapy for Transplant-Eligible Patients

A number of different regimens can be used in the frontline setting for transplant-eligible patients. These usually consist of two- or three-drug combinations, and the choice of therapy is individualized based on factors such as patient comorbidities (neuropathy, diabetes), preferred route of administration (oral, intravenous, or subcutaneous), and underlying disease biology (eg, bortezomib in t(4;14) and del 13q). Patients are usually given two to four cycles of therapy before stem cell collection to reduce disease burden before proceeding to high-dose chemotherapy and autologous stem cell rescue. Given the evidence that the depth and duration of response may translate into improved long-term outcomes, we generally prefer the three-drug regimens over the two-drug regimens as initial therapy in newly diagnosed patients.

Lenalidomide and Dexamethasone

The efficacy of the second-generation immunomodulatory drug (IMiD) lenalidomide was shown in a randomized phase 3 study comparing lenalidomide plus high-dose dexamethasone (Len/Dex) versus placebo plus high-dose dexamethasone.[13] Overall response rates (ORR), defined as a partial response or greater, and very good partial response (VGPR) rates were significantly higher in the Len/Dex arm (78% and 63%, respectively) versus the placebo/Dex arm (48% and 16%, respectively). The one-year PFS rate was also higher in the Len/Dex arm (78% vs 52%), although there was no significant difference in OS between the two groups (94% vs 88%). Grade 3 or 4 neutropenia was higher with Len/Dex (21% vs 5%), as was the rate of venous thromboembolism (23.5% vs 5%) despite aspirin prophylaxis.

To possibly decrease the dexamethasone dose, a randomized study was conducted with lenalidomide in combination with high-dose dexamethasone (40 mg on days 1–4,8–11, and 17–20 every 4 weeks) versus low-dose dexamethasone (40 mg on days 1,8, 15, and 22 every 4 weeks).[14] Patients receiving high-dose dexamethasone achieved a higher ORR (79% vs 68%) after four cycles of therapy. However, a second interim analysis at one year demonstrated a statistically significant superior OS in the low-dose dexamethasone arm compared with the high-dose arm (96% vs 87%). This was attributed to increased toxicities of high-dose dexamethasone therapy including venous thromboembolism and infections. Based on this study, lenalidomide is recommended to be given in combination with low-dose dexamethasone.

Bortezomib and Dexamethasone

The proteasome inhibitor bortezomib in combination with dexamethasone was studied as frontline therapy in a large phase 3 trial comparing bortezomib and dexamethasone versus vincristine, doxorubicin, and dexamethasone (VAD) therapy before autologous SCT.[15] Postinduction ORR (78.5% vs 62.8%), higher VGPR rates (37.7% vs 15.1%), and complete response (CR) or near complete response rates (14.8% vs 6.4%) all favored the bortezomib and dexamethasone arm over the VAD arm. There was also a trend toward improved median PFS in the bortezomib and dexamethasone arm (36.0 vs 29.7 months) but no difference in OS. In a separate analysis, initial treatment with bortezomib and dexamethasone before autologous SCT was shown to overcome the adverse prognostic features of t(4;14) in relation to event-free survival (EFS) and OS compared with VAD, although del 17p remained a poor prognostic factor regardless of the treatment regimen. Herpes simplex prophylaxis with acyclovir or valacyclovir should be given with bortezomib-containing regimens. Subcutaneous administration of bortezomib is preferred because it has similar efficacy as the intravenous route with decreased peripheral neuropathy.[16]

Cyclophosphamide, Bortezomib, and Dexamethasone

The addition of oral cyclophosphamide to bortezomib and dexamethasone (CyBorD) was studied in phase 2 trials. In the EVOLUTION phase 2 trial, patients were randomly assigned to receive bortezomib, lenalidomide, and dexamethasone (VRD); bortezomib, lenalidomide, cyclophosphamide, and dexamethasone); or CyBorD, all followed by maintenance bortezomib for four 6-week cycles.[17] The study was later amended to add an additional day 15 dose of cyclophosphamide, in addition to days 1 and 8, in patients receiving CyBorD. Patients receiving the modified CyBorD regimen achieved an ORR of 82%, with a VGPR or better rate of 53% and a CR rate of 47%. The one-year PFS rate was 100%.

In another phase 2 study, standard twice-weekly (days 1,4, 8, and 11) bortezomib was compared with weekly bortezomib (days 1,8, 15, and 22) in combination with weekly cyclophosphamide and dexamethasone.[18] ORR (88% vs 93%) and VGPR rates (60% vs 61%) were similar in both the twice-weekly and weekly bortezomib groups. In addition to demonstrating the efficacy of the three-drug combination of CyBorD, this study also suggested that weekly (instead of twice-weekly) bortezomib could be used to reduce treatment-related toxicity because it resulted in fewer grade 3 and 4 adverse events compared with the twice-weekly schedule (37% and 3% vs 48% and 12%, respectively).

Bortezomib, Lenalidomide, and Dexamethasone

The efficacy of VRD has also been demonstrated in several phase 2 and 3 trials. As mentioned, VRD was

also included as one of the arms in the phase II EVOLUTION trial, which resulted in an 85% ORR, with a VGPR or better rate of 51% and a CR rate of 24%.[17] The phase 3 Southwest Oncology Group (SWOG) S0777 trial showed a median progression free survival (mPFS) of 41 months for VRd vs 29 months for Rd and a medium OS (mOS) for VRd that was not reached vs 69 months.[19] In addition, the role and timing of autologous SCT are being reexamined in the era of novel agents in a large international phase 3 trial of frontline VRD followed by lenalidomide maintenance therapy (with the option of SCT at the time of relapse) versus VRD followed by autologous SCT per the current standard of care (NCT01208662). The phase 3 ENDURANCE trial evaluating the second-generation proteasome inhibitor carfilzomib in combination with lenalidomide and dexamethasone (KRd) in the frontline setting showed similar results to RVD.[20] These studies will clarify the role of triplet combinations in the frontline setting and provide insight as to whether deeper responses, including molecular responses, with the multiple novel agents in combination, ultimately translate into improved long-term outcomes.

Monoclonal antibodies have been gaining interest in the frontline setting as quadruplet therapies, such as in the GRIFFIN trial with daratumumab (CD38 antibody) combined with bortezomib, lenalidomide, dexamethasone, which have shown promising results with superior stringent CR rates.[21] However, not all quadruplet therapies are beneficial, because the addition of elotuzumab (SLAMF7 antibody) to bortezomib, lenalidomide, dexamethasone did not improve PFS in the phase 2 SWOG-1211 trial.[22]

Frontline Therapy for Transplant-Ineligible Patients

Initial treatment regimens for transplant-eligible patients can also be used in transplant-ineligible patients. Without the need to collect autologous stem cells, the alkylating agent melphalan can be incorporated into frontline therapy in nontransplant candidates. For 40 years, melphalan and prednisone (MP) represented the standard of care for transplant-ineligible patients. Trials adding other novel therapies to the MP backbone such as thalidomide,[23] lenalidomide,[24,25] and bortezomib[26] demonstrated improved ORR and PFS. More recently the phase 3 ALCYCONE trial showed that the addition of daratumumab to bortezomib plus MP (VMP) resulted in a 36-month rate of OS of 78% in the D-VMP group compared with 67.9% in the VMP group after a median follow-up of 40.1 months.[27] However, in the US, non–melphalan-containing combinations now form the new standard of preferred regimens.

Lenalidomide and low-dose dexamethasone (Rd) in 4-week cycles until disease progression versus the same regimen for a fixed duration of 72 weeks versus melphalan, prednisone, and thalidomide (MPT) in 6-week cycles for 72 weeks were compared in a randomized phase 3 study in more than 1500 transplant-ineligible patients.[28] Although the ORRs were similar between the three arms, median PFS favored continuous Rd (25.5 months) versus 18 cycles of Rd (20.7 months) and MPT (21.2 months). There was a trend toward improved 3-year OS with continuous Rd (59%) versus fixed-duration Rd (56%) and MPT (51%). There was also a trend toward fewer grade 3 and 4 adverse events in the continuous Rd arm (70%) compared with the MPT arm (78%), in particular grade 3 and 4 neutropenia and neuropathy. However, there was a higher incidence of grade 3 and 4 infections with continuous Rd (29%), likely related to the longer duration of glucocorticoid use.

A community-based phase 3B trial compared bortezomib and dexamethasone (BD) versus bortezomib, thalidomide, and dexamethasone (BTD) versus melphalan, prednisone, and bortezomib (MPB) followed by maintenance bortezomib.[29] The ORR, PFS, and OS were similar across all three arms. Discontinuation because of adverse events was highest in the BTD arm (35%) compared with BD (24%) and MPB (30%). This demonstrates the safety and efficacy of the use of BD in the elderly population. RVD can also be used because patients in the SWOG S0777 trial mentioned above were not required to receive transplant. Furthermore, a regimen with decreased dose of lenalidomide (15 mg instead of the usual 25 mg) and dexamethasone (20 mg vs 40 mg) termed "RVD lite" can also be considered in more frail patients because it was shown to have an ORR of 86% with a mPFS of 35.1 months.[30] In general, the incorporation of novel agents to combination therapy has improved ORR and long-term outcomes in older adult, transplant-ineligible patients. However, treatment must be individualized based on comorbidities and disease characteristics as well as the patient's own goals of care.

Stem Cell Transplantation

Autologous Stem Cell Transplantation

High-dose melphalan without autologous SCT was first reported in 1983 by McElwain and colleagues from the Royal Marsden Hospital. Compared with chemotherapy alone, intensified chemotherapy followed by autologous SCT appears to prolong OS in previously untreated patients with MM. One comparative study and two randomized trials showed that autologous SCT provided survival benefits of approximately 12 months.

In the French IFM 90 trial, high-dose chemotherapy supported by autologous SCT was compared with conventional chemotherapy in 200 previously untreated patients younger than 65 years old with MM.[31] The results showed a higher CR rate (22% vs

5%) and higher rates of 5-year EFS (28% vs 10%) and OS (52% vs 12%) in the autologous SCT group. The median OS in patients assigned to the SCT arm was 13 months longer (57 vs 44 months).

The Medical Research Council Myeloma VII trial compared conventional-dose chemotherapy with high-dose therapy and autologous SCT in 401 previously untreated patients younger than 65 years old with MM.[32] The rates of CR were significantly higher in the autologous SCT group (44% vs 8%). Intent-to-treat analysis showed a significantly higher rate of OS and PFS with SCT. Compared with standard therapy, autologous SCT increased median OS by almost 12 months (54.1 vs 42.3 months). There was a trend toward a greater survival benefit in patients with poor prognosis (defined by β_2-microglobulin level >8 mg/L).

In three other randomized studies, however, there has been no survival benefit with autologous SCT.[33–35] Comparison among these trials is difficult because of the variability in patient eligibility, including age, induction chemotherapy, conditioning regimen for SCT, and definitions of response. The timing of transplantation given the existence of the new triplet regimens was evaluated in the large 700-patient French IFM 2009 trial.[36] Patients received either VRD for eight cycles or VRD for three cycles followed by autologous SCT and two additional cycles of VRD, with both arms receiving lenalidomide maintenance for one year. The transplant group had a significantly longer mPFS of 50 months vs 36 months with a higher CR of 59% versus 48% and MRD negativity of 79% versus 65%. The nontransplant group underwent transplantation after salvage therapy for relapsed disease. Overall survival at four years was not significantly different (82% vs 81%). Thus, autologous SCT has become the standard of care for eligible patients based on performance status and organ function.

Many different preparative regimens have been assessed over the last 20 years, but few have compared the different regimens. One prospective randomized trial by the IFM directly compared two different preparative regimens[37] in 282 newly diagnosed patients younger than 65 years old and found that high-dose melphalan at 200 mg/m^2 to be superior to a combination of melphalan 140 mg/m^2 plus 8 Gy of total-body irradiation, mainly because of reduced toxicity including mucositis and transplant-related mortality. A recent phase 3 randomized clinical trial from MDACC compared busulfan and melphalan with melphalan alone and found that the combination resulted in a median PFS of 64.7 months vs 43.5 months, but at a cost of increased grade 2–3 mucositis (74% vs 14%).[38] Melphalan remains the standard of care, but the addition of novel agents to conditioning is being investigated, especially in high-risk patients.

Transplantation can be performed either early after induction therapy or later at disease progression. Fermand et al compared early and late autologous SCT and reported a similar OS.[35] However, the average time without symptoms, treatment, and treatment toxicity were significantly better with early autologous SCT. A retrospective study of 167 patients who received induction therapy containing at least one of three novel agents (lenalidomide, thalidomide, or bortezomib) followed by autologous SCT, either within 12 months of diagnosis or later, found a higher CR rate in the early autologous SCT arm but no difference in PFS or OS. The potential benefit of early versus late autologous SCT was assessed in a trial that randomly assigned patients between 55 and 65 years of age to either conventional chemotherapy alone or chemotherapy followed by autologous SCT. With a median follow-up of 120 months, a trend toward better event free survival (EFS), but no OS benefit, was observed in patients undergoing early transplantation.[35] Finally, the US Intergroup Trial S9321 found no PFS or OS benefit with early SCT.[33] A recent cost analysis study by Pandya et al suggests that early autologous SCT is cost effective compared with delayed autologous SCT.[39]

At MDACC, we offer autologous SCT to all eligible patients after induction therapy regardless of age. We use a preparative regimen of melphalan 200 mg/m^2 or busulfan and melphalan (unless the patient is treated in a clinical trial with a novel preparative regimen). In selected patients (>70 years old or dialysis dependent), we lower the melphalan dose to 140 mg/m.[2] We offer tandem autologous SCT only in the setting of a clinical trial or if there is significant residual disease after first autologous SCT. A second salvage transplant is an option for patients with relapsed disease; we offer this mainly to patients whose benefit from transplant was more than 18 months and whose disease burden can be significantly reduced by salvage chemotherapy. We offer maintenance therapy after transplantation (discussed later).

At MDACC, we only perform reduced-intensity allogeneic SCT. We use the tandem autologous plus allogeneic SCT approach only in the setting of a clinical trial. Allogeneic SCTs are offered to patients with relapsed, chemotherapy-sensitive disease who are less than 70 years old, have an HLA-identical sibling or unrelated donor, and are in good general physical condition because toxicity is significant. Our preparative regimen is a combination of fludarabine and melphalan (100 or 140 mg/m^2), with antithymocyte globulin added for unrelated donor SCT.

To improve outcomes of autologous transplantation by adding a graft-versus-myeloma component, current laboratory research and clinical trials at MDACC are focused on eradicating MRD after autologous SCT using cellular therapy and vaccines.

Maintenance Therapy

To delay the time to disease recurrence, maintenance therapy after autologous SCT has been explored to limit growth of residual malignant plasma cells. Initial maintenance strategies included interferon-α, although treatment-related toxicities made it challenging to administer. The approval of thalidomide in the late 1990s renewed interest in maintenance therapy. Multiple trials showed improvements in PFS and sometimes OS with thalidomide maintenance after autologous SCT. Toxicities related to long-term therapy, notably peripheral neuropathy, made it difficult to tolerate.

Given its more favorable side effect profile, lenalidomide maintenance therapy after autologous SCT was next explored. The Cancer and Leukemia Group B (CALGB) study randomized patients to lenalidomide or placebo maintenance starting 100 days after autologous SCT.[40,41] With a median follow-up of 91 months, mPFS was significantly greater in the lenalidomide arm (57.3 vs 28.9 months) as was the mOS (113.8 months vs 84.1 months). The IFM reported a similar trial in which patients received two 4-week cycles of consolidation with lenalidomide 25 mg after autologous SCT before being randomly assigned to lenalidomide maintenance versus placebo.[42] PFS also favored lenalidomide maintenance (median PFS, 41 vs 23 months), but there was no difference in OS at four years. Finally, in the Myeloma XI trial, from the UK, PFS was also improved (39 vs 20 months), though with no difference in OS after a median follow-up of 31 months. However, prespecified subset analysis showed that the 3-year OS in transplantation-eligible patients was 87.5% versus 80.2% in the control group. The transplant-ineligible group showed no significant OS benefit. The longer lenalidomide maintenance appears to increase the time of response. In one study, they found that lenalidomide continued for more than 24 months led to an improved mPFS after transplant of 77 months compared with patients who had 12 to 24, and less than 12 months of maintenance, with a mPFS of 6.5 and 26 months, respectively.[43]

Studies have reported an increase in second primary malignancies with lenalidomide maintenance (8% in the CALGB and IFM studies) versus placebo (3% in CALGB and 4% in IFM). However, when all competing factors for death are considered (including death from relapsed MM), patients have a much higher risk of mortality from other causes rather than secondary malignancies.[44,45] Potential risks and benefits of lenalidomide maintenance should be discussed with patients to make informed decisions. Lenalidomide maintenance can also be considered in nontransplant patients after initial therapy based on the phase 3 MPL-L versus MPL versus MP study.[24]

Alternative maintenance strategies have been investigated. Bortezomib maintenance was investigated in the phase 3 Hemato-Oncologie voor Volwassenen Nederland (HOVON)-65/German Multicenter Myeloma Group (GMMG)-HD4 trial, where patients were randomly assigned to receive either vincristine, doxorubicin, dexamethasone (VAD), or bortezomib, doxorubicin, and dexamethasone (PAD) induction, followed by high-dose melphalan and autologous SCT.[46] Patients were then randomized again to receive either thalidomide or bortezomib maintenance therapy for two years. The CR, PFS, and OS rates all favored bortezomib-containing induction and maintenance regimens, and benefit was also noted in high-risk patients with del 17p. The phase 3 TOURMALINE-MM3 study investigated the oral proteasome inhibitor, ixazomib, as maintenance after transplantation and found an increase in mPFS to 26.5 months compared with 21.3 months with placebo.[47] There is an ongoing noninferiority trial comparing ixazomib with lenalidomide maintenance (NCT02253316). In addition, other doublet combination maintenance trials are ongoing; the phase 3 AURIGA (MMY3021) trial is currently evaluating the rate of conversion to MRD negativity after one year of treatment (NCT03901963).

In general, at MDACC we offer patients lenalidomide maintenance therapy after autologous SCT. In the setting of high-risk cytogenetic features, a combination proteasome inhibitor with IMiD maintenance should be considered based on available data for bortezomib and carfilzomib.[48,49]

Treatment of Relapsed/Refractory Multiple Myeloma

We recommend enrollment in clinical trials when possible for all patients with relapsed/refractory MM. Alternatively, there are a number of therapeutic options that have gained regulatory approval that may be considered in this setting. Treatment usually involves combinations of triplets.

Immunomodulatory Drugs

Many patients may already be on maintenance lenalidomide at the time of disease recurrence.

Pomalidomide is a third-generation IMiD with greater in vivo potency than thalidomide and lenalidomide. In a phase 3 study in relapsed/refractory MM, patients were randomly assigned to receive either pomalidomide plus low-dose dexamethasone (Pd) versus only high-dose dexamethasone.[50] Around 75% patients were double refractory to both lenalidomide and bortezomib. The ORR was 35% with Pd versus 10% with high-dose dexamethasone. The median PFS was 4.0 months with Pd versus 1.9 months with

high-dose dexamethasone. Based on these results, pomalidomide gained FDA approval for refractory MM with prior bortezomib and lenalidomide exposure.

Proteasome Inhibitors

Bortezomib has shown efficacy in relapsed MM in two large randomized phase 3 trials. The APEX phase 3 trial compared intravenous bortezomib to high-dose dexamethasone; ORR, PFS, and OS were all superior in the bortezomib arm. As mentioned, subcutaneous bortezomib is favored over the intravenous route because of similar efficacy and less peripheral neuropathy.[16]

Bortezomib has also been studied in combination with other agents. The addition of pegylated liposomal doxorubicin in combination with bortezomib gained regulatory approval after demonstrating superior PFS compared with bortezomib monotherapy in relapsed/refractory bortezomib-naïve patients with MM, although the ORRs were not statistically different between the two groups.[51] Phase 2 data of VRD in relapsed/refractory MM resulted in an ORR of 64%. Median PFS was 8.5 months, and median OS was 30 months.[52] The CyBorD regimen may also be considered in relapsed MM based on phase 2 data.

The second-generation proteasome inhibitor carfilzomib has gained regulatory approval for patients exposed to bortezomib and an IMiD and whose disease was refractory to the last therapy. Like bortezomib, carfilzomib inhibits the chymotrypsin-like activity of the 20S proteasome, but its unique structural properties allow for greater specificity and irreversible binding to its target. The efficacy of carfilzomib in relapsed/refractory MM was established in a single-arm phase 2 trial of 266 patients, with an ORR of 24%, all of whom received prior IMiD therapy, and all but one patient received prior bortezomib.[53] Only 12% of patients reported any grade of treatment-emergent peripheral neuropathy. In the phase 3 ENDEAVOR study, carfilzomib was compared with bortezomib,[54] with approximately 50% of the patients receiving prior bortezomib, and approximately 70% receiving a prior immunomodulatory agent. The mPFS was 18.7 versus 9.4 months, which led to an increase in the mOS to 47.6 compared with 40 months.

The role of carfilzomib in relapsed and/or refractory MM continues to evolve while it is being tested in combination with other novel agents. Results of the phase 3 ASPIRE study comparing KRd with lenalidomide and dexamethasone (Rd) have been reported.[55] In this study, 66% of patients received prior bortezomib and 20% received prior lenalidomide. The mPFS was significantly longer with KRd compared with Rd (26.1 vs 16.6 months), and the mOS was 48.3 vs 40.4 months. The combination of carfilzomib, pomalidomide, and dexamethasone has also shown promising results,[56] with one study showing an ORR of 87% with 31% CR when given at first relapse.[57] OS results are still immature. Although earlier studies established the maximum tolerated dose of carfilzomib at 20 mg/m^2 for cycle 1 and 27 mg/m^2 twice weekly for subsequent cycles, phase 1 and 2 data have emerged demonstrating the safety and efficacy of higher doses of carfilzomib up to 56 mg/m^2 administered over 30 minutes compared with a 2- to 10-minute intravenous bolus given in earlier studies.[58] However, the SWOG randomized phase 2 study comparing high-dose versus low-dose carfilzomib (with dexamethasone in both arms) demonstrated no difference in response rate, PFS, or OS, but with higher rates of fatigue, thrombocytopenia, and peripheral neuropathy with the higher dose.[59] Finally, based on the ENDEAVOR, A.R.R.O.W., and CHAMPION-1 trials, weekly dosing of carfilzomib at 70 mg/m^2 has an efficacy profile comparable with carfilzomib at twice-weekly dosing of 56 mg/m^2 and offers a convenient and well-tolerated option. Regression analyses of all patients in the trials who received carfilzomib 70 mg/m^2 weekly versus 56 mg/m^2 twice weekly, estimated a PFS hazard ratio of 0.91 and an ORR odds ratio of 1.12.[60]

Monoclonal Antibodies

The FDA has approved the anti-CD38 antibodies, daratumumab and isatuximab, and the anti-SLAMF7 antibody, elotuzumab. Antibody therapy has modest to no efficacy as monotherapy and is thus used in combination with other drugs.

A number of different proteasomes, IMiD combinations with daratumumab, have been tested. For example, the phase 3 POLLUX trial comparing lenalidomide, dexamethasone with or without daratumumab in patients with one or more prior treatments, found that after a follow-up of more than 3.5 years, the ORR was 92.9% with daratumumab versus 76.4% without, leading to a mPFS of 44.5 months versus 17.5 months.[61] Patients who only had one prior therapy had a mPFS that was not reached compared with 19.6 months with lenalidomide, dexamethasone alone. In patients with two prior lines of therapy, daratumumab has been combined with pomalidomide and dexamethasone, which led to an ORR of 60%, with a mPFS of 8.8 months, and mOS of 17.5 months.[62] Daratumumab and PI combinations have also shown improved outcomes for relapsed or refractory myeloma. Per the CASTOR trial, daratumumab with bortezomib and dexamethasone demonstrated a 1-year PFS rate of 60.7% versus 26.9% in the control group of bortezomib and dexamethasone.[63] More recently, the CANDOR trial showed a significant improvement in PFS for the triplet combination of daratumumab, carfilzomib, and dexamethasone versus carfilzomib and dexamethasone

(median PFS not reached vs 15.8 months, respectively, with a median follow-up of 17 months).[64]

Intravenous daratumumab has been associated with a high rate of infusion reactions, and thus requires prolonged infusion times. To overcome this, subcutaneous daratumumab was developed and was recently approved by the FDA based on the PAVO trial, which showed similar responses to IV daratumumab.[65]

Isatuximab has also been FDA approved based on the phase 3 ICARIA-MM trial. In patients who progressed on two prior treatments including lenalidomide and a proteasome inhibitor, patients who received isatuximab with pomalidomide and dexamethasone had a mPFS of 11.5 months compared with 6.47 months with pomalidomide, dexamethasone alone.[66]

Elotuzumab has not been effective as a single agent.[67] However, in the phase 3 ELOQUENT-2 trial of patients who have received one to three prior lines of therapy, elotuzumab in combination with lenalidomide and dexamethasone had a mPFS of 19.4 months compared with 14.9 months with lenalidomide and dexamethasone alone,[68] which led to a mOS of 48.3 months versus 39.6 months after patients had been followed for at least 5.9 years.[69] Later in the randomized phase 2 ELOQUENT-3 trial, elotuzumab in combination with pomalidomide and dexamethasone demonstrated a mPFS of 10.3 months versus 4.7 months for pomalidomide and dexamethasone.[70]

Nuclear Export Inhibitor

It has been found that myeloma cells overexpress the nuclear exporter protein, exportin 1 (XPO1).[71] XPO1 is involved in the movement of many proteins across the nucleus, including important tumor suppressor proteins such as p53, retinoblastoma, and proteins that regulate the cell cycle, immune response, and more. Recently, an XPO1 inhibitor, selinexor, was tested in triple-refractory patients who had progressed on a proteasome inhibitor, IMiD, and daratumumab.[72] There was an ORR of 26% with a mPFS of 3.7 months and a mOS of 8.6 months. Thrombocytopenia and anemia were major adverse events, with 58% and 44%, respectively, having grade 3 or 4 toxicity. Fatigue, nausea, decreased appetite, and weight loss were also significant adverse events with 73%, 72%, 56%, and 50%, respectively, having any grade toxicity. Based on these results, the FDA has approved the medication for patients who have received at least four prior therapies and have progressed on at least two proteasome inhibitors, two IMiDs, and an anti-CD38 antibody. The ongoing phase 3 BOSTON trial will introduce selinexor in combination with bortezomib and dexamethasone to patients after one to three prior treatments (NCT03110562).

Antibody Drug Conjugate

An antibody drug conjugate couples an antibody with a chemotherapeutic agent to deliver a higher dose of the chemotherapy to a cancer cell than is normally possible because of toxicity. The phase 2 DREAMM-2 study tested belantamab mafodotin, an anti–B-cell maturation antigen (BCMA) antibody coupled to a microtubule-disrupting agent, mono-methyl auristatin F (MMAF), as single-agent treatment in triple-refractory patients who have progressed on at least three prior lines of treatment including a proteasome inhibitor, IMiD, and anti-CD38 antibody.[73] The study compared two doses and achieved a response rate of 31% to 34%. The mPFS ranged from 2.9 to 4.9 months. The most serious adverse event was keratopathy, which affected 70% to 74% of patients and was the most common reason treatment was discontinued. Recently, the FDA approved single-agent use in relapsed refractory patients with a rigorous REMS program. The ongoing DREAMM-6 trial combines belantamab with bortezomib and dexamethasone in patients with one or more prior lines of therapy (NCT03544281).

Histone Deacetylase Inhibitor

Although histone deacetylase (HDAC) inhibitors only have modest activity as single agents, the potential of HDAC inhibitors has been most pronounced in combination with other anti-MM drugs, namely bortezomib. Disruption of aggresome formation by HDAC inhibition may provide potent synergy with proteasome inhibition by interfering with protein turnover and inducing the unfolded protein response. Based on this rationale, the pan-deacetylase inhibitor panobinostat was studied in combination with bortezomib and dexamethasone and compared with placebo, bortezomib, and dexamethasone in a large phase 3 trial.[74] Patients receiving panobinostat with bortezomib and dexamethasone had a significantly longer mPFS of 12 versus 8.1 months, although OS was not significantly different between the groups. Concerns have been raised about drug efficacy (measured only by PFS) in the setting of significant toxicities, particularly grade 3 and 4 thrombocytopenia, diarrhea, and fatigue.

Unfortunately, other HDAC inhibitor trials have shown mixed benefits. For example, the phase 3 VANTAGE 088 trial comparing bortezomib in combination with or without vorinostat showed only a modest improvement in mPFS of 7.6 months versus 6.8 with placebo, and the trial with belinostat was stopped due to instances of toxicity.[75]

In the future, more selective HDAC inhibitors with fewer off-target effects may need to be developed and tested for the full potential of this therapeutic approach to be realized.

Investigational Agents

Although IMiDs and proteasome inhibitors now form the backbone of most MM regimens, both in the upfront and relapsed settings, several promising new classes of investigational agents have shown both safety and promising efficacy in phase 1 and 2 clinical trials.

Chimeric Antigen Receptor T Cells

Cellular therapy with chimeric antigen receptor (CAR) T cells are T cells modified with an activating receptor that binds to specific antigens present on the myeloma cell surface. The most popular target is the BCMA, which is an ideal target because it is primarily found only on mature B cells. CAR T cells against BCMA alone is being investigated in more than 60 trials around the world. The largest and most mature trial to date is the phase 2 KarMMA trial, which tested the BCMA CAR T cell, idecabtagene vicleucel, at three different doses in patients with three or more prior treatments.[76] They found an ORR of 73% in the 128 patients treated in all doses combined with a mPFS of 8.6 months or 11.3 months at the highest dose. Like other CAR therapies, cytokine release syndrome was common, affecting 84% of patients, though most were grade 1 or 2. Neurotoxicity was also present in 18% of patients across all doses. Other BCMA CAR T cell trials include the EVOLVE trial, which tests different ratios of CD4 to CD8 T cells and modified antigen–binding domain,[77] or the CARTITUDE-1 trial, which tests two BCMA-binding domains in a single CAR.[78] Early results also showed high response rates of 91% to 100%, though with smaller numbers and shorter follow-up compared with the KarMMA trial.

A number of other targets on the myeloma cell surface are also being investigated, such as CD38, CS1, and others.[79] CAR T cells have also been combined with other medications such as with a gamma-secretase inhibitor that prevents the cleavage of BCMA from the myeloma cell surface, which leads to increased BCMA surface expression and decreased circulating BCMA that could act to neutralize BCMA therapy.[80] To overcome the possibility of complete antigen loss, CAR T cells that target multiple antigens simultaneously are also being investigated.[81]

Bispecific T-Cell Engager

A bispecific T-cell engager (BITE) is an antibody that couples a tumor-binding domain with an anti-CD3 domain, thus bringing the tumor cells in close proximity to T cells. In a dose-finding study, a BITE coupling anti-BCMA to CD3, AMG 420, has been tested in patients who progressed after two or more lines of treatment, and was found to have an overall response rate of 31% with a response rate of 70% at the maximum tolerated dose.[82] Unfortunately, the antibody requires four weeks of continuous infusion. The longer-acting and thus shorter-infusion version, AMG 701, is also being investigated in a phase 1/2 trial (NCT03287908).

CELMoDs

Unique from immunomodulatory drugs such as lenalidomide and pomalidomide, CELMoDs are larger molecules that are potent modulators of the Cereblon E3 ligase complex and work by quickly degrading the proteins Ikaros and Aiolos. Data from the phase 1 trial for Iberdomide (CC-220) revealed that the dose ranged from 0.3 to 1.2 mg; however, the maximum tolerated dose (MTD) was not reached. Grade 3–4 adverse events were reported in 72% patients and included neutropenia, thrombocytopenia, neuropathy, and fatigue (in 26%, 11%, 2%, and 0% patients, respectively). This study is ongoing, including combinations with daratumumab and bortezomib.[83] Recently, the phase 1 data from a trial evaluating CC-92480 confirmed the maximum tolerated dose of 1 mg for 21 or 28 days, and a 55% ORR in a group of patients where 90% were refractory to lenalidomide and pomalidomide and had a median of six lines of therapy. Grade 3–4 adverse events were reported in 88% of patients and included neutropenia (53%), infections (30%), anemia (29%), and thrombocytopenia (17%), with 9% having grade 3 fatigue.[84]

BCL-2 Inhibitor

The BCL-2 inhibitor, venetoclax, has also been investigated in MM. The phase 3 BELLINI trial investigated venetoclax in combination with bortezomib and dexamethasone in patients who had received one to three prior lines of therapy.[85] The addition of venetoclax showed a significantly longer mPFS of 23.2 months compared with 11.4 months with placebo. However, this resulted in a decrease in OS, with the venetoclax arm having a mOS of 33.5 versus not reached with the placebo. Subset analysis found that most of the response came from the t(11:14) patients, and those patients had improved OS compared with the non-t(11:14) patients treated with venetoclax. There is now an ongoing phase 3 trial looking at just the t(11:14) subset of patients comparing venetoclax with pomalidomide in combination with dexamethasone (NCT03539744).

Melflufen

Melflufen is a peptide drug conjugate between an alkylating agent and a lipophilic peptide. When the drug enters myeloma cells, the peptide is cleaved, which traps the hydrophilic alkylating agent within the cell.[86]

The HORIZON study looked at patients who were refractory to pomalidomide or anti-CD38 and had received two or more lines of therapy and found that patients who received melflufen and dexamethasone had an ORR of 29%, with a mPFS of 4.2 months and mOS of 11.6 months.[87] The phase 3 OCEAN trial is ongoing (NCT03151811).

Kinesin-Spindle Protein

Kinesin-spindle protein (KSP) is a protein involved in the separation of the centrosome during cell division. A KSP inhibitor, filanesib is being evaluated as a single agent or in combination with other medications such as bortezomib. In a phase 1 trial investigating filanesib, carfilzomib, and dexamethasone in patients with a median of five prior lines of therapy, the ORR was 37%.[88]

Monoclonal Gammopathy of Undetermined Significance

The 2014 IMWG guidelines define MGUS as a serum M-protein less than 3 g/dL, less than 10% clonal marrow plasma cells, and absence of end-organ damage (CRAB criteria and myeloma-defining events; see Table 16–1) attributed to an underlying plasma cell proliferative disorder. The 2014 standard of care for MGUS is surveillance every 6 to 12 months with a physical examination and typical MM serum and urine studies. Patients with MGUS can also be risk stratified for progression to MM according to established models, with some arguing for only history and physical examination in low-risk MGUS (IgG subtype, M-protein <1.5g/dL, normal serum-free light-chain ratio) because risk of progression at 20 years is only 5% in this group (Table 16–4).[89]

Table 16–4 Risk Stratification Models for MGUS and SMM

MGUS			
Mayo Clinic[100]	**No. of Risk Factors**	**No. of Patients**	**20-Year Progression (%)**
Risk factors: 1) M-protein >1.5 g/dL 2) Non-IgG MGUS 3) FLC ratio <0.26 or >1.65	0 1 2 3 **Total**	449 420 226 53 **1148**	5% 21% 37% 58% **20%**
PETHEMA[101]			**5-year progression (%)**
Risk factors 1. ≥95% abnormal PCs by bone marrow flow cytometry 2. DNA aneuploidy	0 1 2 **Total**	127 133 16 **276**	2% 10% 46% **8.5%**
SMM			
Mayo Clinic[102]	**No. of Risk Factors**	**No. of Patients**	**5-Year Progression (%)**
Risk factors: 1. Bone marrow plasma cells ≥10% 2. M-protein ≥3g/dL 3. FLC ratio <0.125 or >8	1 2 3 **Total**	76 115 82 **273**	25% 51% 76% **51%**
PETHEMA[101]			
Risk factors: 1. ≥95% abnormal PC 2. Immunoparesis	0 1 2 **Total**	28 22 39 **89**	4% 46% 72% **46%**
SWOG[103]			**2-Year Progression (%)**
Risk factors: 1. GEP70 score >–0.26[104] 2. M-protein >3 g/dL 3. Involved serum FLC >25 mg/dL	0 1 ≥2 **Total**	33 29 17 **79**	3% 29.1% 70.6% **34.2%**

FLC, free light chain; GEP70, gene expression profiling 70; IgG, immunoglobulin G; immunoparesis, decreased in uninvolved immunoglobulins below the lower limit of normal; MGUS, monoclonal gammopathy of undetermined significance; PC, plasma cells; PETHEMA, Program para el Tratamiento de Hemopatias Malignas; SMM, smoldering multiple myeloma; SWOG, Southwest Oncology Group.

Smoldering Multiple Myeloma

Smoldering MM is defined as having a serum M-protein of at least 3.0 g/dL and/or at least 10% more marrow plasma cells without evidence of end-organ damage as defined by CRAB criteria and MM-defining events (see Table 16–1). Compared with MGUS, this premalignant clonal plasma cell proliferation carries a higher risk of progression to overt MM. In a large retrospective study of 276 patients with SMM followed over 26 years, the risk of progression to MM was 10% per year for the first 5 years, 3% per year for the next 5 years, and 1% per year for the last 10 years.

There is great heterogeneity in the SMM disease course. Some patients may remain asymptomatic for the rest of their lives, whereas others may rapidly develop disease that meets MM criteria. Efforts have been made to risk stratify SMM to help predict the clinical course, guide surveillance strategies, and design trials for early intervention. The Mayo 2008 risk stratification model found that patients with both clonal bone marrow plasmacytosis of at least 10% and serum M-protein at least 3 g/dL had an 87% chance of MM progression at 15 years compared with 70% with only 10% or more marrow plasma cells (but monoclonal protein of <3 g/dL) and 39% with only monoclonal protein of at least 3 g/dL (but <10% bone marrow plasma cells).[90] The model was later revised in the Mayo 2018 risk stratification, where they found that bone marrow plasma cells higher than 20%, M-protein more than 2 g/dL, and free light-chain ratio more than 20 where independent predictors of progression.[91] Patients with no risk factor had a time to progression of 110 months compared with 68 months if patients had one risk factor, and 29 months with two or more risk factors. A number of other factors have been shown to increase the risk of progression such as high-risk cytogenetics (del 17p, t(4;14), amplification of 1q21), ≥95% aberrant marrow plasma cells by flow cytometry, IgA M-protein, immunoparesis of uninvolved immunoglobulins, circulating plasma cells by slide-based immunofluorescence, and proteinuria.[92]

The benefits of preemptive treatment of high-risk SMM are still unclear. Until this is further clarified, treatment of high-risk SMM should be undertaken preferentially through clinical trials. A phase 3 trial from the Spanish myeloma group comparing lenalidomide and dexamethasone versus observation in high-risk patients found an improvement in median PFS in the treatment arm (median PFS, not reached vs 26 months) and a significant 3-year OS benefit (94% vs 80%, $P = .03$).[93] However, the excessive mortality rate in the observation arm for patients with SMM has raised concerns that some of these patients should have been classified as having symptomatic myeloma given that advanced imaging was not used to detect bone metastasis. A recent phase 3 trial addressed this issue by using modern imaging techniques and found that the 3-year PFS was 91% for the lenalidomide group compared with 66% in the observation group.[94] The benefit was found in all risk groups, though it was more pronounced in the Mayo 2018 high-risk group with a HR of 0.09. No OS benefit has been shown yet and 51% of the patients on the lenalidomide arm came off trial with a median of 11 cycles of treatment; 15.6% of these patients came off as a result of disease progression.

At MDACC, we recommend that patients with high-risk SMM be enrolled in a clinical trial. In the absence of clear data, we would otherwise recommend observation and close surveillance in these patients, although this practice may change soon as we gather data from relevant trials focused on high-risk SMM.

Solitary Plasmacytoma of Bone

A solitary plasmacytoma of bone is defined by the presence of a plasmacytoma without bone marrow evidence of monoclonal plasma cells, lytic bony lesions, or other clinically significant sequelae of MM. About 24% to 72% of patients with a solitary plasmacytoma have a monoclonal protein in the serum or urine. Initial workup should include all of the aforementioned serum and urine laboratory studies used in evaluation of MM, as well as advanced imaging with PET-CT or MRI to rule out multifocal disease that would upstage the disease to MM. Biopsy of the solitary plasmacytoma to demonstrate clonal plasma cells and a unilateral bone marrow biopsy to rule out systemic disease are necessary. Treatment should include radiation therapy of at least 40 Gy, although one may consider a dose of up to 50 Gy for lesions greater than 5 cm. After radiation therapy, surveillance should be performed with serial measurements of serum and urine M-protein levels and imaging studies, initially done every three months and then less frequently. Patients who progress to overt MM during surveillance should follow the treatment guidelines for MM.

Patients with solitary plasmacytoma of bone often progress to MM within 2 to 4 years, with a median OS of 7.5 to 12 years. In one study, persistence of a serum M-protein one year after radiation therapy was an adverse prognostic factor predicting a 10-year myeloma-free survival of 29% compared with 91% with undetectable M-protein. Another study found that an abnormal free light-chain ratio and a serum M-protein greater than 0.5 g/dL were significant adverse factors for disease progression at 5 years.

POEMS Syndrome

POEMS syndrome, also known as osteosclerotic myeloma, is a paraneoplastic syndrome related to an underlying clonal plasma cell disorder. The major

diagnostic criteria are polyneuropathy, monoclonal gammopathy, sclerotic bone lesions, elevated vascular endothelial growth factor (VEGF), and Castleman disease. Minor features include organomegaly, endocrinopathy, characteristic skin changes, papilledema, extravascular volume overload, and thrombocytosis. The diagnosis of POEMS syndrome is made with three of the major criteria, two of which must include polyneuropathy and a clonal plasma cell neoplasm, and at least one of the minor criteria (Table 16–5).[95] Patients may have delays in diagnosis because it is rare and resembles other neurologic diseases, most commonly chronic inflammatory demyelinating polyradiculoneuropathy. The natural history of POEMS syndrome is defined by progressive polyneuropathy and sclerotic bone disease, which leads to significant morbidity, along with mortality if respiratory compromise occurs. POEMS syndrome should be distinguished from the Castleman disease variant of POEMS syndrome, which has no clonal plasma cell association and usually no peripheral neuropathy.

The pathogenesis of this syndrome is not known. Risk stratification is based solely on the clinical phenotype. The extent of plasma cell clonal disease correlates with prognosis in POEMS, but the number of clinical criteria does not. Treatment is aimed at eradicating the underlying plasma cell clone and control of symptoms. With one to three sclerotic plasmacytomas (usually <1 cm in diameter each) without marrow infiltration, localized radiation therapy may suffice. For patients with a dominant sclerotic bone lesion, frontline radiation therapy may be appropriate. Patients with diffuse sclerotic lesions, disseminated marrow involvement, or relapsed disease within 6 months of completing radiation therapy should receive systemic therapy adapted largely from therapy for MM. Alkylators such as melphalan are the mainstay of treatment; lenalidomide has shown promise with manageable toxicity.[96,97] Therapies based on CHOP also show responses. Thalidomide and bortezomib have activity but could exacerbate disease-related peripheral neuropathy. Benefit from anti-VEGF antibodies is unproven.[96]

High-dose melphalan and autologous SCT can lead to prolonged remission and significant improvement in clinical symptoms. Sixteen patients with POEMS syndrome underwent autologous SCT at MDACC[99,100]; all had significant or complete resolution of clinical symptoms, and 4-year PFS and OS rates for the entire cohort were 80.2% and 100%, respectively. Ten-year PFS and OS rates were 59.4% and 80%, respectively. Prompt recognition and institution of supportive care measures and therapy directed against the plasma cell clone result in the best outcomes.

Table 16–5 Diagnostic Criteria for POEMS Syndrome

Major criteria	**Polyneuropathy** **Monoclonal plasma cell disorder** Sclerotic bone lesion Castleman disease VEGF elevation
Minor criteria	Organomegaly Extravascular volume overload Endocrinopathy Skin changes Papilledema Thrombocytosis/polycythemia
Other	Pulmonary hypertension Clubbing Weight loss Hyperhidrosis Thrombosis Low vitamin B_{12} level

Diagnosis of POEMS syndrome is made with three of the major criteria, two of which must include polyneuropathy and a clonal plasma cell neoplasm, and at least one of the minor criteria.
VEGF, vascular endothelial growth factor.

FUTURE DIRECTIONS

The last decade has seen unprecedented advances in the treatment of plasma cell dyscrasias. The advent of novel agents, notably proteasome inhibitors, IMiDs, and monoclonal antibodies have resulted in a doubling of the life expectancy in patients with MM. Many challenges remain. For example, MM is still considered mostly an incurable disease, and a subgroup of patients with high-risk MM have not benefited as substantially from recent therapeutic advances. Promising investigational agents including immunotherapeutic approaches and rational combinations to overcome resistance are being tested.

Future work involves identifying predictive biomarkers to help individualize therapy in MM and related plasma cell dyscrasias to help maximize efficacy while balancing treatment toxicity. In high-risk SMM, the role of early preemptive therapy needs to be clarified. Improving our understanding of the molecular pathogenesis of MM and its genetic drivers through molecular profiling and refining current risk stratification models remain our key priorities. Another important question is the role and timing of autologous SCT in the era of novel agents. Finally, as new drug combinations induce deeper responses in the frontline setting, significance of achieving molecular remissions is an area of intense research focus. Bridging these knowledge gaps will improve on the advances achieved over the last decade and offer greater individualized treatment approaches, leading to possible cure of MM and its related disorders.

MD ANDERSON PRACTICE TIPS

- Patients suspected to have MM, and all smoldering myeloma patients should receive advanced imaging, such as whole-body low-dose CT, PET-CT, or MRI to evaluate for asymptomatic bone disease.
- Transplant-eligible patients should receive a three-drug combination up front, comprised of a proteasome inhibitor, immunomodulatory drug, and steroids.
- Patients should receive autologous SCT after induction chemotherapy. The treatment regimen is melphalan, but high-risk patients receive busulfan/melphalan.
- Patients should be placed on maintenance after autologous SCT with either single-agent lenalidomide or bortezomib. High-risk patients should be placed on doublet maintenance.
- Proteasome inhibitors, immunomodulatory drugs, and CD38 monoclonal antibodies represent drugs used in up-front and early relapse therapies.
- Supportive therapies such as shingles prophylaxis (monoclonal antibodies and PIs), appropriate anticoagulation for DVT prevention (IMiDs and steroids), bisphosphonate therapy for bone strengthening, and bacterial prophylaxis for frail patients are imperative.

17 Cellular Therapy for Lymphoma

Sairah Ahmed
Simrit Parmar
Sattva Neelapu

KEY CONCEPTS

- Adoptive cellular immunotherapy with chimeric antigen receptor (CAR) T-cell therapy has changed the treatment landscape of B-cell non-Hodgkin lymphoma (NHL), especially for aggressive B-cell lymphomas.
- CAR T-cell therapy is FDA approved for poor-risk diffuse large B-cell lymphoma (DLBCL) and mantle cell lymphoma (MCL) when no other effective treatment options are available, and it has shown long-term remissions in up to 40% of patients without other treatment options.
- CAR T-cell–related toxicities remain important potential complications of this therapy, which includes acute toxicity with cytokine-release syndrome and neurotoxicity, as well as long-term complications such as infection and cytopenias.
- Relapse after CAR T-cell therapy remains a significant challenge and, although the exact mechanisms causing tumor escape remain unknown, relapse after CAR T-cell therapy that targets the CD19 antigen can be categorized broadly as (1) antigen loss, (2) lack of CAR T-cell persistence, or (3) host-specific factors.
- Real-world analyses highlight that patient response rates and toxicity profiles were similar to the pivotal trials, while being inclusive of patients who would not fit within the highly restrictive parameters of clinical trials.
- Trials are ongoing in multiple lymphoma histologies including T-cell lymphoma and Hodgkin lymphoma, in addition to novel autologous CAR constructs and allogeneic CAR T and natural killer (NK) cells.

For decades, the standard treatment for hematologic malignancies has been systemic chemotherapy, radiation, and stem cell transplantation (SCT). Exploiting the immune system to attack cancer cells is not a novel concept. In fact, the development of allogeneic stem cell transplantation (allo-HCT) first highlighted the potential of T-cells to eliminate cancer cells. As of this writing, immune effector cells, including T-cells and natural killer (NK) cells, which have been genetically engineered to express a chimeric antigen receptor (CAR), constitute a powerful new class of therapeutic agents to treat patients with hematologic malignancies, and have resulted in a paradigm shift in the treatment of relapsed lymphoma in particular. However, this emerging therapy also brings with it a different toxicity profile compared with chemotherapy and challenges in management related to cytokine-release syndrome (CRS) and immune effector cell–associated neurotoxicity syndrome (Fig. 17–1). Adoptive cell therapy is FDA approved for the treatment of certain non-Hodgkin lymphoma (NHL) types, as well as B-cell acute lymphoblastic leukemia (ALL) and is currently being evaluated in clinical trials for follicular lymphoma (FL), marginal zone lymphoma (MZL), T-cell lymphoma (TCL), and Hodgkin lymphoma (HL). There are more than 750 cellular therapies in development, and approximately half of these are in clinical trials.[1] This chapter will review current paradigms in cellular therapy for lymphoma.

CAR T-CELL DESIGN

The concept of using CAR T-cells to target tumor surface antigens was described in the late 1980s, but first-generation CARs, which included only the receptor component CD3ζ as an intracellular domain, showed limited efficacy.[2] These first-generation designs did

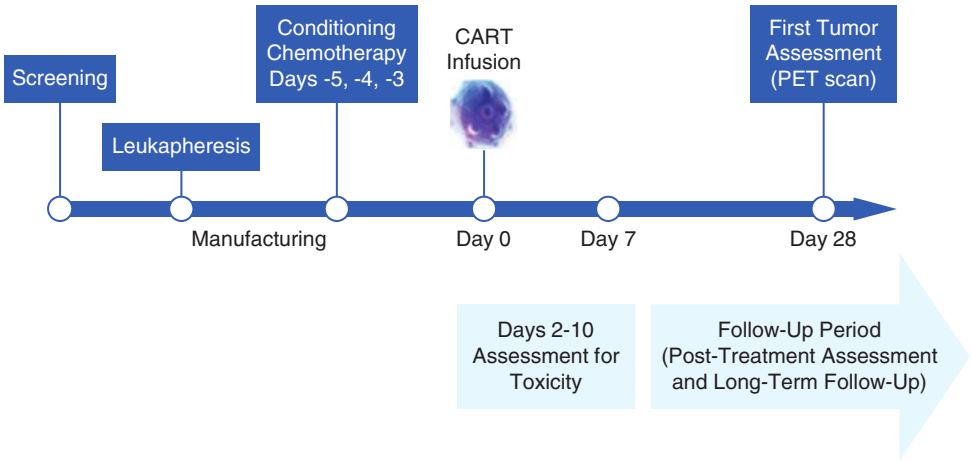

FIGURE 17–1 Graphic representation of CAR T-cell therapy from screening to post-treatment assessment.

not include costimulatory domains and, as such, did not provide a second signal for full T-cell activation; were more prone to apoptosis; and had limited in vivo expansion potential, resulting in poor cytotoxicity.[3]

Significant responses were observed only after researchers went back to the gene construct and added a single costimulatory domain derived from either CD28 or 4-1BB—the so-called "second-generation" CAR T-cells.[4] The addition of costimulatory signaling domains and intracellular signal transduction molecule (CD3ζ, derived from the T-cell receptor) in second-generation CARs led to improvement in T-cell activation, enhanced survival capabilities, and a more selective expansion of modified T-cells in vivo. A viral vector is usually used to deliver the genetic material, which includes the targeting antibody-based single-chain fragment variable region, a hinge and transmembrane domain, a costimulatory domain, and the CD3ζ signaling domain, into the patient's T-cells. These second-generation receptors form the basis of the currently approved CAR T-cell therapies. It is now becoming increasingly clear that each type of costimulatory domain has specific roles in CAR T-cell signaling; for example, CD28-based CAR T-cells exhibit more potent effector cell functions but limited persistence, whereas 4-1BB tends to drive the CAR T-cells toward a central memory phenotype, resulting in improved persistence.[5,6] Third-generation CAR T-cells combine the signaling potential of two costimulatory domains (eg, both CD28 and 4-1BB), with the aim to further improve proliferation, cytokine secretion, and in vivo persistence; and in comparison with the outcomes of second-generation CAR T-cells, they have shown improved effector functions and in vivo persistence in preclinical studies.[7]

The CAR molecule is composed of three key domains: an ectodomain, a transmembrane domain, and an endodomain. The extracellular part redirects the specificity of the receptor to recognize antigens on the cell surface independently of major histocompatibility complex molecules. CD19 has frequently been the target antigen in B-cell lymphoid malignancy because of its frequent and high-level expression in these malignancies, the fact that it has higher expression relative to other potential targets like CD20 or CD22, and its inherent restriction to B-cell lineages in healthy tissue. The transmembrane domain of the CAR construct primarily plays a role in stabilizing the CAR, whereas the intracellular endodomain provides the necessary signals to activate the T-cells after antigen recognition. The intracellular part is based on the structure of the T-cell receptor (TCR) coupled with one or more costimulatory domains, allowing to transduce the antigen recognition into T-cell activation.[8]

The antitumor activity of fourth-generation CAR T-cells are even further enhanced by additional genetic modifications—for example, by the addition of transgenes for cytokine secretion (eg, interleukin [IL]-12).[9–11]

CAR T-CELL MANUFACTURING AND ADMINISTRATION

Most CARs are manufactured from autologous T-cells, collected from the patients via leukapheresis. The process typically involves washing of the apheresis product, T-cell selection, T-cell activation, gene transfer, T-cell expansion, formulation, and cryopreservation. The T-cells are stimulated ex vivo, a viral vector or alternative transfer technology (ie, electroporation) is used to transmit genes containing the CAR to the T-cell, the CAR T-cells are expanded, and a pharmaceutical intravenous cell infusion product is usually administered as a single infusion. The median time from leukapheresis to CAR T-cell administration differs depending on the product and manufacturing process but usually

requires two to five weeks, and the entire process from referral to infusion can take up to two months.[12] Many of the initial clinical trials did not allow bridging therapy; however, in practice many patients require therapy for disease control before infusion of CAR T-cells. The optimal therapeutic regimen for bridging depends on the patient's treatment history and prior toxicities; however, it is important that enough time be allowed between bridging and CAR T-cell infusion—a washout period—to allow recovery from any adverse events. In general, recommended washout times are at least two weeks for systemic chemotherapy, four weeks for pegylated l-asparaginase, and 72 hours for steroids.[13] Bridging therapy can include steroids for symptom control, radiation, chemotherapy, or a combination.

Lymphodepleting (LD) chemotherapy is administered before the infusion of CAR T-cells and most commonly consists of fludarabine and cyclophosphamide. The choice of drug used for LD chemotherapy may impact adoptively transferred T-cell expansion and persistence because LD decreases the number of T-cells in vivo, including regulatory T-cells, and consequently upregulates cytokines such as IL-7 and IL-15, which promote T-cell expansion and enhance the anti-lymphoma activity of the CAR T-cells.[14,15] Patients with B-ALL and B-cell lymphoma who received cyclophosphamide and fludarabine lymphodepletion before CAR T-cell infusion had better in vivo CAR T-cell expansion and persistence, compared with those who received cyclophosphamide alone who had shorter in vivo persistence of CAR T-cells.[16–18] Patients generally receive LD chemotherapy for three days (days –5 to –3), followed two days later by a single infusion of cells on day 0; this can take place outpatient or inpatient based on institutional preference.

CAR T-CELL THERAPY IN AGGRESSIVE B-CELL LYMPHOMA

As of this writing, two CAR T-cell products, tisagenlecleucel (tisa-cel) and axicabtagene ciloleucel (axi-cel), have approval by the FDA for the treatment of certain B-cell NHL types in adults; and a third, lisocabtagene maraleucel (liso-cel), is also submitted to the FDA for approval. Both tisa-cel and axi-cel are commercially available for relapsed or refractory (rel/ref) large B-cell lymphoma in patients who have received at least two prior regimens.

Axi-cel is an anti-CD19 CAR T-cell product generated using a retroviral vector and uses a CD28 costimulatory domain. The pivotal phase 1/2 registration trial, ZUMA-1, enrolled 111 patients with the diagnoses of DLBCL (n = 77), transformed follicular lymphoma (n = 16), and primary mediastinal B-cell lymphoma (n = 8).[19] All patients had chemotherapy-refractory disease, defined as refractory to second-line or subsequent therapy, or relapsed disease within one year after autologous SCT (auto-SCT). Median age was 58 years and the oldest patient treated was 76 years. Eligibility criteria included Eastern Cooperative Oncology Group (ECOG) performance status of 0 or 1, an absolute lymphocyte count greater than 100 cells/μL, and adequate bone marrow and organ function. Patients with primary or secondary central nervous system (CNS) lymphoma were not eligible, and patients could not have received prior allogeneic SCT. The patient population was heavily pretreated with a median of three prior therapies.[19]

Of 111 patients enrolled, axi-cel was successfully manufactured for 110, and 101 were treated. Median time from leukapheresis to the delivery of the T-cell product to the treating center was 17 days. Per protocol, bridging chemotherapy after apheresis was not allowed. LD chemotherapy consisted of 500 mg/m^2 per day of cyclophosphamide and 30 mg/m^2 per day of fludarabine on days –5 to –3, and the axi-cel dose was 2 × 10^6 CAR T-cells per kilogram of body weight. The best overall response rate (ORR) as determined was 83%, including 58% of patients who achieved complete response (CR). At two years of follow-up, 39% of patients were in ongoing remission. Median progression-free survival (PFS) for the entire population was 5.9 months, median duration of response was 11.1 months, and the two-year rate of overall survival (OS) for the entire population was 50.5%.

The incidence of any grade CRS was 93% occurring at a median of 2 days from CAR T-cell infusion, though only 13% of patients had severe CRS (grade 3–5). Sixty-four percent of patients experienced neurotoxicity with a median time to onset of 5 days, whereas 28% experienced severe neurotoxicity (grade ≥3). This study used the grading criteria by Lee and colleagues for CRS and Common Terminology Criteria for Adverse Events criteria for neurologic toxicity.[19,20] Among all patients, 43% and 27% received tocilizumab and corticosteroids, respectively. Additional toxicities included cytopenias and hypogammaglobulinemia. Four adverse event–related deaths occurred on study, two of which were attributed to axi-cel.

Tisa-cel targets the same CD19 antigen as axi-cel but uses a lentiviral vector and a 4-1BB costimulatory domain.[21] Eligibility for this trial included patients having received at least two prior lines of therapy for DLBCL, transformed follicular lymphoma, or high-grade B-cell lymphoma with rearrangements of MYC and BCL2 or BCL6 (double-/triple-hit lymphoma). As with axi-cel, adequate organ and bone marrow function were required, and patients could not have received prior allo-SCT or have history of CNS disease. LD chemotherapy preceding tisa-cel infusion was most commonly cyclophosphamide (250 mg/

m^2/day) and fludarabine (25 mg/m^2/day) for 3 days, although bendamustine (90 mg/m^2/day) for 2 days was permissible. The dose of tisa-cel was 0.6–6.0 × 10^8 CAR T-cells. One hundred sixty-five patients were enrolled, of whom 111 received tisa-cel infusion. Patients had a median age of 56 years, and the oldest patient was 76 years. Of 70 patients assessed for gene arrangement, 27% had double-/triple-hit lymphoma, and the median number of prior treatments for all patients was three. Approximately one-half of patient had experienced relapse after an auto-SCT. In contrast to ZUMA-1, the majority (92%) of patients received bridging therapy after apheresis, while median time from enrollment to infusion was 54 days. The best ORR was 52%, with 40% of patients achieving CR and at 1 year, approximately one-third of all treated patients were in an ongoing remission including 65% of those who responded to treatment, and 1-year overall survival was 49%.

In contrast to axi-cel, CRS was graded using the University of Pennsylvania scale and observed in 58% of patients, occurring at a median of 3 days after treatment. Twenty-three percent of patients had severe CRS and 21% had neurologic toxicity, of which 12% was categorized as severe. Tocilizumab was administered to 14% of patients, with 10% of patients receiving corticosteroids. No deaths were attributable to CAR T-cell therapy with tisa-cel. As with other anti-CD19 CAR T-cell products, cytopenias were common and could be prolonged. On-target B-cell depletion and hypogammaglobulinemia were observed, with 30% of patients receiving intravenous immunoglobulin at the discretion of the treating physician.[21]

Liso-cel is also a CD19-directed CAR T-cell product using a lentiviral vector and 4-1BB costimulation domain and is currently under review with the FDA for approval for commercial use. Compared with axi-cel and tisa-cel, which are both produced using bulk autologous T-cells, liso-cel manufacturing separately transduces and expands CD4+ and CD8+ CAR T-cells and administers them at a fixed 1:1 ratio that allows for precise dosing to every patient.[22] The TRANSCEND study was designed as a dose-escalation and dose-expansion study followed by a pivotal cohort in relapsed/refractory (R/R) DLBCL. Patients were treated at doses of 5 × 10^7 dose level (DL; DL1) or 1 × 10^8 (DL2) or 1.50 × 10^8 (DL3) CAR T-cells. Eligible patients had DLBCL, double-/triple-hit lymphoma, primary mediastinal B-cell lymphoma (PMBCL), FL grade 3b, and DLBCL transformed from indolent histologies. There was no minimal absolute lymphocyte count required for enrollment, though patients did have to exhibit adequate organ and bone marrow function similar to the other pivotal trials. Patients with both prior allo-HSCT off immune suppression and/or secondary CNS involvement with measurable systemic disease were allowed on trial. Eligibility included a minimum of two prior lines of therapy, and this protocol did allow bridging chemotherapy after apheresis before infusion of cells. LD chemotherapy consisted of 300 mg/m^2 of cyclophosphamide and 30 mg/m^2 of fludarabine for 3 days, followed 2 to 7 days later by liso-cel infusion.

Three hundred forty-four patients received leukapheresis; 269 patients received liso-cel (DL1, n = 51; DL2, n = 177; DL3, n = 41). Twenty-five patients received nonconforming product; product could not be manufactured for two patients. Thirteen percent of patients had double-/triple-hit lymphoma, and median prior lines of therapy was 3, with 67% of patients having chemo-refractory disease. The median age was 63 years and the oldest patient treated was age 86 years. Among patients evaluable for efficacy (n = 256), the best ORR was 73% with a best CR rate of 53%; and at 1 year, 58% of patients remained alive. At 12 months of follow-up, the median duration of response had not been reached, and 44% of patients were in ongoing remission.[12] The median PFS was 6.8 months, and median OS was 21.1 months. As with prior studies, durable responses were observed across all high-risk subsets, including double-/triple-hit lymphoma and chemo-refractory disease.

Toxicity and CRS was graded using the same criteria by Lee et al[20] that was used for axi-cel in Zuma 1; and in this study was 37% and occurred at a median of 5 days, with severe CRS observed only in one patient (1%). The rate of any neurologic toxicity was 23%, with 13% of patients experiencing severe neurologic toxicities. There were no deaths related to CRS or neurologic toxicities in the study. Tocilizumab and corticosteroids were administered to 17% and 21% of patients, respectively. Prolonged grade 3 or higher cytopenia (based on laboratory assessment at day 29) was reported in 37% of patients. The pivotal cohort of this study has completed accrual but has not yet been reported, and this product remains investigational pending FDA approval.

Given the outcomes of the pivotal trials, these three products—axi-cel, tisa-cel, and liso-cel—can all be considered effective treatments for patients with chemo-refractory DLBCL or transformed follicular lymphoma beyond second-line therapy. However, there are distinct differences among the products, which require appropriate treatment selection for a given patient. Axi-cel has proven to have the most rapid vein to vein time from apheresis to infusion, which is important for patients with rapid disease kinetics. Conversely, incidence of CRS and neurotoxicity seems to be higher with axi-cel than with either of the two 4-1BB costimulated products, tisa-cel and liso-cel, likely reflecting differences in the kinetics of T-cell expansion and proliferation conferred by the costimulation domains. Tisa-cel and liso-cel have lower overall rates of CRS

and neurologic toxicity and, overall, a later onset of these toxicities; therefore, centers often choose to administer this treatment in the outpatient setting.[23] Of note, toxicity grading scale selection was not standardized with the pivotal trials. Tocilizumab and steroids were received by 43% and 27% of patients treated with axi-cel and 14% and 10% of patients treated with tisa-cel, respectively, suggesting less toxicity with tisa-cel. Because of anticipated toxicity differences, axi-cel–treated patients received CAR T-cell therapy as an inpatient, whereas 61% of patients received tisa-cel as an outpatient.[24,25]

Two multicenter retrospective analyses evaluated the use of commercial axi-cel after FDA approval.[26,27] In these studies, patients often did not strictly meet the eligibility criteria of the pivotal trial but were treated in accordance with the FDA label. Most commonly, the difference was with the administration of bridging therapy after apheresis; however, patients were also older than those in the pivotal trial, with patients treated up to age 83 years. The study reported by Nastoupil et al included 295 patients, with 274 patients treated. The final CAR T-cell product did not meet FDA specifications in seven patients.

The median time from apheresis to start of LD chemotherapy was 21.5 days; however, the delivery of the product was approximately 15 to 16 days after apheresis. The time to initiation of LD was delayed awaiting count recovery because of bridging therapy, which a majority of patients received; this is in contrast to the ZUMA-1 trial, in which approximately 55% patients received any form of bridging therapy. General characteristics included a median age of 60 years (range, 21–83), stage III/IV in 83%, ECOG performance status (PS) 0–1 in 81%, three or more lines of therapy in 75% of cases, and relapsed post auto-HCT in 33%. Interestingly, 43% of patients (124/286) would not have been eligible for the ZUMA-1 trial per the trial eligibility criteria, yet overall efficacy was similar to the ZUMA-1 trial, with 3-month ORR and CR rates of 81% and 57%, respectively.[26] Jacobson et al reported on 108 patients who received axi-cel; of those, 104 were evaluable for efficacy. The median age was 63.8 years, ECOG PS 0–1 in 90% of cases, prior auto-HCT in 27%, and prior allo-HCT in 3%. About 52% of the evaluable patients received bridging chemotherapy after apheresis; 60% of patients would have not met criteria for the ZUMA-1 clinical trial. In the 95 patients evaluable for response, the best ORR and CR rates were 71% and 44%, respectively. Similarly, about 50% of patients who initially had a PR, achieved CR at a later time.[27] These studies highlight that response rates and toxicity profiles were similar to the pivotal trial while being inclusive of patients who would not fit within the highly restrictive parameters of clinical trials (Table 17–1).

TOXICITY AND SIDE EFFECTS

Distinct from chemotherapy-associated side effects, CAR T-cell–mediated toxicities are unique and potentially life threatening such as CRS and immune effector cell–associated neurotoxicity syndrome (ICANS, previously termed *CAR-T-cell–related encephalopathy syndrome*). Many of these effects are on target and reverse when the CAR T-cell expansion subsides.[28] CRS is caused by cytokine elevations as a result of immune activation of large numbers of lymphocytes, which can manifest as fever, hypotension, and/or hypoxia.[20,29] CRS typically occurs within the first week after CAR T-cell infusion and peak CAR T-cell levels and serum IL-6 levels have strongly correlated with the severity of CRS. Those at highest risk for adverse outcomes from severe CRS include patients with large tumor burdens, comorbidities, or development of early-onset CRS within three days of infusion.[30] Comparisons of CRS severity across CAR T studies is complicated by the use of different grading systems, which before the consensus guidelines, were product specific—ie, the Penn scale (tisa-cel)[31] and the Lee scale (axi-cel).[20] A consensus statement to standardize CRS grading was endorsed by American Society of Transplantation and Cellular Therapy (ASTCT) in 2019, which employs a grading scale using fever, and/or hypoxia, and hypotension (Table 17–2).[32]

Although many cases of CRS may be self-limited and treated with supportive care alone, the mainstay for treatment of severe CRS are tocilizumab and corticosteroids. Tocilizumab is an anti–IL-6 receptor antagonist approved by the FDA in August 2017 to treat CRS when the first CAR T-cell product was approved. It can induce a rapid reversal of CRS and has become the standard of care for this complication.[19,33] Corticosteroids are also effective in the management of toxicities after CAR T-cell therapies because they suppress inflammatory responses. Corticosteroids are often administered if the patient does not have a rapid response to IL-6 receptor blockade, and it can be given in a number of ways including with initial tocilizumab, concurrently with subsequent doses of tocilizumab if there is inadequate response, or as a single agent after tocilizumab. The general principle guiding steroids for treatment of CART toxicity is that they should be prescribed at the lowest effective dose for the shortest possible duration to limit the risk of abrogating CAR T-cell efficacy and persistence. However, as of this writing, the dose and duration of steroids required to irreversibly impair CAR T-cell efficacy is unknown. There are reports that early and prolonged use of high-dose corticosteroids are associated with early progression and death in patients treated with axi-cel.[34]

Table 17–1 Pivotal Trials for Anti-CD19 CAR T-Cell therapy Multicenter Trials in Aggressive B-Cell NHLs

Cell Product	Axi-cel	Tisa-cel	Liso-cel
Trial	ZUMA-1[19]	JULIET[21]	TRANSCEND[22]
Costimulatory and T-cell activation domains	CD28 and CD3ζ	4-1BB and CD3ζ	4-1BB and CD3ζ
Vector	Retrovirus	Lentivirus	Lentivirus
Number of cells infused	2×10^6 CAR T-cells per kg	$0.6–6.0 \times 10^8$ CAR T-cells	5×10^7 or 1×10^8 or 1.5×10^8 CD4:CD8 ratio = 1:1
Median prior LOT	3	3	3
LD regimen	Cy 500 mg/m²/day for 3 days Flu 30 mg/m²/day for 3 days	Cy 250 mg/m²/day for 3 days Flu 25 mg/m²/day for 3 days OR Bendamustine 90 mg/m² IV daily for 2 days	Cy 300 mg/m²/day for 3 days Flu 30 mg/m²/day for 3 days
Number enrolled (infused)	111 (101)	165 (111)	342 (268)
Number response-evaluable	101	93	256
Lymphoma subtypes	DLBCL, TFL, PMBCL	DLBCL, TFL	DLBCL, HGBCL, DLBCL transformed from FL, CLL and MZL, PMBCL and FL3B
Best ORR (CR)	83% (58%)	52% (40%)	73% (53%)
Median DoR	11.1 months after median follow-up of 27.1 mo	Not reached after median follow-up of 14 mo	Not reached after median follow-up of 12 mo
12-month PFS	44%	31%	44%
12-month OS	59%	49%	58%
FDA Approval Status	Approved	Approved	Under review
Toxicity			
CRS All grades	93%	58%	42%
CRS grade ≥3	13%	22%	2%
NT all grades	64%	21%	30%
NT grade ≥3	28%	12%	10%

LOT, lines of therapy; NR, not reached; NT, neurotoxicity.

Neurologic toxicity is the second clinically significant adverse event associated with CAR T-cell therapy. Early descriptions often combined CRS and ICANS under the overarching term CRS, but growing understanding of these toxicities suggest they are distinct entities with different pathophysiology and management recommendations. ICANS typically occurs after the peak of CRS (often >3 days later) and rarely occurs without antecedent CRS, and peak symptoms occur on days 5 to 9. ICANS may be affected by patient-specific factors including disease type, disease burden, treatment history, and patient age, as well as product-specific factors such as CAR design, cell manufacturing conditions, CAR T-cell dose, preconditioning regimen, and product potency.[33] Anecdotal data indicate that the IL-1 antagonist, anakinra, may be effective in patients with severe CRS and ICANS,[35] and it is being explored in clinical trials to assess its role in mitigation of CRS and ICANS.

Common clinical manifestations of ICANS are expressive aphasia or language disturbance, impairments of attention, cognitive processing, and changes in handwriting. However, symptoms can be diverse and include encephalopathy (confusion or delirium), motor weakness, tremor, headache, seizures, depressed level of consciousness, and, rarely, diffuse cerebral edema.[36,37] In both ICANS and CRS, there is likely overlap in the pathophysiology of toxicity in which it is suggested that endothelial activation is the driving mechanism. ICANS is characterized by increased blood-brain barrier (BBB) permeability, capillary leak, and disseminated intravascular coagulation, with increased inflammatory cytokines, CAR T-cells, and myeloid cells in cerebrospinal fluid.[38] The ASTCT

Table 17–2 ASTCT CRS Consensus Grading[32]

CRS Parameter	Grade 1	Grade 2	Grade 3	Grade 4
Fever[a]	Temperature ≥38 °C	Temperature ≥38 °C	Temperature ≥38 °C	Temperature ≥38 °C
WITH				
Hypotension	None	Not requiring vasopressors	Requiring a vasopressor with or without vasopressin	Requiring multiple vasopressors (excluding vasopressin)
AND/OR[b]				
Hypoxia	None	Requiring low-flow nasal cannula[c] or blow-by	Requiring high-flow nasal cannula,[c] facemask, nonrebreather mask, or Venturi mask	Requiring positive pressure (eg, CPAP, BiPAP, intubation and mechanical ventilation)

[a]Fever is defined as temperature ≥38 °C not attributable to any other cause.
[b]CRS grade is determined by the more severe event: hypotension or hypoxia not attributable to any other cause.
[c]Low-flow nasal cannula is defined as oxygen delivered at ≤6 L/minute. High-flow nasal cannula is defined as oxygen delivered at >6 L/minute.
BiPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure.

consensus guidelines for grading ICANS uses an updated encephalopathy screening tool, the Immune Effector Cell Encephalopathy (ICE) score, in addition to assessment of level of consciousness, seizure, motor findings, and elevated intracranial pressure/cerebral edema (Tables 17–3 and 17–4).

In contrast to CRS, tocilizumab is not effective for ICANS as a single agent, which is likely both a function of the multifactorial pathogenesis of ICANS, in addition to the inability of tocilizumab to cross the BBB.[37] Most centers are using corticosteroids as first-line therapy for isolated ICANS with the addition of tocilizumab to corticosteroids given for ICANS that develops concurrently with CRS.

Steroid recommendations are based on clinical trial experience because no randomized trial data are available and the absolute benefit is unknown. Different corticosteroids are used depending on institutional standards, although dexamethasone use is most common because it has excellent CNS penetration, whereas high-dose methylprednisolone is used in the more severe cases of ICANS based on experience with fulminant neuroinflammatory disorders.[38] Prophylactic anticonvulsants are largely standard, although the data supporting their use are lacking.

Table 17–3 ASTCT ICE Assessment Tool for Encephalopathy in Adults

Orientation	Orientation to year, month, city, hospital: 4 points
Naming	Ability to name 3 objects: 3 points
Following Commands	Ability to follow simple commands: 1 point
Writing	Ability to write a standard sentence: 1 point
Attention	Ability to count backwards from 100 by 10: 1 point

Grading by score:
Grade 1: 7–9 points
Grade 2: 3–6 points
Grade 3: 0–2 points
Grade 4: unarousable, unable to complete assessment

In addition to CRS and ICANS, there are CAR T-cell–associated side effects as well as organ-specific toxicity associated with CAR T-cell therapy. Cytopenias have been commonly documented after CAR T-cell infusion with grade 3–4 anemias, thrombocytopenia, or leukopenia reported beyond 28 days in more than 30% of patients.[21,39] Although not life threatening, hypogammaglobulinemia as a result of prolonged B-cell aplasia can lead to infectious complications. Some centers routinely administer intravenous immunoglobulin, whereas others restrict usage to patients who have repeated infections. In severe CRS, a cytokine signature mirroring that of hemophagocytic lymphohistiocytosis/macrophage activation syndrome (HLH/MAS) can occur, with optimal treatment still to be defined although high-dose steroids, tocilizumab, and sometimes anakinra have been used with success.[6,40]

Most patients who receive CAR T-cell immunotherapy have poor immune function caused by the effects of their malignancy, prior cytotoxic treatment, and management for CRS and ICANS, including steroids, which can cause further immune suppression. Data on infectious complications are still preliminary, but there is a suggestion that prolonged neutropenia and higher-grade CRS, which may be a surrogate for prolonged corticosteroid

Table 17–4 ASTCT ICANS Consensus Grading for Adults[32]

Neurotoxicity Domain	Grade 1	Grade 2	Grade 3	Grade 4
ICE score	7–9 points	3–6 points	0–2 points	0 Unarousable
Depressed level of consciousness	Awakens spontaneously	Awakens to voice	Awakens only to tactile stimulus	Unarousable or requires vigorous or repetitive tactile stimuli to arouse; stupor or coma
Seizure	NA	NA	Any clinical seizure, focal or Generalized, that resolves rapidly or nonconvulsive seizures on EEG that resolve with intervention	Life-threatening prolonged seizure (>5 min); or repetitive clinical or electrical seizures without return to baseline in between
Motor findings	NA	NA	NA	Deep focal motor weakness such as hemiparesis or paraparesis
Raised ICP/cerebral edema	NA	NA	Focal/local edema with or without hemorrhage on neuroimaging	Diffuse cerebral edema on neuroimaging; decerebrate or decorticate posturing; or cranial nerve VI palsy; or papilledema; or Cushing triad

EEG, electroencephalogram; ICP, intracranial pressure.

use, increase the risk of all infections (viral, bacterial, and fungal.) The increased risk for invasive fungal infections in patients who have a history of prior auto- or allo-HCT or development of life-threatening CRS and/or neurotoxicity has led most centers to broaden fungal prophylaxis in these high-risk patients.[41] At our center, patients receive prophylaxis for *Pneumocystis jiroveci* pneumonia, herpes zoster, and herpes simplex infection from time of CAR infusion to at least 12 months post infusion. Fungal prophylaxis is divided into low risk and high risk, with mold coverage for high-risk patients continuing at least 30 days after completion of steroids or the time point when high-risk features were identified. High risk is defined as history of leukemia, recipient of auto- or allo-HCT, history of mold infection, neutropenia lasting more than 14 days, grade 3 or 4 CRS/ICANS, receipt of more than 3 days of steroids, or history of HLH/MAS.

RELAPSE AND FAILURE OF CAR T-CELL THERAPY

Despite the success with CAR T-cell therapy, treatment failure remains a major challenge. Although the exact mechanisms causing tumor escape remain unknown, relapse after CAR T-cell therapy that targets the CD19 antigen can be categorized broadly as (1) antigen loss, (2) lack of CAR T-cell persistence, or (3) host-specific factors.

A well-characterized mechanism of resistance in patients with ALL is the loss of tumor expression of the extracellular CD19 epitope, to which the CAR binds. This can occur because of alterations in CD19 secondary to acquired mutations and loss of heterozygosity.[42,43] Patients treated on ZUMA-1 with DLBCL who received axi-cel demonstrated a loss of tumor CD19 as evaluated by immunohistochemistry or flow cytometry by local pathologic evaluation and was described in 3 of 11 (27%) patients with biopsies at relapse after CAR T-cell therapy.[19] Approaches to overcome antigen loss include multispecific CAR T-cells to target more than one antigen, coadministration of two separate CAR T-cell products, or even a mixed product with heterogeneous CAR T-cells.[44]

Lack of persistence has been attributed to T-cell exhaustion. CAR T-cell exhaustion may arise from factors before chemotherapy, alterations in the tumor microenvironment, contributions from circulating cells, or it could be associated with variations in the manufacturing process. "Exhausted" CAR T-cells are less proliferative, have a higher number of inhibitory receptors (ie, programmed death 1 [PD-1]), and are

less potent/cytotoxic than nonexhausted T-cells. T-cell exhaustion is a complex phenomenon and is accompanied by an upregulation of inhibitory receptors, such as PD-1, TIM-3, and LAG-3.[45] Multiple environmental and T-cell–intrinsic mechanisms contribute toward the acquisition of an exhausted phenotype and, as a result, these cells have poor effector cell function and reduced efficacy.[25] Off-label use of the PD-1–blocking antibodies, pembrolizumab and nivolumab, has resulted in clinical responses with evidence for enhanced CAR T-cell function and antitumor activity through the re-expansion and restored antitumor activity of exhausted CAR T-cells.[25] The phase 1 results of ZUMA-6, which adds PD-L1 blockade with atezolizumab after axi-cel infusion, has shown a manageable safety profile with CRS and neurotoxicity rates that are not significantly increased, despite a suggestion for greater CAR T-cell expansion compared with ZUMA-1. The expansion cohort is currently under investigation.[46] In addition to T-cell exhaustion, regulatory T-cells and myeloid-derived suppressor cells may suppress CAR T-cell proliferation and cytokine production, leading to a dampening of the antitumor response. It is important to note that persistence has not been correlated directly with the presence or lack of durable long-term response. Long-term follow-up from ZUMA-1 demonstrates that 75% of patients with ongoing responses had B-cell recovery, and data from JULIET showed no link between expansion, T-cell concentration, and clinical outcomes.

Host factors driving CART efficacy continue to be defined. The depth of lymphodepletion before CAR T-cell infusion has been shown to impact treatment outcomes. Data comparing fludarabine/cyclophosphamide as LD conditioning versus cyclophosphamide alone LD conditioning showed the former was associated with increased CAR T-cell expansion, persistence, and improved response rates, indicating that lymphodepletion is an important driver of response.[18] Tumor burden may also correlate to outcomes; patients with ALL with less than 5% blasts demonstrated a superior OS compared with those with a higher disease burden in multiple reports.[47] Locke et al reported data from ZUMA-1 suggesting that high tumor volumes are associated with inferior durable responses in DLBCL.[48] Although bridging therapy was not allowed on the initial ZUMA-1 trial, when CAR T-cell therapy is used in the real-world setting, often bridging chemotherapy is used to control disease until the time of cell infusion. Pinnix et al reported patients who received subsequent axi-cel infusion with or without bridging therapy (BT) and reported that those who received BT had a worse PFS and OS when compared with those who did not receive BT. In this study, BT consisted of chemotherapy, radiation, or a combination of both. Patients who received bridging were more likely to have adverse factors at leukapheresis, including worse PS, international prognostic index (IPI) score of at least 3, bulky disease, and elevated lactate dehydrogenase. Of note, while in this group of 124 patients, BT was administered to 50%, the patients who received radiation as BT had an apparent increased CR rate (82%) compared with those treated with chemotherapy alone (38%), without any increase in CAR T-cell–related toxicity.[49]

INDOLENT LYMPHOMAS

Early trials with CAR T-cells initially commenced with enrollment of indolent NHLs (iNHL); however, the first-generation anti-CD19 CAR T-cells (without costimulation) reported no clinical efficacy in FL cases.[50] Turtle et al reported on 8 FL patients treated with the 4-1BB CAR T-cell construct (1:1 CD4/CD8 ratio),7 of 8 patients achieved CR rates with all ongoing at a median follow-up of 24 months.[51] The largest single-institution data in CAR T-cell therapy for the treatment of FL to date come from the analysis of tisa-cel from the University of Pennsylvania that included 14 FLs. These FL patients had relapsed within 24 months of initial diagnosis and remained refractory to at least two lines of therapy.[52,53] Patients received a variety of conditioning regimens and included FL patients with poor prognosis features, including prior multiple therapies (median of 5), relapsed post auto-HCT (21%) and allo-HCT (1 patient). The updated analysis showed a 3-month ORR and CR of 79% (11/14) and 71% (10/14), respectively. The median PFS was not reached, and 70% of patients with FL were disease free at a median follow-up of 28.6 months.[53]

Interim results from ZUMA-5, a phase 2, multicenter study of axi-cel in patients with R/R iNHL, was reported in abstract form earlier this year. The trial eligibility included R/R FL (grades 1–3a) or MZL (nodal or extranodal) after at least two lines of therapy, and ECOG PS of 0–1. Patients received LD chemotherapy followed by axi-cel infusion at 2×10^6 CAR T-cells/kg. To date, 96 pts (80 FL; 16 MZL) received axi-cel with a median follow-up of 12.8 months (range, 1.9–28.8). These patients had a median age of 63 years (range, 34–79), 49% of patients were male, 52% had stage IV disease, 51% had follicular lymphoma IPI of at least 3, and 49% had high tumor bulk. This was a heavily pretreated population with a median 3 prior lines of therapy, and 54% of patients had progressed less than 2 years after initial anti-CD20 monoclonal antibody (mAb)-containing therapy (POD24), whereas 73% were refractory to the last prior treatment. Of 96 patients evaluable for efficacy, ORR was 93% (80% CR rate). Patients with FL (n = 80) had an ORR of 95% (81% CR rate). Patients with MZL (n = 16) had an ORR of 81% (75% CR rate). Overall, 68% of FL patients

had ongoing responses as of the data cutoff. The rate of grade 3 or higher CRS was 8%, whereas grade 3 or higher ICANS was 17%.[54] These data support anti-CD19 CAR T-cell therapy as a promising therapy in iNHL, and there are a number of trials that are ongoing in this patient population.

CENTRAL NERVOUS SYSTEM LYMPHOMA

The early CAR T-cell trials excluded patients with primary (PCNSL) or secondary CNS (SCNSL) lymphoma because of the concern of increased risk of neurotoxicity. In general, CNS lymphoma is challenging to treat because of the limited penetration of chemotherapy and immunotherapy through the BBB. Although there are reports of documented CNS penetration of CAR T-cells in leukemia, small studies have only recently shown active CAR T-cells in lymphoma.[55–57] There have now been a number of reports that have shown efficacy of commercial CAR T-cell therapy without a significant increase in ICANS in patients with SCNSL. Fifteen patients with a recent history or active SCNSL treated with axi-cel reported an ORR of 75% (including two achieving CR with active SCNSL) without a significant difference in toxicity compared with patients without CNS involvement.[58] In another series, eight patients with CNS involvement were treated with tisagenlecleucel. Two of eight patients had systemic disease in addition to CNS involvement at the time of infusion. All patients received CNS-directed therapy for refractory disease up until lymphodepletion. No patients required tocilizumab or high-dose steroids for the management of CRS and/or ICANS, with durable responses noted in a small minority of patients.[55] This experience is echoed by Siddiqi et al, who report on an ongoing phase 1 trial investigating an autologous CD19-specific, hinge-optimized, CD28 costimulatory CAR with a truncated estimated glomerular filtration rate, which does not exclude patients with PCNSL or SCNSL. Three patients with PCNSL and four with SCNSL were treated without any grade 3 or higher CRS or ICANS and an ORR of 57%.[59] Further data are needed to qualify the long-term durable response of autologous CD19–directed CAR T-cell therapy in CNS lymphoma, but there are ample data that confirm no increase above baseline in terms of toxicity, specifically neurotoxicity.

T-CELL LYMPHOMA

TCLs are associated with an overall poor prognosis and do not have as many treatment options as B-cell lymphomas. Because of shared antigen expression between normal, malignant, and therapeutic T-cells, CAR T-cell therapy targeting T-cell malignancies can potentially lead to CAR T-cell fratricide (self-killing) and prolonged T-cell aplasia.[60,61] CD5 and CD7 have been identified as potential targets, with significant antitumor activity seen in preclinical models.[62] The phase 1 results were reported in abstract form of a CD5 CAR T-cell trial for treatment of CD5-positive T-cell malignancies in five patients at two dose levels (1×10^7 and 5×10^7 CAR T-cells/m^2) with a median of four prior lines of therapy (range, 2–8). CRS occurred in three of five patients (all at DL2); however, the highest-grade CRS or ICANS observed was grade 2. On disease reevaluation 4 to 8 weeks post-CD5 CAR T-cell infusion, three of five evaluable patients obtained an objective response (one on DL1 and two on DL2). Two patients achieved CR and a third had a mixed response and then responded to an additional infusion. All of the patients who achieved a response then proceeded to allo-HCT.[63] Although this is a small series, it shows efficacy targeting CD5 as an antigen for CAR T-cell therapy. Larger studies with longer follow-up are needed to assess whether this is a pathway that could be feasible, devoid of the allogeneic transplant as consolidation.

CD30 is almost universally expressed in anaplastic large-cell lymphomas (ALCL), and in a proportion of other T-cell lymphoma types, including cutaneous T-cell lymphomas. CD30 is an excellent candidate for immune-based therapies because of its restricted expression on tumor cells, with limited expression on a small subset of activated normal (nonmalignant) lymphocytes, leading to low risk for off-tumor, on-target toxicity.[64] Two trials of CD30-directed CAR T-cells published have included T-cell lymphomas in addition to other CD30-expressing disease. The largest series reported on 18 patients with R/R CD30+ lymphoma (17 with HL and one with cutaneous ALCL) with an anti-CD30 CAR,[65] which utilized the 4-1BB costimulatory endodomain and a lentiviral vector for T-cell engineering. The patient population was heavily pretreated and there was no CRS observed; however, the responses were modest, with seven patients attaining a PR and six patients with stable disease. There were no CRs and the ORR was 39%. The median PFS was 6 months.

Using a different construct, Ramos et al reported the results of nine patients with R/R CD30+ lymphoma (six with HL, two with ALCL, and one with DLBCL evolved to HL). For this trial, the CD30 CAR included a CD28 costimulatory endodomain and was delivered into T-cells via a gamma retroviral vector. These patients exhibited mild CRS and three patients attained CR, whereas another three had stable disease; notably, those who attained CR had prolonged disease-free time periods.[66]

There are a number of clinical trials investigating CD30 as a target for CAR T-cell therapy, both with autologous and allogeneic constructs.[67]

MANTLE CELL LYMPHOMA

Mantle cell lymphoma (MCL) comprises about 5% of newly diagnosed NHL, and the median age at diagnosis is about 68 years, with a subset of patients who do exceptionally poorly based on histology, TP53 gene mutation, and factors that define the mantle cell international prognostic index.[68,69] MCL is uniformly CD19 positive and amenable to CD19-directed immunotherapies or cellular immunotherapies. Preliminary data from the TRANSCEND study, using liso-cel, in nine heavily pretreated MCL patients (all with prior Bruton tyrosine kinase inhibitor exposure, three with prior auto-HCT) showed an encouraging ORR of 78%. In the pivotal ZUMA-2 trial, KTE-X19 product (brexucabtagene autoleucel) was tested in patients with R/R MCL.[70] KTE-X19 is an anti-CD19 CAR T-cell therapy produced in a manufacturing process that removes circulating CD19-expressing malignant cells for use in patients with leukemia or MCL. The removal of these cells reduces the possible activation and exhaustion of anti-CD19 CAR T-cells during the ex vivo manufacturing process. Brexucabtagene autoleucel has just recently received commercial approval based on the results of the ZUMA-2 pivotal trial. Conditioning chemotherapy consisted of fludarabine at a dose of 30 mg/m^2 per day, and cyclophosphamide at a dose of 500 mg/m^2 per day was administered on days –5, –4, and –3 before a single intravenous infusion of brexucabtagene autoleucel (brexu-cel) was administered at a dose of 2 × 10^6 CAR T cells/kg on day 0. There was no phase 1 study because the dose was determined on the basis of studies of axi-cel in patients with large B-cell lymphoma and of KTE-X19 in patients with ALL.[19,71] In contrast to the ZUMA-1 trial, before conditioning and after apheresis, patients who had a high disease burden could receive BT. The choice was at the investigator's discretion—glucocorticoid, ibrutinib, or acalabrutinib (or a combination of glucocorticoid plus ibrutinib or acalabrutinib)—with the intent of BT to keep the disease stable during the manufacturing period. Seventy-four patients were enrolled and product was manufactured for 71 patients and administered to 68; 96% of the patients had a dose successfully manufactured, with KTE-X19 delivered to the site in a median of 16 days after apheresis. The efficacy analysis showed 85% had an objective response and 59% had a CR. At a median follow-up of 12.3 months, 57% of the 60 patients in the primary efficacy analysis were in remission, whereas the 12-month PFS and OS were 61% and 83%, respectively. In terms of toxicity, 26% of patients had grade 3 or higher cytopenias lasting beyond 90 days after the administration of brexucel. Overall, any grade CRS occurred in 91% of the patients and most cases were grade 1 or 2 (in 76% of patients), whereas 15% were grade 3 or higher. A total of 63% of patients had neurologic events without any deaths attributed to ICANS. ICANS grade 1 or 2 occurred in 32% of the patients and events of grade 3 or higher occurred in 31%. The median duration of a neurologic event was 12 days, with events fully resolving in 37 of 43 patients (86%). There were two deaths associated with infection. Given these results, we will likely see a shift in paradigm as with DLBCL in timing of transplantation for MCL.

HODGKIN LYMPHOMA

HL is characterized by Reed-Sternberg cells that are CD19 negative and CD30 positive within an immunosuppressive tumor microenvironment containing CD19+ B cells. Studies using autologous anti-CD30 CAR[65] with the 4-1BB costimulatory endodomain and a lentiviral vector have recently reported the outcomes of 41 patients with R/R HL treated at two independent centers. Documented CD30 expression by immunohistochemistry was required, but there was no specific cutoff. Bridging chemotherapy was allowed before lymphodepletion, and LDC consisted of either cyclophosphamide 500 mg/m^2 per day and fludarabine 30 mg/m^2 per day for 3 days (flu/cy); bendamustine alone at 90 mg/m^2 per day for 2 days or bendamustine 70 mg/m^2 per day and fludarabine 30 mg/m^2 per day for 3 days (flu/benda). The cell dose at the expansion level was 2 × 10^8 cells/m^2. The bendamustine-alone arm did not have any patients who responded, whereas the flu/cy arm had an ORR of 65% with a CR rate of 47%, and the flu/benda arm had an ORR of 80% and CR rate of 73%. The 1-year PFS for patients with measurable disease was 41% for all patients who received fludarabine-based lymphodepletion and 61% for those who achieved CR as initial response.[72] Given these results, a planned phase 2 trial is pending using the flu/benda regimen for lymphodepletion.

ALLOGENEIC CAR T-CELLS

To overcome the cumbersome and expensive process of manufacturing patient-specific autologous CAR T-cells, there are also efforts ongoing to develop allogeneic off-the-shelf CAR T-cell therapy approaches, which allows generation of about 100 doses from each apheresis product and therefore could lower

the cost of this therapy. Allogeneic CAR T-cells have many potential advantages, such as a decreased cost as a result of the implementation of industrialized and scaled-up production pathways. "Off-the-shelf" allogeneic CAR T-cells are premanufactured from third-party healthy donors and expanded in high numbers before treatment to be made available to patients on demand and therefore may provide potential solutions to the delays faced by the autologous CAR T-cell therapy including: (1) Time to manufacturing, (2) need for interim bridging therapies, (3) risk of malignant contamination, (4) T-cell variability, (5) risk of insufficient T-cell expansion, (6) T-cell dysfunction, and (7) limited opportunity for redosing. However, certain unique challenges arise as a function of the allogenic cell source, including graft-versus-host disease (GVHD) and the durability of the injected cells.

Most of the allogeneic CAR T-cell candidates utilize cellular gene-editing approaches to ensure complete removal of the TCR. Transcription activator–like effector nucleases (TALEN) were the first technology to be used in patients for αβTCR removal,[73] including for ALLO-501 (described below). There are a number of gene-editing technologies currently being used preclinically in addition to those in clinical trials for allogeneic CARs. These include clustered, regularly interspaced, short palindromic repeat (CRISPR), as well as antigen receptor complex (ARC) – editing mega-nucleases for genome engineering which is the incorporation of the DNA-binding domain from transcription activator–like effectors into hybrid nucleases (mega-transcription activator–like effectors) and zinc fingers.[74]

Of note, ALLO-501 is an investigational anti-CD19 CAR T-cell product that has been genetically modified to eliminate TCRα expression, with the goal of reducing the risk of GVHD. ALLO-647 is an investigational mAb that selectively targets and binds CD52 on T-cells, triggering a host immune response that depletes CD52-positive T-cells. The ALLO-501 CAR T-cell product is also genetically engineered to remove the CD52 cell surface protein. When the anti-CD52 mAb is administered during lymphodepletion, the patient's CD52-positive T-cells are targeted. This strategy supports the persistence and expansion of the donor CAR T-cells. The multicenter, open-label, phase 1 ALPHA study examined the safety and efficacy of sequential treatment with ALLO-647 and ALLO-501 in 22 patients with R/R DLBCL or FL who were treated with at least two prior lines of therapy, including an anti-CD20 mAb.[75] Among 19 patients evaluable for efficacy, the ORR was 63% and the CR rate was 37%. Although numbers are small, higher ALLO-647 doses during lymphodepletion were thought to be associated with deeper responses, with 27% and 50% of patients in the ALLO-647 39 mg and ALLO-647 90 mg groups, respectively, achieving a CR.

An alternative strategy for allogeneic CAR T-cell therapy is to use a different cell type such as NK cells, NK T-cells, or γδ T-cells, which are not known to cause GVHD and therefore do not require the additional gene editing such as knocking out the TCR. Indeed, in a small phase 1 study of 11 patients with B-cell malignancies, administration of allogeneic anti-CD19 CAR NK cells with NK cells–derived cord blood induced CR in eight patients with no CRS, ICANS, or GVHD.[76] These early data are highly encouraging regarding the safety, feasibility, and short-term efficacy of allogeneic CAR T-cell therapy. However, longer follow-up is needed to determine the durability of the responses.

NOVEL CAR DESIGNS

Empowering CAR T-cells to be able to recognize a combination of antigens on the cell surface of the tumor may help avoid antigen escape and/or reduce toxicity. These next-generation CARs, including multitargeted CAR configurations, include the following.

"OR"-gate CARs, where the binding of either CAR to its cognate antigen is enough to drive full T-cell activation. This strategy is to overcome tumor resistance. These include:

- Dual CARs[77]: coexpress two different CARs in one cell
- Tandem CARs[78]: contain two different single-chain variable fragments in a single CAR molecule that can either be stacked in a series or as a looped structure

The major advantage resides in the fact that the presence of *both* targets allows for an enhanced T-cell function, which makes them more efficient than a pooled combination of CAR T-cells at inducing antitumor responses.[79,80] However, such a strategy of targeting two antigens may result in increased risk for toxicity, especially when treating solid tumors.

"AND" -gate CARs, where CAR T-cells are fully activated only when antigen A *and* antigen B are recognized.[81] This strategy is to minimize toxicities.

These include:

- Combinatorial CARs[82]: combine two constructs where one bears the CD3z signaling motif and the other bears the costimulatory signaling domain. In this split-signal approach, recognition of a single antigen, which may happen in normal cells, leads to suboptimal T-cell activation and limited killing of normal cells. In tumors where both antigens may be expressed, full T-cell activation is achieved after engagement of both single-chain variable fragments (scFvs) to their cognate antigens.
- Synthetic notch (synNotch) receptor CARs that induce the transcription of a CAR after antigen recognition of their cognate antigen.[81] Activation of

one receptor (synNotch) induces the expression of a second receptor (CAR) that induces T-cell activation after antigen recognition. Full T-cell activation and tumor elimination occur only when both antigens are expressed. However, tumor escape of CAR T-cells through loss of the first antigen targeted by the synNotch receptor is a major limitation of this strategy.

On-switch CARs[83], which remain inactive until specific activating agents are added, assembling a fully functional receptor. These are designed as fragmented CAR receptors, where the extracellular antigen-binding module is dissociated from the intracellular signaling components. Assembly of these two receptors in the presence of a heterodimerizing small molecule, such as tacrolimus-based analogs, leads to CAR T-cell activation. The magnitude of responses depends on the dosage of the drug, which allows for titratable control.

Inhibitory CARs (iCARs),[84] which inhibit T-cell activation after antigen recognition in normal cells. This is a strategy to limit toxicity. This includes the coexpression of a classic CAR with an antigen-specific iCAR bearing the signaling domain of an immunoinhibitory receptor (ie, CTLA-4 or PD-1). Engagement of iCARs to antigens in normal cells can constrain T-cell functions, which can be resumed in the absence of the iCAR-targeted antigen and after antigen recognition by the activating CAR. One of the challenges of this approach is the identification of cell surface antigens that are expressed in normal cells but absent in tumor cells, a problem that is complementary to the obstacle of identifying tumor-specific antigens absent in normal tissues.

Universal or switchable CAR T-cells, which remain inactive until antibody-based molecules targeting a tumor antigen are supplied to reconstitute a fully active CAR construct. A different strategy that could simultaneously address antigen escape while mitigating toxicities is the utilization of so-called "universal CARs." Instead of engineering T-cells with fixed-antigen specificities, these CAR therapies are composed of two parts:

1. An antibody-based molecule that recognizes a tumor antigen and is modified to express a "switch"; and
2. A universal CAR T-cell without tumor specificity by itself, which contains a construct with an extracellular portion that binds to the switch and is linked to the intracellular signaling domains.

In a first approach, universal CAR T-cells were designed to bind to:

a. biotinylated antigen-specific molecules[85];
b. small-molecule fluorescein isothiocyanate[86]; and
c. short peptide in the antibody-based switch, allowing activation of the corresponding switchable CAR T-cells after tumor recognition by the antibody switch.[86,87]

In a more recent approach, universal CAR T-cells are designed where the split-CAR system named "SUPRA CAR" combines zipCAR T-cells containing an extracellular leucine zipper with an scFv domain fused to a second leucine zipper (zipFv).[88]

These versatile systems allow for the combination of universal CAR T-cells with zipFvs targeting different antigens to avoid tumor escape. At the same time, modulating the dose or affinity of the antibody-based switches may control toxicities. In the case of SUPRA CAR T-cells, T-cell activation can be prevented when necessary by the addition of a competitive zipFv that can bind with high affinity to the zipFv with tumor specificity.[88]

FUTURE DIRECTIONS

Although CAR T-cell therapy is among the most dynamic therapies developed for lymphoma over the past few decades, further work is needed to improve its safety, efficacy, and affordability. Several reports indicate that altering the design of the CAR molecule could improve the safety profile without affecting the efficacy. Ghorashian and colleagues showed that lowering the binding affinity of the scFv by having a similar on-rate but faster off-rate to the CD19 target lowers the incidence of severe CRS without affecting efficacy in patients with B-cell ALL.[89] Ying et al demonstrated that altering the length of the hinge and transmembrane domain of the CAR molecule confers different properties, such as different cytokine profiles with preserved cytolytic activity.[90] In a phase 1 trial in 25 patients with B-cell lymphoma, an optimized hinge and transmembrane domain resulted in a 55% CR rate with only grade 1 CRS and no ICANS.[90] As discussed previously, the 4-1BB costimulatory domain appears to induce lower toxicity rates compared with the CD28 costimulatory domain.[19,81,92] Preclinical studies also indicate that the CD3ζ signaling domain could be modified to favor better persistence of the CAR T-cells while reducing inflammation.[93]

Preclinical and correlative studies from clinical trials suggest that the functional phenotype of the T-cells in the apheresis and CAR T-cell products could affect safety and efficacy. In patients with lymphoma, the polyfunctionality of the CAR T-cells was associated with both response and toxicity.[94] In patients with CLL, apheresis products with higher frequency of early memory CD8+ T-cells defined by CD27+CD45RO– resulted in better-quality CAR T-cell products and better clinical efficacy.[95] Deng and colleagues demonstrated that a higher frequency of memory phenotype in the CAR T-cell product was associated with better

durability of response, whereas a higher frequency of exhausted phenotype was associated with inferior outcome.[96] Together, these results indicate that the safety and efficacy of CAR T-cell therapy could be improved by transducing the CAR gene into specific subsets of T-cells. Other strategies to improve efficacy of CAR T-cell therapy include targeting multiple antigens simultaneously to overcome antigen escape, which has been reported in around 30% of patients after anti-CD19 CAR T-cell therapy in DLBCL.[19,26] CAR T-cells targeting other pan–B-cell antigens such as CD20, CD22, CD79b, and BAFF-R are in various stages of preclinical and clinical development, either as CARs against single targets or CARs against multiple antigens targeted simultaneously.[97–100]

In summary, three anti-CD19 CAR T-cell therapy products have been approved for the treatment of R/R LBCL and/or MCL. These products are now being evaluated in other subtypes of NHL, and randomized trials are ongoing to directly compare CAR T-cell therapy with SCT at first relapse in patients with DLBCL. In additional, use of CAR T-cell therapies against novel targets in B-cell lymphoma and HL and T-cell lymphomas are in development. The high efficacy of CAR T-cell therapy together with the appeal of a single infusion to induce durable remission and possible cure suggests that this may be the beginning of a paradigm shift on how the management of lymphomas is likely to evolve in the future.

MD ANDERSON PRACTICE TIPS

- Current data suggest that CAR T-cell therapy is preferred over allo-SCT as the first choice in patients whose disease has relapsed after auto-SCT in most clinical situations. Allogeneic transplant should be reserved for patients who either have no CAR therapy options or have had disease relapse after CAR T-cell therapy.
- Delivering CAR T-cell therapy requires a comprehensive multidisciplinary approach with highly specialized medical teams, including subspecialty medicine and emergency and critical care groups that quickly evaluate and treat patients for complications. At MDACC, we have a core group of hematologic malignancy, stem cell transplant, critical care, neurology, emergency medicine, cardiology, infectious disease, pulmonary, renal, psychiatry, physiatry, and palliative medicine specialists who take part in the care of patients.
- It is vital to appreciate that patients may exhibit toxicity at variable time points after infusion of cells. CRS generally develops within the first week after infusion, whereas ICANS occurs after the peak of CRS (often >3 days later), with peak symptoms occurring during days 5 to 9. Upon standard treatment with high-dose steroids, ICANS is mostly transient, with a median duration of 5 to 11 days, but can follow a prolonged course in individual patients. Correctly identifying CRS and ICANS is imperative for appropriate treatment with IL-6 antagonists and corticosteroids.
- More than 20% of CD19 CAR T-cell–treated patients have protracted or recurrent neutropenia and/or thrombocytopenia beyond 4 weeks after infusion. Our standard procedure is for patients to remain on viral and *Pneumocystis* pneumonia prophylaxis for one year post infusion of CAR T-cells.
- In the relapsed/refractory setting, patients with lymphoma continue to have a poor prognosis, and these patients should be referred to high-volume centers where clinical trials are available

18 Autologous Hematopoietic Progenitor-Cell Transplantation

Neeraj Saini
Yago Nieto

Key Concepts

- The use of autologous hematopoietic progenitor-cell transplant (AHPCT) overcomes myelotoxicity of high-dose chemotherapy (HDC). Therefore, drugs with a markedly myelosuppressive side effect profile and a steep dose-response effect are preferred. The most common nonhematologic regimen-related toxicity (RRT) is oropharyngeal mucositis, which is rarely life threatening. The most common among the potentially severe extramedullary RRT are interstitial pneumonitis and veno-occlusive disease of the liver.
- HDC with AHPCT has been the standard of care for chemosensitive, relapsed diffuse large B-cell lymphoma (DLBCL) for the last three decades. However, the results remain suboptimal in patients whose disease relapses less than one year after completion of frontline chemoimmunotherapy (eg, R-CHOP).
- In follicular lymphoma, HDC with AHPCT should be considered for high-risk relapses occurring within two years of completing frontline therapy (POD24) or second or more advanced relapses.
- Management of relapsed or primary refractory Hodgkin lymphoma in patients should be a salvage strategy using one or more lines of therapy, including regimens such as bendamustine/brentuximab vedotin or ifosfamide/carboplatin/etoposide aiming at a positron emission tomography–negative remission before AHPCT. Patients with a high-risk for disease relapse should be considered for post-AHPCT maintenance with brentuximab vedotin.
- Modern treatment of newly diagnosed myeloma should include induction with a proteasome inhibitor and an immunomodulatory drug (eg, bortezomib/lenalidomide/dexamethasone [VRD]) followed by melphalan-based HDC and AHCPT, and consolidation and/or maintenance with drugs like lenalidomide, with the goal of achieving a minimal residual disease-negative remission.
- Tandem cycles of carboplatin-containing HDC with AHPCT should be considered for any patient with a germ-cell tumor in the second or later relapse. Their role in the first relapse is still undetermined.

BASIC CONCEPTS

High-dose chemotherapy (HDC) with autologous hematopoietic progenitor-cell transplant (AHPCT) is an effective treatment modality for a variety of hematologic malignancies and selected solid tumors. This chapter reviews its current role in the treatment of cancer, outlining future directions of progress.

Doses of radiation and chemotherapy are limited by toxicity to normal tissues and, particularly, the bone marrow. However, the doses of certain chemotherapeutic agents and radiation can be substantially escalated, exploiting their dose-response effect, when followed by autologous or allogeneic transplantation of HPCs to restore hematopoiesis. Pluripotent HPC progenitors present in the graft proliferate and differentiate into the mature blood and immune cells. AHPCT involves the collection, cryopreservation, and infusion of the patient's own HPCs.

GENERAL PROCEDURES FOR AUTOLOGOUS TRANSPLANTATION

Figure 18–1 shows the different procedures related to autologous transplantation.

Preceding Standard-Dose Chemotherapy

Standard-dose chemotherapy is usually given to cytoreduce the tumor before proceeding to AHPCT. In general, the best outcomes are seen in patients with chemosensitive disease in complete remission, or with minimal tumor burden at the time of transplantation.

Peripheral Blood Progenitor Cell Collection

Peripheral blood progenitor cells (PBPCs) should be collected while the patient's marrow is normocellular and uninvolved by the malignancy. PBPCs are normally present in very low numbers in the blood but are mobilized into the blood at postchemotherapy recovery with granulocyte colony-stimulating factor (G-CSF). PBPCs are collected using apheresis with continuous-flow cell separation. The minimal and optimal CD34+ cell doses for an autologous HPC transplant are 2×10^6/kg and 5×10^6/kg, respectively. The collected PBPCs are cryopreserved until infusion to the patient.

Multiple factors have been shown to predict poor success in mobilization and collection, including advanced age, amount of preceding chemotherapy, presence of marrow-infiltrating disease, history of pelvic radiation, prior exposure to certain drugs such as melphalan, carmustine or bendamustine, low premobilization platelet counts, short interval from last chemotherapy cycle to mobilization, inadequate chemotherapy mobilizing regimens and/or low-dose G-CSF,[1] and previous treatment with multiple cycles of lenalidomide.[2] A count of CD34+ cells greater than 10/mL in peripheral blood is highly predictive of an adequate collection. Plerixafor is a useful second PBPC-mobilizing agent, which acts synergistically with G-CSF and is effective in patients predicted or shown to be "poor mobilizers."[3]

High-Dose Therapy

Autologous transplants are most effective in diseases where a several-fold dose escalation of myelosuppressive drugs leads to a markedly increased cytotoxic effect on the malignancy. Given their steep dose-response effect, alkylating agents constitute the backbone of HDC regimens. The activity of alkylating agents depends on the extent of DNA damage and repair. Thus, drugs that inhibit DNA damage repair, such as the nucleoside analogs fludarabine or clofarabine for leukemia, or gemcitabine for lymphomas, have been combined with alkylating agents, with resulting synergy and improved clinical results.[4,5]

The optimal HDC regimen is specific to each disease. The most common cause of failure after AHPCT is relapse of the underlying malignancy as a result of insufficient antitumor effect of HDC. Venues to improve the activity of HDC include the incorporation of novel chemotherapy agents (such as gemcitabine or clofarabine), monoclonal antibodies (such as rituximab for CD20+ lymphomas), or epigenetic modulators (such as vorinostat or azacitidine).[6,7] The use of sequential cycles of HDC has been thoroughly evaluated in myeloma and is usual practice in treating germ-cell tumors. A major pitfall of efforts to improve the efficacy of established HDC is that merely increasing the total dose of antineoplastic drugs may improve the tumor response but will certainly increase the severity of side effects. Thus, novel HDC regimens must have a solid pharmacologic rationale, with careful consideration of scheduling, and be developed in well-designed clinical trials aiming for the optimal therapeutic index.

Reinfusion of Collected Stem Cells

Stem cells are infused intravenously after HDC is cleared from the patient's bloodstream, usually 1 to 3 days after completion of this treatment. The cells circulate transiently and then home to the bone marrow. Hematopoiesis is restored within a few weeks.[8] Neutrophils recover typically in 7 to 10 days and platelets recover in 10 to 21 days after infusion.

Supportive Care

Patients usually receive G-CSF or other hematopoietic growth factors to accelerate neutrophil recovery. Patients are routinely prescribed a prophylactic antibiotic, antiviral, and antifungal therapy for the prevention of infection during the initial phase of marrow engraftment and hematologic recovery.

AUTOLOGOUS VERSUS ALLOGENEIC HPC TRANSPLANTS

The relative role of autologous versus allogeneic transplants varies for each hematologic malignancy. AHPCT is a process that carries less overall morbidity and mortality because the reinfused cells are neither subject to immunologic rejection nor will produce graft-versus-host disease. On the other hand, there is a potential risk of tumor contamination of the autologous graft, particularly in patients with bone marrow tumor involvement. In vivo bone marrow purging with monoclonal antibodies preceding PBPC mobilization and apheresis in particular, rituximab for CD20+ B-cell lymphomas, has be shown to be effective. Finally, there is no evidence that the immune-mediated graft-versus-tumor effect associated with allogeneic HPC transplantation occurs with AHPCT.

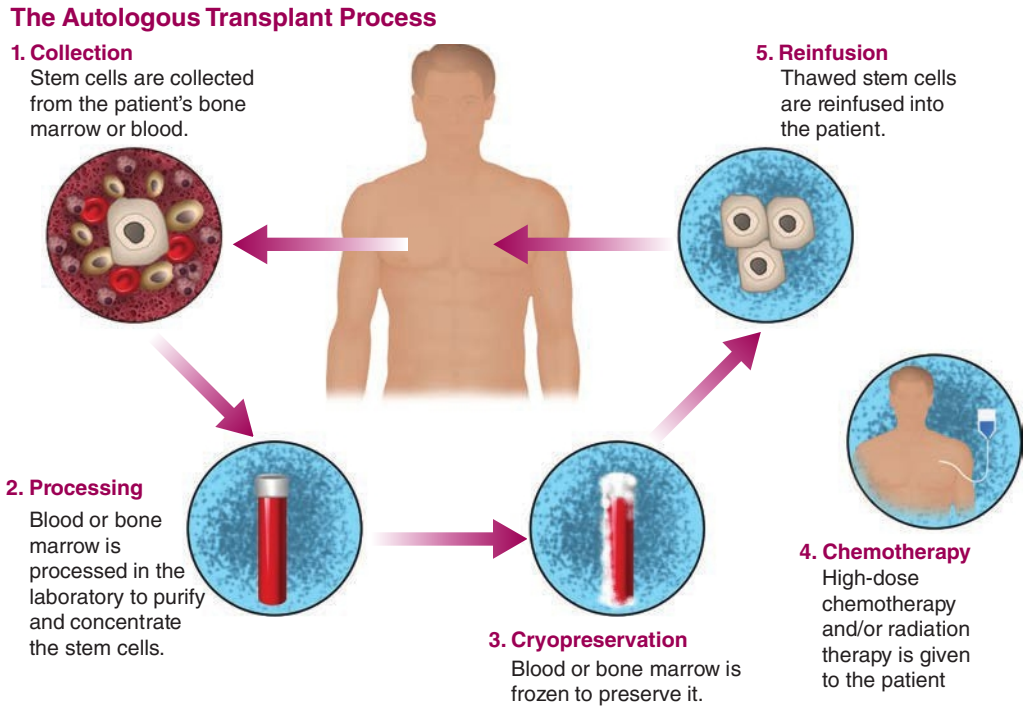

FIGURE 18–1 **Autologous hematopoietic progenitor-cell transplantation process.**

COMPLICATIONS OF HIGH-DOSE CHEMOTHERAPY

HDC produces profound pancytopenia that usually lasts from 7 to 10 days. Infectious complications can occur during the neutropenic period (ranging from uncomplicated neutropenic fever to life-threatening sepsis) and up to 6 months or more post-transplant in the case of *Pneumocystis jiroveci*, fungal infections or zoster reactivation. Antibacterial prophylaxis with a fluoroquinolone, antiviral prophylaxis with acyclovir/valacyclovir, and antifungal prophylaxis with fluconazole are generally started at the time of stem cell infusion and continued throughout neutropenia. *Pneumocystis jiroveci* pneumonia prophylaxis (eg, trimethoprim/sulfamethoxazole) is usually started at 3 to 4 weeks post-transplant for at least 6 months. Antiviral prophylaxes (acyclovir, valacyclovir) are given for 6 to 12 months.[9]

Regimen-related toxicity (RRT) are the side effects of HDC in nonhematopoietic tissues, which depend on the specific regimen. The oral mucosa and the gastrointestinal tract are the most sensitive tissues to these effects. Several agents have shown some efficacy in randomized clinical trials in the prevention of mucositis (such as amifostine, palifermin, topical glutamine, or laser therapy), whereas many others in common use have not been shown to be effective (such as steroids, sucralfate, "magical mouthwash," or topical anesthetics).

The lungs, heart, liver, brain, and kidneys are less commonly affected, generally in heavily pretreated patients or in those with comorbid conditions. Overall, 1% to 4% of patients die from RRT or infections, which makes AHPCT substantially safer than allogeneic transplantation.

Toxic interstitial pneumonitis can occur in up to 40% of patients receiving HDC. It has been described with several different chemotherapy agents, such as carmustine, busulfan, and total-body irradiation.[10] It is particularly common in patients previously treated with mediastinal radiotherapy. Prompt diagnosis is essential, and steroids are usually effective in its treatment.

Cardiac toxicity is uncommon. It can be seen after high doses of cyclophosphamide or melphalan. Prior radiation therapy to the mediastinum or left chest wall, as well as advanced age are also predictors of an increased risk of cardiac complications.[11] Central nervous system complications are rare, but dementia and leukoencephalopathy have been described, particularly from drugs that penetrate the cerebrospinal fluid, such as carmustine or thiotepa.[12] Hypothyroidism and hypoandrogenism are frequent and occur 6 months to 2 years after transplant.[13] Hemorrhagic cystitis, after high-dose cyclophosphamide or ifosfamide, is uncommon and can be effectively prevented with mesna.[14]

Sinusoidal obstruction syndrome (SOS) (formerly known as venoocclusive disease) of the liver is clinically characterized by fluid retention (despite

optimal use of diuretics), rising direct hyperbilirubinemia, and hepatomegaly that can be painful.[15] Its severity depends on the presence of multiorgan failure and the velocity of bilirubin rise. Although mild cases are often self-limited, severe cases can be fatal in more than 80% of patients. Several factors predisposing to SOS include prior liver impairment, older age, and iron overload. The use of oral busulfan and total-body irradiation has been most commonly associated with SOS, particularly if it is used with cyclophosphamide.[16] Recently, the introduction of new calicheamicin immunotoxin conjugated drugs, inotuzumab ozogamicin,[17] and gemtuzumab ozogamicin, in treatment of leukemia before transplant has contributed to increased incidence of SOS. Andersson et al at MDACC have pioneered the use of intravenous busulfan, which effectively addressed the issue of intrapatient dose-to-dose variability of oral busulfan and substantially decreased the risk of SOS compared with its oral formulation.[18] This group also developed the pharmacokinetic-guided dosing of intravenous busulfan, which corrects interpatient variability and further decreases the incidence of SOS. Systemic anticoagulant and thrombolytic therapies have been shown to be ineffective and are associated with major bleeding complications. The only FDA-approved drug for the treatment of SOS is defibrotide. In a phase 3 trial, the day +100 complete response (CR) rate was 25.5% for the defibrotide group compared with 12.5 % for the historical control group.[19] Defibrotide was associated with significant improvement in day +100 CR and overall survival (OS) rate. Supportive care also plays a crucial role, using diuretics and sodium restriction, avoidance of hepatotoxins, oxygen support, and renal replacement therapy if needed.

Finally, therapy-related MDS (t-MDS) and therapy-related acute myeloid leukemia (t-AML) are potentially devastating complications of AHPCT, with a cumulative probability that ranges from 1.1% at 20 months to 23% at 4 years.[20] With improvement in the management of post-AHCPT infections and RRT, t-MDS/t-AML have emerged as the main cause of nonrelapse mortality after AHPCT. There are two main types of t-MDS/t-AML: those related to alkylating agents or radiation, and those related to topoisomerase II inhibitors. The former group appears 4 to 7 years post-AHPCT, with two-thirds of patients presenting with MDS and one-third with AML with myelodysplastic features. There is a high incidence of abnormalities of chromosomes 5 (-5/del(5q)) and 7 (-7/del(7q)). In contrast, topoisomerase II inhibitor–related AML often appears as overt acute leukemia without preceding MDS, with a shorter latency period of 6 months to 3 years. Most often, it is associated with translocations involving 11q23 or 21q22. Risk factors for t-MDS/t-AML include older age at transplant, pre-HDC exposure to alkylating agents, topoisomerase II inhibitors and radiotherapy, use of etoposide to mobilize the PBPC, use of total-body irradiation as part of the AHPCT conditioning, infusion of lower numbers of CD34+ cells, and multiple transplantations (as in myeloma or germ-cell tumors). The prognosis for t-MDS/t-AML is poor, and the only potentially curative treatment is an allogeneic stem cell transplant (SCT).

RESULTS OF AUTOLOGOUS TRANSPLANTATION

Non-Hodgkin Lymphoma

Autologous transplantation has been extensively studied in patients with non-Hodgkin lymphoma (NHL), either as frontline consolidation or in patients who are refractory to firstline therapy or in relapse.

Diffuse large B-cell lymphoma

HDC and AHPCT has been for several decades the standard of care for patients with chemosensitive relapsed diffuse large B-cell lymphoma (DLBCL) (Fig. 18-2).[21] Factors such as resistance to salvage chemotherapy, increased lactic dehydrogenase at the time of relapse or progression, prior CR of less than 12 months, and secondary international prognostic index (IPI) (ie, at the time of relapse or progression) score higher than 1 are adverse predictors of survival in patients receiving HDC. In the modern era of exposure to rituximab as part of firstline therapy (R-CHOP), the CORAL study has shown 3-year event-free survival (EFS) rates of around 25% in patients with chemosensitive relapsed disease who are undergoing autologous SCT.[22]

In contrast to relapsed disease, the efficacy of HDC as frontline consolidation for DLBCL patients in first CR has not been demonstrated after many randomized trials, especially when patients previously receive R-CHOP instead of CHOP.[23] Thus, AHPCT is not indicated as consolidation of the first remission for DLBCL patients.

Follicular Lymphoma

The role of AHPCT in the treatment of patients with chemosensitive relapsed follicular lymphoma (FL) remains unclear. The classical regimen of high-dose cyclophosphamide/total-body irradiation has been largely abandoned because of its high risk of t-MDS/t-AML. Historically, a major challenge has been contamination of the autologous graft by malignant cells.[24] More recently, systemic treatment with rituximab has

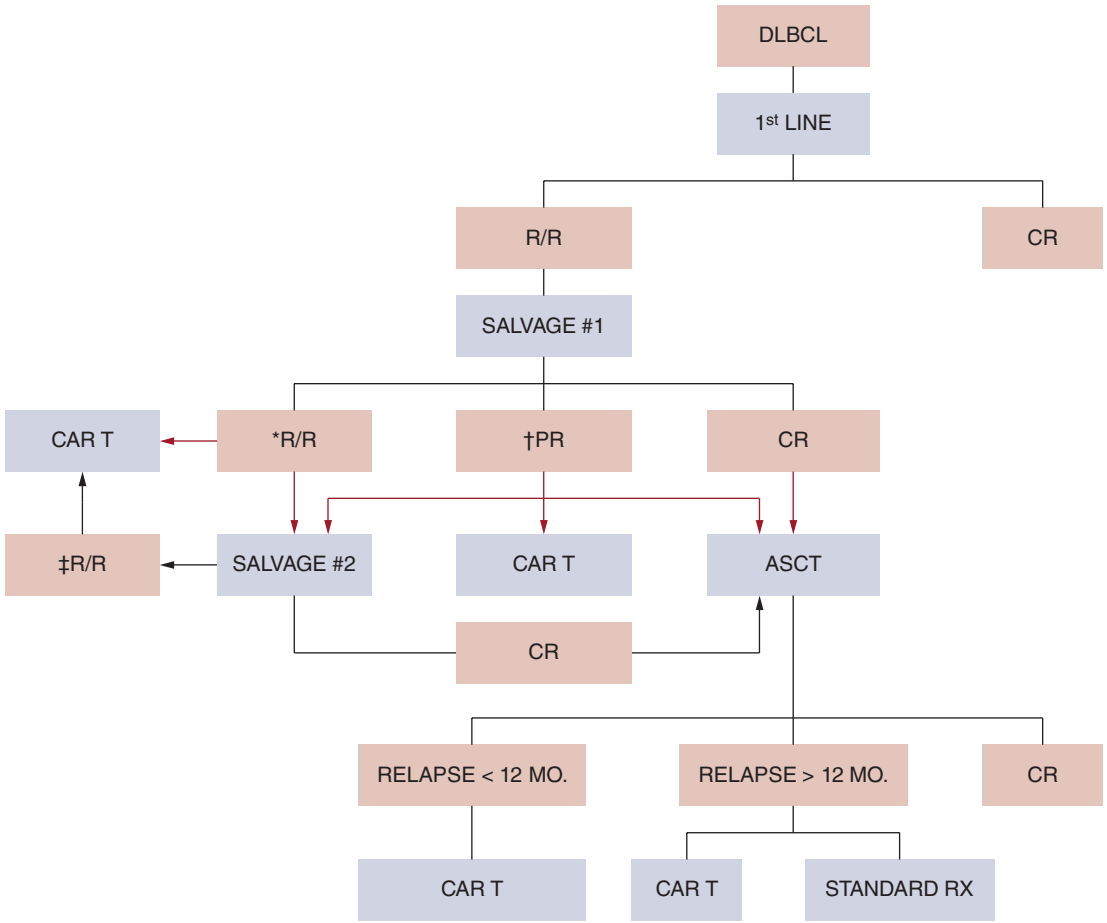

FIGURE 18–2 **Algorithm for treatment of DLBCL: stepwise description of DLBCL treatment approach and the role of autologous and allogeneic progenitor-cell transplantation after relapse. ASCT, allogeneic stem cell transplant.**

reduced the numbers of circulating lymphoma cells, thus yielding effective in vivo purging with high likelihood polymerase chain reaction–negative tumor-free PBPC grafts.[25] A European randomized trial showed improved PFS and OS after HDC for chemosensitive relapsed FL.[26] However, that study was conducted in the prerituximab era and is not entirely applicable to modern patients.

Approximately 20% of patients with FL develop progression of disease within 2 years (POD24) after completing frontline chemoimmunotherapy. This subset of patients has a poor prognosis (5-year OS ~50%). In a retrospective combined registry analysis of CIBMTR and National Lymphocare database, early AHPCT within a year of relapse was associated with a decreased risk of mortality (HR = 0.63, P = .02) in POD24 FL patients.[27,28] Also, subset analyses from two German prospective randomized trials in FL confirmed the OS benefit of early AHPCT in POD24 FL patients, with a 5-year OS rate of 77% with transplant versus 59% with no transplant (HR = 0.54, P = .03).[29]

HODGKIN LYMPHOMA

Most patients with Hodgkin lymphoma (HL) are cured with firstline therapy. However, 20% of patients will not respond to firstline chemotherapy and approximately 30% will have relapse after an initial response. HDC has been proven to be beneficial in those two settings with expected long-term EFS of 30% to 40% for patients with primary refractory tumors that subsequently respond to salvage therapy, and of 30% to 65% for patients with chemosensitive relapsed HL (Fig. 18-3).[30,31]

Unfavorable prognostic features for AHPCT include a first CR shorter than 1 year, extranodal relapse, B symptoms at the time of relapse or progression, bulky (>5 cm) lesions at relapse, and relapse within a prior radiation field. Patients with no unfavorable prognostic features have a long-term EFS of around 70% at 4 years, compared with 20% or less in patients with adverse features. PET scan uptake at the time of HD has emerged as the main prognostic factor.[32] Therefore,

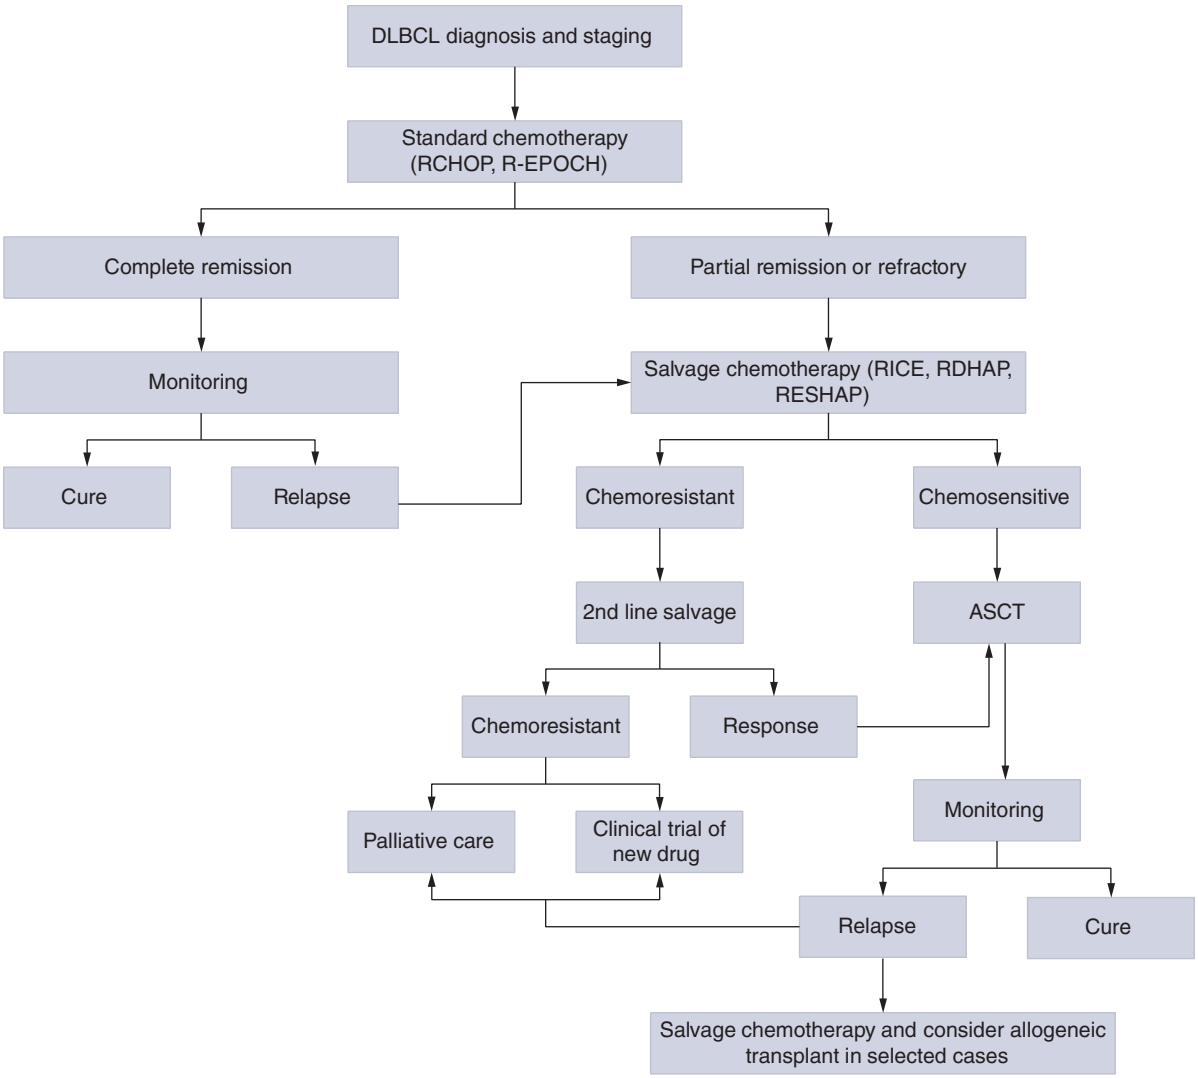

FIGURE 18–3 Algorithm for treatment of HL: stepwise description of HL treatment approach and the role of autologous and allogeneic progenitor-cell transplantation after relapse.

PET-adapted salvage therapy aiming at a PET-negative CR before transplant using non–cross-resistant lines of therapy has been shown to result in improved post-AHPCT outcomes.[33,34] Approaches to improve survival outcomes and prevent relapses after autologous SCT have included the development of more effective HDC regimens and/or post-AHPCT maintenance treatment. The combination of gemcitabine/busulfan/melphalan, developed at MDACC, resulted in improved 2-year PFS (65% vs 51%, $P < .01$) and OS (89% vs 73%; $P < .001$) when compared with matched-pair historical patients treated with BEAM, the standard HDC regimen in HL.[35,36]

In a phase 3 randomized trial, the use of post-AHPCT maintenance brentuximab vedotin for 16 cycles in patients with primary refractory disease or high-risk relapse (defined as prior CR1 shorter than 1 year or extranodal disease at the start of pretransplant salvage chemotherapy) resulted in a significant PFS advantage (59% vs 41% at 5 years), but without OS differences, compared with placebo.[37,38] In a small phase 2 trial, maintenance pembrolizumab led to 18-month PFS and OS rates of 82% and 100%, respectively.[39]

MULTIPLE MYELOMA

HDC with AHPCT is an established treatment for multiple myeloma (MM) (Fig. 18–4). In the era preceding the introduction of novel antimyeloma agents, AHPCT showed significantly superior PFS and OS rates compared with standard-dose chemotherapy (SDC) in several randomized trials.[40–42] Subsequently, the introduction of proteasome inhibitors (PI), immunomodulatory drugs

(IMiDs), and monoclonal antibodies in the up-front induction treatment led to significant improvement in the depth of response. In this modern setting, randomized trials have still shown benefit of AHPCT consolidation over nontransplant management including novel agents. In the randomized IFM 2009 trial, which included both PIs and IMiDs in frontline induction treatment, a higher CR rate (59% vs 48%; $P = .03$) and minimal residual disease negativity (79% vs 65%; $P < .001$) was observed among patients assigned to the frontline AHPCT arm, which translated into a significant PFS advantage (median 50 vs 36 months; $P < .001$) and no OS differences at short follow-up.[43]

Maintenance therapy post-transplant with lenalidomide has been shown to prolong EFS and perhaps OS, as shown in several randomized studies.[44,45] There is uncertainty about the optimal duration of lenalidomide treatment, because its use after ASCT has been associated with a small risk of secondary malignancies in the French, but not in the US, study. In the recent updates of the US trial, lenalidomide discontinuation at 3 years was associated with inferior PFS (80% vs 61%) and therefore, depending on patient preference and tolerability, our preference has been to continue maintenance therapy indefinitely. Some centers have adopted a risk-adapted maintenance approach in newly diagnosed myeloma with double-agent maintenance (PI + IMiD) in high-risk patients that has led to significant improvement in survival rates.

The use of a second course of high-dose melphalan ("tandem" transplants) has been compared with a single transplant in randomized trials in Europe and the US, which have shown conflicting results. In the European trial, patients who received a tandem AHPCT had greater 3-year PFS than patients who received a single AHPCT (73% vs 60%, respectively) and improved 3-year OS compared with single AHCT (89% vs 85%, respectively).[46] In contrast, in the US Intergroup study, the 3-year PFS rate was 58% for tandem AHPCT with maintenance lenalidomide, 58% for single AHPCT/consolidation with four cycles of bortezomib/lenalidomide/dexamethasone (VRD)/maintenance lenalidomide, and 54% for AHPCT/maintenance with lenalidomide.[47] Important differences in study design between both trials probably account for their differing results. Importantly, one group which appears to benefit from tandem transplant is that of patients with high-risk cytogenetics. Both in the European and the US trials, the subgroups with high-risk cytogenetics have shown superior PFS with tandem AHPCT compared with a single AHPCT.[46,48]

Role of Salvage or Second Transplant

Several retrospective analyses have demonstrated durable responses of a second salvage course of HDC with autologous SCT for patients with relapsed disease.[49] In general, the outcomes appear more favorable for patients who had relapse later than 12 months after a first AHPCT and who respond to subsequent salvage treatment.[50] A randomized controlled trial conducted in the UK comparing salvage AHPCT with salvage SDC showed superior PFS (median 19 months vs 11 months, HR 0.36; $P < .0001$) and OS (median 67 months vs 52 months, HR 0.56; $P = .01$) for the transplant arm.[51,52]

Newer HDC Regimens

For the past 40 years, the standard HDC regimen for AHPCT in MM has been high-dose melphalan (200 mg/m^2). The only regimen that has shown superiority over melphalan as frontline consolidation has been intravenous busulfan/melphalan (Bu/Mel) in a randomized trial conducted at MDACC, where Bu/Mel resulted in significantly better PFS (64 months vs 43 months, HR 0.53; $P = .02$), particularly in the subset of patients with high-risk cytogenetics.[53] Gemcitabine/busulfan/melphalan, a regimen built from Bu/Mel exploiting the inhibition by gemcitabine of DNA damage repair, showed in a phase 2 trial conducted at MDACC in patients with relapsed or refractory myeloma, significantly superior PFS and OS compared with matched-pair historical controls who received high-dose melphalan.[54] The combinations of PI with high-dose alkylators, which shows synergy when given in the correct sequence, has shown promising clinical results.[55–57]

Other promising new therapies under current investigation in myeloma that could be easily implemented in the post-AHCT setting include tumor vaccines[58] and cellular immunotherapy with chimeric antigen receptor T-cells.[59]

SOLID TUMORS

Germ-Cell Tumors

Testicular germ-cell tumors (GCTs) are the most common malignancy in young men between the ages of 20 and 35 years. GCTs are highly curable, even in patients with advanced disease. Frontline cisplatin-based SDC cures 90% of advanced good-risk patients, 80% of those with intermediate risk and 50% of those with poor risk. To study whether AHPCT could improve results in intermediate- and poor-risk patients, tandem cycles of HDC were compared with SDC in a US Intergroup trial, with no significant differences in EFS or OS.[60]

In patients with relapsed disease, the best approach for salvage therapy remains unsettled. Salvage cisplatin–based SDC regimens, such as paclitaxel/ifosfamide/

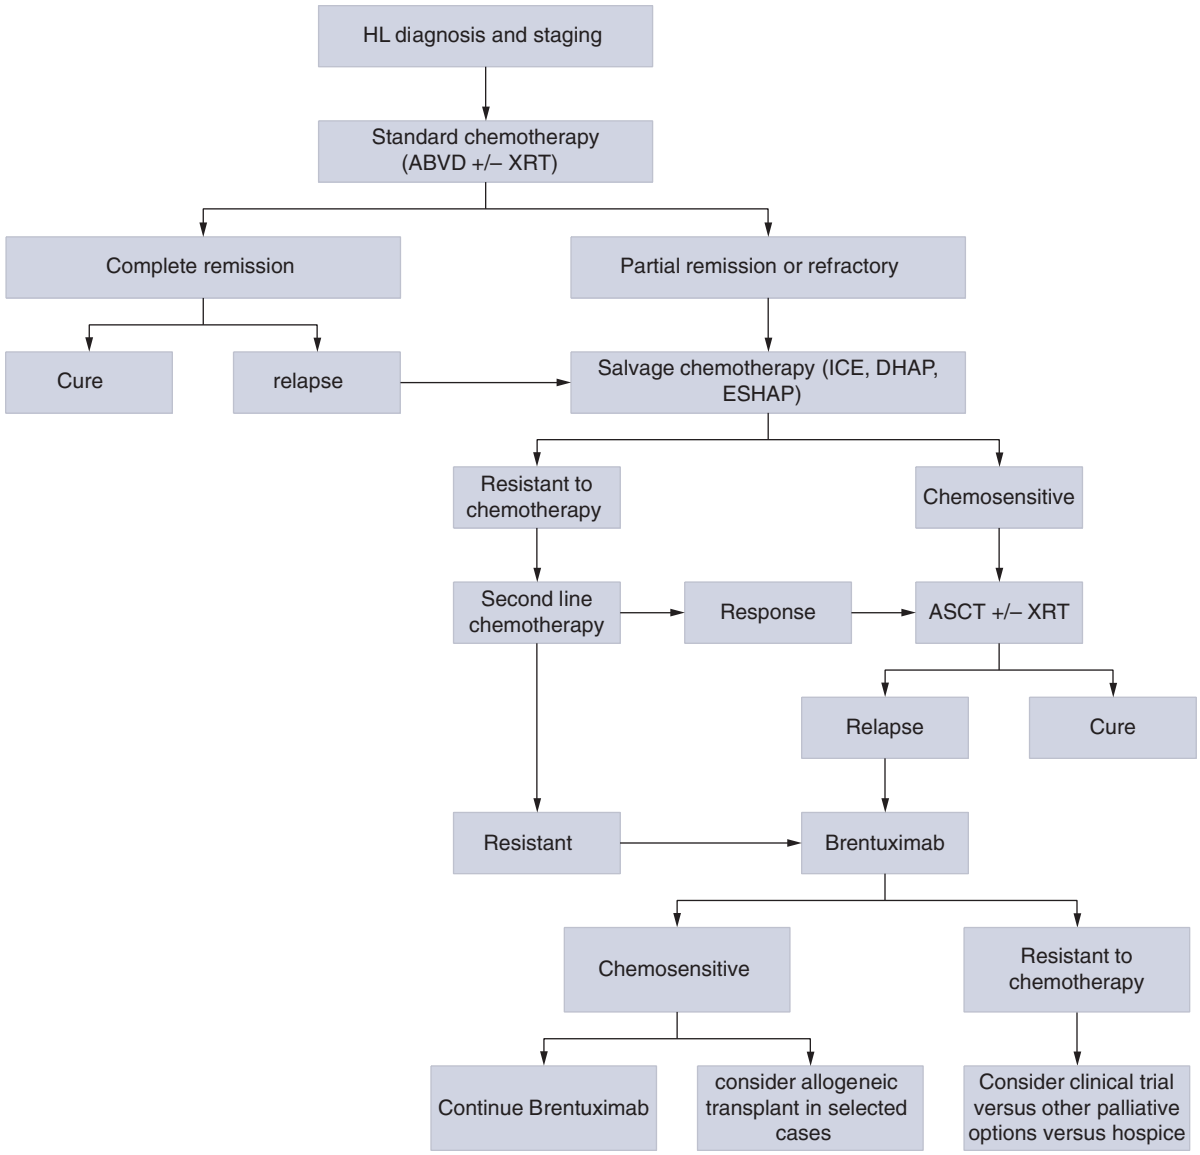

FIGURE 18–4 Algorithm for the treatment of MM: stepwise description of MM treatment approach and the role of autologous and allogeneic progenitor-cell transplantation after relapse.

cisplatin (TIP), result in CR rates of 50% to 60% and long-term EFS of 20% to 30%.[61] The use of tandem cycles of HDC with carboplatin and etoposide (CE) with AHPCT, developed at Indiana University, has shown efficacy. A retrospective analysis of a cohort of 364 patients transplanted with tandem CE in 2004 to 2014 showed that patients transplanted in the first relapse had better outcomes than those transplanted in the second or later relapse (2-year EFS of 63% and 49%, respectively).[62] The addition of a third drug, such as cyclophosphamide, ifosfamide, paclitaxel, or thiotepa, to CE, results in cure of 40% to 50% of patients with cisplatin-sensitive tumors, but only of 4% to 20% of those with refractory disease.[63–66]

Feldman et al tested the use of three cycles of HDC in 107 patients with relapsed disease and unfavorable prognostic features. Of them, 76% were transplanted at first relapse, 20% at second relapse, and 4% at third or later relapse; 76% were cisplatin refractory. These patients received two cycles of paclitaxel/ifosfamide followed by three cycles of high-dose CE, with 47% EFS at 5 years.[67] The EFS rates in patients in first relapse and second or later relapses were 55% and 23%, respectively.

Our group at MDACC focused on patients with a very poor prognosis for the development of more potent HDC seeking new synergistic interactions. Testing the potential synergy between bevacizumab and chemotherapy, we conducted a phase 2 trial of

tandem cycles of bevacizumab-HDC in patients with advanced refractory relapses.[68] In our initial report, 42 patients with heavily pretreated tumors (median 3 prior relapses), 87% of them cisplatin refractory, received a first HDC cycle with bevacizumab and gemcitabine/docetaxel/melphalan/carboplatin followed by a second AHPCT with bevacizumab + ifosfamide/carboplatin/etoposide. At a median follow-up of 46 months, the EFS and OS rates were 56% and 58%, respectively, clearly exceeding the expected outcomes in this population with very poor prognosis. Bevacizumab was subsequently omitted in a second cohort seeking to increase treatment tolerability.[69] At median follow-up of this second cohort of 26 months, the EFS and OS rates were 71% and 74%, respectively. These encouraging results, with or without bevacizumab, likely result from a synergistic interaction between gemcitabine and the other agents based on DNA damage repair inhibition through suppression of nucleotide excision repair, a major mechanism of cisplatin resistance in GCT cells.[70]

There is no consensus yet about whether HDC should be considered for all patients in first relapse. Two cycles of HDC seem more effective than a single cycle.[71] Results of tandem cycles of HDC as salvage treatment appear superior to those expected with SDC.[72] The randomized phase 3 TIGER trial is underway and addresses this important question, comparing TI-CE, with three cycles of HDC, with SDC (TIP × 4).[73]

In summary, the current data available from randomized trials do not support a standard role for HDC in frontline treatment of GCT. Further clarity in its role as part of salvage treatment in first relapse awaits completion of the ongoing randomized TIGER trial. Finally, HDC is widely accepted as an established treatment for patients in second or later relapse.

OTHER SOLID TUMORS

Initial phase 2 studies of HDC in patients with high-risk primary breast cancer (HRPBC) sparked enthusiasm by showing encouraging long-term PFS rates of 57% to 72% in patients with involvement of 10 or more axillary lymph nodes.[74,75] These results led to a significant increase in the number of transplantations performed in the 1990s and prompted randomized phase 3 trials. Fifteen randomized trials of HDC with AHPCT were conducted for HRPBC, defined as 4 or more positive nodes and, in some trials, 10 or more positive nodes. Although most trials showed EFS benefit, only two showed OS benefit. A meta-analysis of those trials (N = 6210) demonstrated at a median follow-up of 6 years a significant benefit in EFS (HR 0.87, $P < .001$) but no significant difference in OS (HR 0.94, $P = .13$).[76] More recently, a long-term report at 20-year follow-up of the largest of those randomized trials, conducted in the Netherlands, showed an improved OS for the subset of patients with very high risk (≥10 more involved nodes) in the HDC arm.[77]

Similar to HRPBC, the initial prospective HDC trials in metastatic breast cancer (MBC) showed very high response and CR rates and apparently improved long-term disease control. Those results led to randomized trials comparing HDC with SDC in chemosensitive MBC. Six of those eight trials demonstrated an EFS advantage for HDC, but only one showed OS benefit. A meta-analysis showed a statistically significant improvement in PFS (median 11 vs 8 months, HR 0.76; $P < .001$), however with no statistically significant OS benefit.[78]

In conclusion, randomized trials in the MBC and HRPBC settings have shown improvement in PFS but have largely failed to show OS benefit. The meta-analyses did detect a statistically significant 13% decrease in the risk of relapse in HRPBC and a 24% decrease in the risk of progression in MBC. Although there are still populations that might benefit from HDC, such as patients with 10 or more involved nodes,[77] inflammatory breast cancer,[79] or oligometastatic disease,[80] HDC has been largely abandoned as a treatment for breast cancer.

HDC has been evaluated in other chemosensitive solid tumors in adults, including ovarian cancer, small-cell lung cancer, melanoma, malignant gliomas, and sarcomas. Most of those studies were small and failed to show a survival benefit.[81]

CONCLUSIONS

In summary, HDC with AHPCT is a safe treatment that achieves major tumor cytoreduction and is curative for NHL, HL, MM, and GCT in a variety of settings. Current studies focus on improvement of current HDC regimens and post-transplant strategies to prevent regrowth of minimal residual disease.

MD ANDERSON PRACTICE TIPS

- As of this writing, there is no role of up-front autologous transplant in first remission in B-cell non-Hodgkin (except for selected patients with high-risk IPI aggressive lymphoma) and Hodgkin lymphomas. In contrast, most patients with T-cell lymphoma (except those with ALK-positive anaplastic large-cell lymphoma) seem to benefit from an up-front consolidation autologous transplant.
- A subset of patients with follicular lymphoma who have disease progression within 2 years after frontline chemoimmunotherapy have a poor prognosis, and early autologous transplantation is recommended in these patients.
- High-risk patients with MM benefit from dose intensification of conditioning chemotherapy. Patients with high-risk characteristics are offered a combination of intravenous busulfan and melphalan at our center.
- Maintenance with brentuximab vedotin after autologous transplant in HL has led to significant improvement in PFS and is routinely considered for patients with high-risk relapse at MDACC.
- The novel HDC regimen of vorinostat/gemcitabine/busulfan/melphalan for autologous transplant in Hodgkin and non-Hodgkin lymphomas has produced impressive outcomes in high-risk disease-relapsed patients. Patients with refractory diseases and high-risk features are offered this novel HDC regimen, preferably as part of a clinical trial, at MDACC.
- Relapsed GCTs are considered for tandem ASCT at MDACC. High-risk relapses or advanced (second or later) relapses are offered our tandem approach of gemcitabine/docetaxel/melphalan/carboplatin for the first ASCT and ICE for the second ASCT, which have shown results that appear to be superior to those with the more traditional tandem approach of carboplatin/etoposide × 2.

19 Allogeneic Transplantation

Rohtesh S. Mehta
Chitra Hosing

KEY CONCEPTS

- The numbers of allogeneic hematopoietic stem cell transplantation (HCT) are increasing over time, with an increasing use of alternative donors, and with increasing use of reduced-intensity conditioning (RIC).
- Myeloablative conditioning (MAC) for HCT is associated with a lower risk of relapse compared with RIC, but it is also associated with a higher risk of nonrelapse mortality (NRM).
- Age, performance status, and HCT-specific comorbidity index are some of the predictors of NRM and are taken into consideration along with the risk of relapse of the underlying disease, when deciding about conditioning intensity.
- Relapse of the underlying disease is the leading cause of deaths after allogeneic HCT, while graft-versus-host disease (GVHD) and infections are the leading causes of NRM after allogeneic HCT.
- Risk of relapse may be reduced with the use of maintenance therapy after allogeneic HCT, which is an area of active investigation.
- Novel GVHD prophylaxis strategies are being explored to reduce the risk of GVHD and its associated morbidity and mortality.

Allogeneic hematopoietic stem cell transplantation (HCT) is a potentially curative approach for a variety of malignant and nonmalignant disorders. With the development of novel techniques of transplantation including the refinement of conditioning regimens and improved management of transplantation-associated toxicities, increasing numbers of patients with advanced age and/or comorbidities are now being transplanted. More than 9000 allogeneic HCTs were performed in the United States in 2018[1]; about 30% of patients were age 60 years or older and 6% were 70 years or older.[2] This chapter reviews the current state of the allogeneic HCT in general, with particular attention paid to strategies used at MDACC. The in-depth discussion of specific diseases and their indications for HCT can be found in their respective chapters.

HISTORICAL BACKGROUND

Research in the field of HCT intensified after the unfortunate events of nuclear bombing in 1945,[3] with one of the first HCT in humans performed in the late 1950s. The initial attempts at transplantation of bone marrow (BM) from fetal or adult cadavers in six patients with terminal conditions was unsuccessful without engraftment. However, it did provide important safety data about the infusion of BM with no case of pulmonary emboli.[4] A few years later, syngeneic BM transplantation (BMT) in two children with acute lymphoblastic leukemia (ALL) after lethal dose of total-body irradiation (TBI) led to successful engraftment, but the conditioning intensity was insufficient to prevent disease relapse.[5] Thereafter, modifications were made to intensify the conditioning regimen before transplantation. There was a vigorous interest in BMT in the early 1960s, with occasional success stories, but interest waned owing to extremely poor outcomes, engraftment in less than 40% of cases, and mortality in about 75% of patients.[6] This was partly related to the lack of knowledge about graft-versus-host disease (GVHD), which was not recognized until the mid-1960s,[7] and inadequate understanding of the human leukocyte antigen (HLA) system—the concept of which was

incorporated into the HCT setting in the late 1960s. The initial cases of successful "HLA-matched" sibling donor (MSD) HCTs were reported in 1968 in two children with nonmalignant hematologic disorders.[8,9] Of note, the HLA matching at that time was performed using historic serologic methods that detected antibodies in human serum that were capable of agglutinating human peripheral blood (PB) T-cells or B cells. With these successful cases, and with the mounting understanding of GVHD and the HLA system, the interest in BMT reemerged. Soon, the donor pool was expanded to involve unrelated donors, and the first successful HCT with an HLA-matched unrelated donor (MUD) was performed in 1973 on a 2-year-old boy with X-linked chronic granulomatous disorder.[10,11] Thereafter, successful cases of partially matched/mismatched haploidentical donor and umbilical cord blood (UCB) HCT were reported.

COMPONENTS OF ALLOGENEIC STEM CELL TRANSPLANTATION

The key components of allogeneic HCT include recipient, donor (related or unrelated), stem cell graft source (BM, PB, or UCB), HLA matching between the recipient and the donor (matched or mismatched), conditioning regimen intensity (myeloablative [MAC], nonmyeloablative [NMA], or reduced-intensity conditioning [RIC]), GVHD prophylaxis, and post-HCT supportive care. Each of these are discussed next individually.

Recipient

Allogeneic HCT is indicated for a variety of malignant (mostly hematologic and some solid tumors) and nonmalignant disorders (such as aplastic anemia, Fanconi anemia and other BM failure syndromes, hemophagocytic lymphohistiocytosis, severe combined immunodeficiency, Wiskott-Aldrich syndrome, sickle cell disease, thalassemia major, advanced autoimmune diseases, etc). However, for the purpose of brevity, this chapter will focus primarily on hematologic malignancies in adults, because acute myelogenous leukemia (AML), ALL, myelodysplastic syndrome (MDS), and myeloproliferative neoplasms (MPNs) are the most common indications that accounted for about 75% of all allogeneic HCTs performed in the United States in 2018.[1] Other hematologic malignancies, such as lymphoma, multiple myeloma, chronic lymphocytic leukemia, chronic myelogenous leukemia (CML), and nonmalignant diseases accounted for the rest.[1]

Given the risk of morbidity and mortality associated with allogeneic HCT, it is important to distinguish patients who are likely to do well without transplantation from those who will benefit the most from it while minimizing the risk of non-elapse mortality (NRM). Among several other elements, two patient-related factors that independently affect outcomes are (1) comorbidities, which determine the risk of NRM; and (2) disease risk, which impacts the risk of relapse and related mortality post-HCT.

One of the most commonly used tools to assess the risk of NRM is the HCT-specific comorbidity index (HCT-CI),[12] which is a combined score of several individual comorbidities, including cardiovascular, pulmonary, hepatic, or renal dysfunction, prior solid tumor, and diabetes, to name a few, each of which is assigned a distinct weighted score. Based on the total score, patients are divided into three risk categories—low (0), intermediate (1–2), and high (≥3), with corresponding NRM at 2 years of 14%, 21%, and 41%, respectively.[12] Subsequently, a composite scoring system incorporating age and HCT-CI was developed where one additional point was assigned for patients with 40 years or older. Patients with a score of 2 or lower had no increased increase of NRM compared with those with score 0, whereas those with a score of 3 or higher had a significantly higher risk. The risk of NRM varied by the conditioning intensity; it was significantly lower with NMA—but not after RIC—than with MAC. For patients with a score of 3 or 4, the incidence of NRM at 2 years was 17% (NMA), 36% (RIC), and 37% (MAC); and for patients with scores of 5 or above, it was 35% (NMA), 41% (RIC), and 49% (MAC).[13]

To determine disease risk, several systems can be used for prognostication that are either disease specific (eg, European LeukemiaNet [ELN] classification for AML,[14] Revised International Prognostic Scoring System [R-IPSS], for MDS[15]) or generic, such as the revised disease risk index (DRI).[16] The revised DRI (rDRI) classifies patients into one of the four risk groups based on the underlying disease and remission status at the time of HCT, with a 2-year overall survival (OS) of 66% (low risk), 51% (intermediate risk), 33% (high risk), or 23% (very high risk).[16] In general, patients with intermediate or high/very-high rDRI have an indication for transplantation, whereas low-risk patients benefit from nontransplantation approaches.

At MDACC, all patients undergo an extensive evaluation before transplantation to determine disease risk and to assess comorbidities. There is no specific age cutoff for transplantation, rather a patient's performance status, HCT-CI score, DRI, family and social support, and personal wishes are all taken into consideration. In addition, patients older than 60 years and those with poor performance status are also evaluated by a personalized, multidisciplinary team of the "Enhanced Recovery program," which includes HCT physicians, advanced care providers, nutritionists, physical and occupational therapists, pharmacists,

rehabilitation physicians, and geriatricians to assess and address patient frailty issues before HCT.

Donor

A majority of allogeneic HCTs in the United States are performed using an unrelated donor. The numbers of haploidentical HCT are increasing (21% of all HCT in 2018) and appear to be converging with that of MSD (25% of all HCT in 2018), whereas UCB transplantations have decreased over the past few years (Fig. 19–1).

The degree of HLA matching is one of the single most important determinants of GVHD and graft-versus-tumor (GVT) effect. Therefore, it is essential to have a thorough grasp of the topic. The major histocompatibility complex (MHC), called HLA in humans, is the most polymorphic gene cluster of the entire human genome, and encodes for a set of proteins on the cell surface that are responsible for antigen presentation to T-cells. The HLA complex is located on the short arm of chromosome 6 within the 6p21.3 region and contains more than 220 genes categorized into various classes. The class I includes three "classical" genes (HLA-A, B, C), three "nonclassical" genes (-E, -F, -G), and several pseudogenes (-H, -J, -K, -L, -N, -P, -S, -T, -U, -V, -W, -Y) with more than 19,000 alleles.[17] The HLA class I antigens are expressed on all nucleated cells (except those of the central nervous system) and on platelets, and its gene products present endogenous peptides to CD8+ T-cells. The class II genes include HLA-DR (-A, -B1 though -B9), -DQ (-A1, -A2, -B1), -DP (-A1, -A2, -B1, -B2), -DM (-A, -B), -DO (-A and -B) in humans, with more than 7000 alleles identified.[17] The HLA class II antigens are expressed on classical antigen-presenting cells (monocytes, macrophages, dendritic cells, Langerhans cells, and B lymphocytes) and others, including endothelial cells and thymic epithelial cells; and they encode proteins that display processed antigenic peptides for presentation to CD4+ T-helper cells. The HLA class III region includes genes involved in the inflammatory response and encode for proteins of the complement system, heat shock proteins, and tumor necrosis family genes.[18,19] Further, there are several minor histocompatibility antigens (miHAs), which may differ even when the donor and recipient are identical with regard to MHC genes.[20] These miHAs are further classified as either hematopoietic-restricted minor H antigens (crucial for GVT effects), or broadly-expressed minor H antigens (crucial for both GVT and GVHD).[20,21]

For HCT outside the context of clinical trials, only the classical HLA class I genes (A, B, C) and class II genes (DP, DQ, DR) are tested, whereas HLA class III genes and miHAs are not. The definition of "HLA matching" depends on which loci are tested. For example, a donor may be labeled as a 6/6-HLA match (matched at HLA-A, -B, and -DRB1), 8/8-HLA match (HLA-A, -B, -C, and -DRB1), 10/10-HLA match (HLA-A, -B, -C, -DRB1, and -DQB1) and 12/12-HLA match (HLA-A, -B, -C, -DRB1, -DQB1-, and -DPB1). In general, a HLA-identical sibling is considered the gold standard and is the preferred donor when available versus MUD because of a significantly lower risk of development of GVHD[22,23] and survival advantage noted in some studies in a subset of patients.[22,24] In the absence of a suitable MSD, MUD can lead to comparable outcomes,[25–28] especially because the techniques of HLA typing are becoming more sophisticated, and allele-level matching across several loci is now being routinely performed. Among patients who are 10/10-HLA matched with an unrelated donor, -DPB1 mismatch, which is further categorized as permissive or nonpermissive based on the T-cell epitope grouping,[29] is of added significance. For instance, nonpermissive -DPB1 mismatches are associated with an increased risk of NRM and severe acute

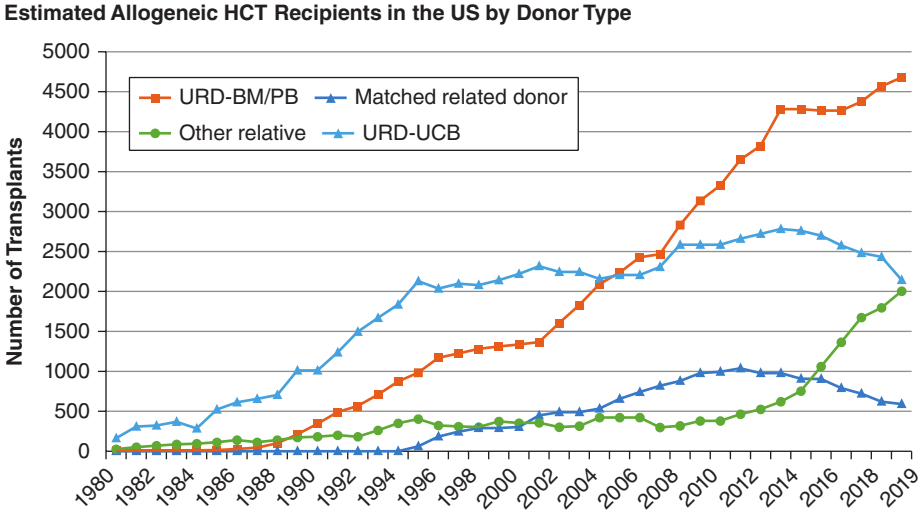

FIGURE 19–1 **Allogeneic HCT recipients in the United States by donor type. (Reproduced with permission from Phelan R, Arora M, Chen M: Current use and outcome of hematopoietic stem cell transplantation: CIBMTR US summary slides, 2020. https://www.cibmtr.org/ReferenceCenter/SlidesReports/SummarySlides/pages/index.aspx)**

GVHD, leading to poor OS compared with permissive -DPB1 mismatches. Compared with -DPB1–matched patient-donor pairs, permissive -DPB1 mismatches have a lower risk of relapse counterbalanced by a high risk of NRM, which leads to similar OS.[29] The current standard at MDACC is to test HLA-A, -B, -C, -DRB1, -DQB1, and -DPB1 using high-resolution molecular methods, such as the polymerase chain reaction, sequence-based typing, or Sanger- or next-generation sequencing, in an attempt to find a donor matched at all loci ("12/12-HLA match"). The HLA matching requirements for UCB transplantation are somewhat different.

Although the terms *HLA-matched* and *HLA-identical* are often used interchangeably, especially with sibling donors, in its strictest sense, *HLA identity* means that the donor and recipient are matched for the entire amino acid sequence encoded by all HLA loci. Identity is assumed in the setting of related donor transplantation when segregation analysis demonstrates that the donor and recipient have inherited the same maternal and paternal haplotypes (genotypic HLA identity).[30] Otherwise, HLA identity can only be verified by sequencing all HLA loci (phenotypic HLA identity), which is impractical and rarely done. Because there is a strong linkage disequilibrium between HLA-B and -C genes and HLA-DRB1 and -DQB1 genes,[31] HLA matching in a sibling donor can generally be defined by HLA-A, -B, and -DRB1 typing ("6/6 HLA match"), because this would imply matching at HLA-C and -DQB1 as well ("10/10 HLA match"). However, there is a chance that the HLA-*matched* sibling may not be HLA-*identical*, even when they have inherited the same maternal and paternal haplotypes, although this is rare. One study using single-nucleotide polymorphism genotyping and full MHC genomic sequencing to estimate the level of the MHC identity in HLA-matched sibling HCT identified that only 4/255 (1.5%) "6/6-HLA-matched" pairs were mismatched at HLA-DPB1, and about 4% of the 6/6-HLA-matched sibling-patient pairs had large genomic differences in the MHC segment.[32]

Preparative/Conditioning Regimen

The goal of a conditioning regimen before stem cell infusion is (a) to eradicate or reduce tumor cell burden ("myeloablation," in the case of malignant disorders), and (b) to eradicate the recipient's cytotoxic lymphocytes ("lymphoablation"), thereby providing immunosuppression to prevent graft rejection. Conditioning regimens are categorized as either MAC, NMA, or RIC.[33] By definition, MAC regimens lead to prolonged and potentially irreversible pancytopenia without hematopoietic stem cell support, whereas NMA regimens cause minimal or no cytopenia and can thus be administered without stem cell infusion. The regimens that cannot be classified as either MAC or NMA are labeled as RIC regimens; these do cause cytopenia and require hematopoietic stem cell support.[33,34] Historically, all preparative regimens were myeloablative and included high doses of chemotherapy (generally alkylating agents) and/or TBI. However, older patients and those with high comorbidities were considered ineligible for allogeneic HCT because of significant regimen-related toxicities. Therefore, doses of radiation and/or chemotherapy in preparative regimens were inconsistently reduced to minimize these toxicities, and such regimens were arbitrarily labeled as either RIC, where, generally, the dose of alkylating agent(s) or TBI was generally reduced by at least 30%.[33,34] A few criteria were then proposed to establish uniformity in defining regimen intensity.[35] One of them, the "Champlin criteria," defined RIC as a regimen that "(1) results in reversible myelosuppression (usually within 28 days) when given without stem cell support; (2) results in mixed chimerism in a proportion of patients at the time of first assessment (usually 28–35 days post stem cell transplantation); and (3) it is associated with low rates of non-hematologic toxicity." A more concrete definition was formulated by an expert panel from the National Marrow Donor Program (NMDP)[36] and by the Center for International Blood and Marrow Transplantation Registry (CIBMTR).[1,37] This defined RIC as a regimen that consisted of: (a) <5 Gy TBI when given as a single fraction or ≤8 Gy if fractionated; (b) ≤9 mg/kg busulfan orally (or intravenous [IV] equivalent, 1.0 mg/kg oral Bu = 0.8 mg/kg IV Bu); (c) <10 mg/kg thiotepa; and (d) <140 mg/m^2 melphalan (or most recently ≤150 mg/m^2 melphalan),[37] generally with purine analogues such as fludarabine or cladribine (Fig. 19–2).

Common Conditioning Regimens in Acute Myelogenous Leukemia (AML) or Myelodysplastic Syndrome (MDS) Allogeneic HCT in the US, 2009-2019

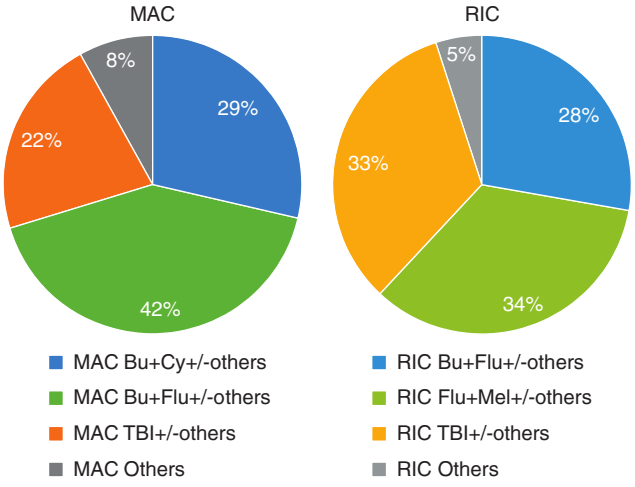

FIGURE 19–2 Common conditioning regimens in AML or MDS in allogeneic HCT in the United States from 2007-2017 (Reproduced with permission from Phelan R, Arora M, Chen M: Current use and outcome of hematopoietic stem cell transplantation: CIBMTR US summary slides, 2020. https://www.cibmtr.org/ReferenceCenter/SlidesReports/SummarySlides/pages/index.aspx)

Myeloablative Conditioning (MAC)

Myeloablative regimens can be broadly categorized as either chemotherapy based or TBI based, the latter used generally in conjunction with chemotherapy. The most commonly used chemotherapy drugs with high-dose TBI are cyclophosphamide (Cy/TBI)[38–42] and etoposide (TBI/Etoposide),[39,40] whereas others such as fludarabine (Flu/TBI),[43–45] cytarabine,[42,46] and melphalan,[43] are used less commonly. Increasing the total dose of TBI is associated with significantly lower risk of relapse, but it is offset by a higher NRM, leading to similar OS.[47,48–50] Hence, the concept of delivering TBI over multiple fractions each day was evaluated with a hypothesis that fractionated regimen would allow some recovery of normal tissues between the doses, thus theoretically lowering the toxicity while achieving satisfactory killing of malignant cells.[51–53]

Although efficacious, high-dose TBI is associated with a number of short- and long-term complications, including gastrointestinal (GI) and pulmonary toxicities, secondary malignancies, retarded growth, and/or intellectual development, cataracts, and endocrine dysfunction, to name a few. These concerns led to the development of radiation-free conditioning regimens. Of these, the combination of busulfan with either cyclophosphamide (Bu/Cy) or fludarabine (Bu/Flu) became the two most commonly used regimens. Busulfan was traditionally administered orally at a total dose of 16 mg/kg divided four times per day given over 4 consecutive days (1 mg/kg × 16 doses) followed by high-dose cyclophosphamide over 2 to 4 days (total dose about 120–200 mg/kg).[54,55] This was often complicated by excessive toxicities, including potentially fatal veno-occlusive disease (VOD)/sinusoidal obstruction syndrome (SOS) as a result of unpredictable intestinal absorption and erratic bioavailability of oral busulfan, especially when combined with an adverse interaction with cyclophosphamide,[56] because its metabolism varies considerably among individuals.[57] Further, the use of high-dose dual-alkylating agents, such as in the Bu/Cy regimen (both of which can deplete the liver of glutathione) can lead to overlapping toxicities.[58] Therefore, at MDACC, we substituted cyclophosphamide with fludarabine, which is as immunosuppressive as cyclophosphamide, has synergistic cytotoxicity with busulfan because it potentiates alkylator-induced cell killing through inhibition of DNA damage repair, and it does not cause SOS because it does not utilize the glutathione (GSH)/glutathione S-transferases (GST) and the hepatic CYP450-pathaways for metabolism. Moreover, replacement of oral busulfan with IV busulfan (0.8 mg/kg × 16 doses) led to dramatic reduction, but not elimination, of the risk of SOS and improved survival.[56] Intravenous busulfan has more predictable systemic drug exposure, especially when coupled with pharmacokinetic dose monitoring ("targeted-busulfan")[58] and allows for once-daily administration of both busulfan and fludarabine as a result of a long plasma half-life, which is much more practical and convenient.

With encouraging outcomes noted in multiple studies with the Bu/Flu regimen, this has become a standard MAC regimen both at MDACC[59,60] and at other major transplantation centers in North America.[61,62] In these Bu/Flu regimens, fludarabine is typically administered at a dose of 40–50 mg/m^2 on days –6 to –3, and each dose is followed immediately by IV busulfan on days –6 to –3, with the dose adjusted to achieve systemic exposure represented by an area under the curve (AUC) of an average 4000–6000 µmol/min per day, or total course AUC of 16,000–24,000 µmol/min. More recently, we developed a novel approach of delivering myeloablative doses of busulfan using a fractionated ("timed-sequential") regimen. Patients receive two doses of IV busulfan (80 mg/m^2 each) one to 2 weeks before HCT (either day –20 and –13, or days –13 and –12), followed by IV fludarabine and IV busulfan once daily on days –6 to –3. The dose of busulfan is guided by pharmacokinetic analysis, to achieve a total dose AUC of 16,000–20,000 ± 12% µmol/min.[63,64] With this approach, we have been able to safely administer MAC to patients up to 75 years of age and in those with significant comorbidities[63,64]—a population that would otherwise be deemed ineligible for MAC HCT.

Reduced-Intensity Conditioning/ Nonmyeloablative

The recognition of donor T-cell-mediated potent GVT effects emerged from studies in the late 1970s that noted inverse correlation between GVHD and leukemia relapse.[65–69] The hypothesis that GVT existed was further substantiated by the observations of a higher risk of relapse with syngeneic[70] than with allogeneic HCT, and higher risk of relapse with T-deplete than with T-replete grafts.[71] These findings collectively led to the origin of NMA/RIC regimens, where reduction in conditioning intensity was compensated by dependence on GVT effects, for patients who otherwise could not tolerate MAC.

Similar to MAC, NMA and RIC regimens can be chemotherapy and/or TBI-based. Preclinical work suggested that a TBI dose as low as 2 Gy was sufficient to allow engraftment of donor stem cells when used in conjunction with postgrafting immunosuppression.[72] Early studies from Fred Hutchinson Cancer Research Center used 2 Gy TBI as the sole conditioning regimen in patients with relative contraindications to MAC who underwent MSD HCT.[69] Donor lymphocyte infusions (DLI) were given post-HCT in patients with persistent malignancy and/or mixed chimerism. Although

20% failed to engraft, and relapse mortality was about 27%, the overall outcomes were encouraging, with about 67% survival as a result of low NRM (~7%).[69] Later, the addition of fludarabine to the regimen (Flu/TBI) improved donor chimerism and decreased graft rejection, but the rate of disease relapse/progression or related mortality remained significant.[73,74] Other studies added cyclophosphamide to fludarabine and low-dose TBI (Flu/Cy/TBI), a regimen popularly used in the setting of CBT[75,76] and haploidentical[77] HCT.

Among RIC, two that are commonly used at MDACC include fludarabine with an alkylating agent—either melphalan (Flu/Mel) or low-dose busulfan (Bu/Flu). Multiple studies from MDACC reported successful use of purine nucleoside analog-based regimens (mostly with fludarabine) and melphalan doses ranging from 100–180 mg/m^2, with or without other chemotherapy agents.[78–81] In the Bu/Flu-based RIC regimens, total dose of busulfan is 8 mg/kg orally (or 6.4 mg/kg IV) or lower. The so-called historical "FB2" regimen administered fludarabine with busulfan 3.2 mg/kg IV daily for 2 days (total dose 6.4 mg/kg IV) versus the traditional myeloablative "FB4" regimen, where busulfan 3.2 mg/kg IV daily was delivered for 4 days (total dose 12.8 mg/kg IV daily).[82,83] These definitions of FB2 versus FB4 are obsolete because a much lower dose of busulfan can also be delivered over 4 days (0.8 mg/kg IV daily × 4 days, with a total dose of 3.2 mg/kg IV).[84] Further, the concept of a fixed standard dose of busulfan is becoming outdated because the dosing is now routinely determined by the pharmacokinetic analysis, and the RIC regimens include doses that target total course AUC of 16,000 µmol/min or lower.[63,64,85]

Whenever possible, the standard at MDACC is to use MAC, at least for patients with myeloid malignancies, given the high risk of relapse and inferior survival with RIC regimens.[37] A phase 3 randomized trial conducted by the Blood and Marrow Transplantation Clinical Trials Network (BMT-CTN) compared RIC with MAC in patients up to 65 years of age with AML or MDS. The trial was stopped prematurely because of a significantly higher risk of relapse with RIC (48% vs 13%; $P < .001$), which translated to inferior disease-free survival (DFS) with RIC (47% vs 68%, $P < .01$) despite much lower NRM (4% vs 16%, $P = .002$) with RIC than with MAC, respectively.[37] Similar randomized trials are lacking patients with ALL, although many large retrospective studies suggested higher relapse and lower NRM with RIC, but similar survival between RIC and MAC.[86–88]

Sources of Hematopoietic Stem Cells

A separate chapter is dedicated to UCB transplantation, but this chapter will focus on BM- or PB-derived stem cells as the source of hematopoietic stem cells. The choice of stem cell/graft source has implications for both donor and recipient. Historically, hematopoietic stem cells were obtained through the harvest of BM from posterior superior iliac crests of normal donors. However, over the past decade, PB has become the most common graft source in adults undergoing MSD or MUD HCT, and more recently in the haploidentical HCT setting as well (Fig. 19–3).[1]

Bone marrow harvest is associated with a generally low incidence of complications for the donor and is usually performed on an outpatient basis.[89] Immediate complications of BM harvest (related to general anesthesia and intubation) are vomiting (about 10%), sore throat and hypotension (<10%). The most common complication is pain at the collection site, which requires analgesics (mostly non-narcotics), and occurs in about half of donors and can persist for up to 2 weeks (median 1 day).[90,91] The NMDP mandates that the duration of anesthesia be less than 150 minutes, duration of collection be less than 120 minutes, and allows for a maximum of 20 mL/kg (donor weight) of marrow to be aspirated, with a predicted median total nucleated cell (TNC) cell count/mL of 0.183 × 10^8/mL.[92,93] Unfortunately, the quality of BM harvest is declining over the years despite increased use of more optimal donors (eg, younger males).[93] This is concerning because the BM TNC dose is a significant prognostic factor for HCT outcomes. One study stratified patients into three groups based on the graft TNC dose: <2.5 × 10^8 cells/kg (low dose), 2.5–5 × 10^8 cells/kg (intermediate dose), and >5 × 10^8 cells/kg (high dose). Compared with low- and intermediate-dose groups, patients in the high-dose arm had significantly lower NRM (41%, 36%, and 28%, respectively; $P = .01$) and improved OS (45%, 51%, and 56%, respectively; $P = .0008$) in addition to faster and improved engraftment.[94]

Since the early 1990s, the use of PB-derived stem cells has become increasingly common; they are collected by using recombinant granulocyte colony-stimulating factor (G-CSF), given for 4 to 6 days at doses of 6–16 µg/kg per day. With this, the hematopoietic stem cells mobilize into the PB, where they may be collected by one or more leukapheresis procedures. A higher dose of CD34+ cells is required when using PB as the stem cell source than what can be achieved with BM graft. The typical dose of infused CD34+ cells ranges from about 2 × 10^6/kg to 10 × 10^6/kg, with about 4 × 10^6/kg being the standard at MDACC. Numerous studies including randomized control trials comparing PB with BM have now confirmed the efficacy and safety of this approach.[95–98] Studies suggest that an almost similar proportion of donors experience adverse events (AEs) with either PB (65%) or BM (57%) collection, most of which are transient and mild to moderate in severity, although the respective AE profiles are different. With PB stem cell collection, donors mostly have AEs related to either high-dose G-CSF (most commonly bone pain/myalgias, headaches or fatigue in

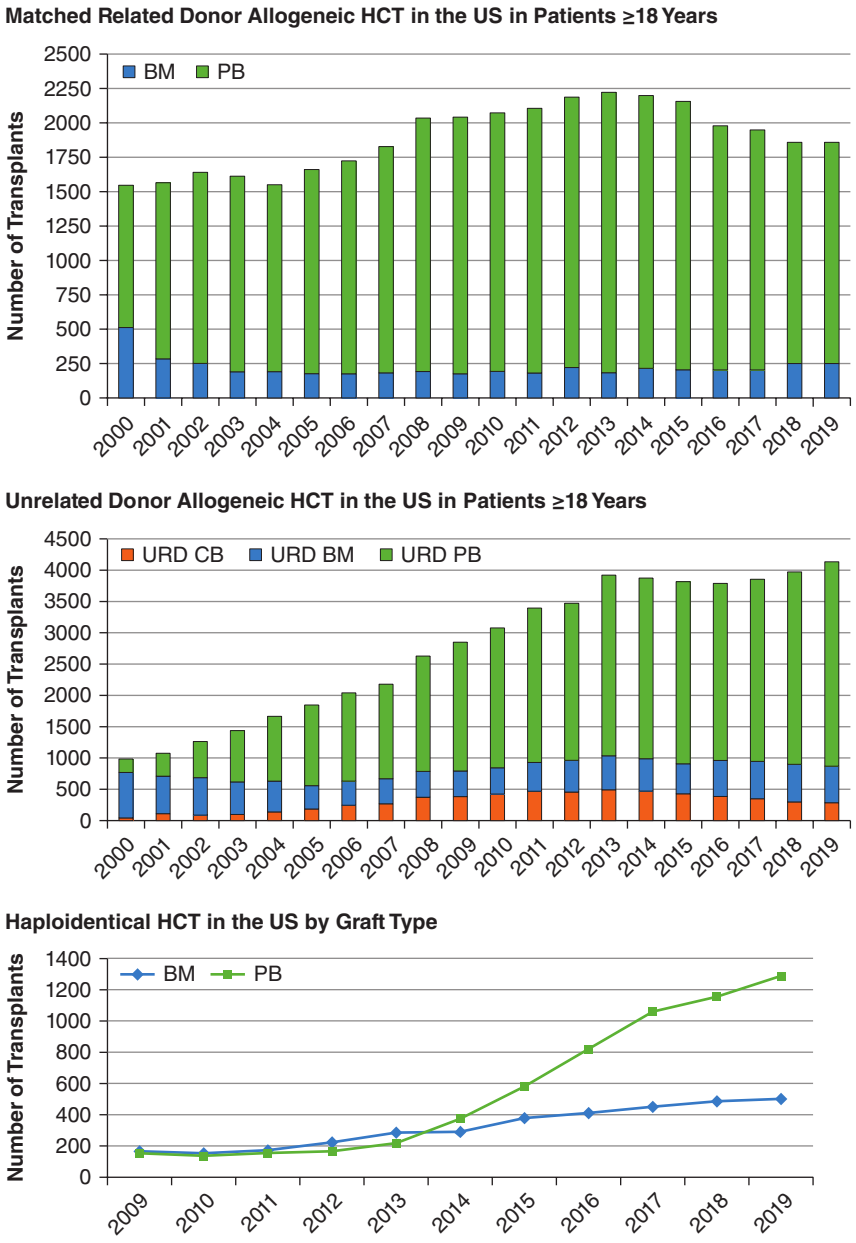

FIGURE 19–3 **Donors and recipients in allogeneic HCT (Reproduced with permission from Phelan R, Arora M, Chen M: Current use and outcome of hematopoietic stem cell transplantation: CIBMTR US summary slides, 2020. https://www.cibmtr.org/ReferenceCenter/SlidesReports/SummarySlides/pages/index.aspx)**

~70% of cases), or related to leukapheresis (tingling, numbness, carpal-pedal spasm, etc, caused by citrate administration, nausea [20%], problems with access [IV-line infiltration, hematomas, poor flow, etc, in ~20%]). Other rare leukapheresis-related AEs include chest pain, headaches, hypotension, syncope, and hypocalcemia-related tetany.[99]

Multiple studies evaluated patient outcomes after BM or PB graft in both MSD and MUD setting. In recipients of MUD HCT, a large phase 3 multicenter randomized controlled trial showed significantly higher risk of chronic GVHD (cGVHD), but not acute GVHD (aGVHD) after PB versus BM grafts (53% vs 41%, P = .01), with no difference in relapse, NRM, DFS, or OS. However, the incidence of graft failure was higher in the BM (9%) than in the PB group (3%), P = .002.[100] In the setting of MSD HCT, a randomized trial of PB versus BM showed significantly higher risk of cGVHD with PB than with BM (73% vs 56%, respectively; P = .021), without any differences in OS (49% vs 57%, respectively) or DFS (13% vs 28%, respectively, for ALL; 62% vs 47%, respectively, for AML; and 40% vs 48%, respectively, for CML).[101] Another study confirmed high risk of cGVHD (61% vs 45% at 6 years)

with no difference in risk of relapse with PB versus BM graft. However, NRM and DFS differed between PB and BM by disease and stage. For example, NRM was similar with PB or BM graft in patients with early leukemia and advanced CML, but higher with PB in early CML, and higher with BM in advanced leukemia. Compared with PB, BM was associated with higher DFS in early CML (41% vs 61%, respectively) but it led to lower DFS in those with advanced CML (33% vs 25%, respectively).[102] Individual patient data meta-analysis of nine randomized trials[103] showed significantly higher risk of grade III–IV aGVHD (odds ratio [OR] 1.39; 95% CI, 1.03–1.88), overall cGVHD (68% vs 52% at 3 years; OR 1.92; 95% CI, 1.47–2.49; $P < .000001$) and extensive cGVHD (47% vs 31% at 3 years; OR 1.89; 95% CI, 1.47–2.42; $P < .000001$), but also with significantly lower risk of relapse (21% vs 27% at 3 years; OR 0.71; 95% CI, 0.54–0.93; $P = .01$) with PB than with BM, respectively, and no differences in NRM. In patients with late-stage disease, OS (46% vs 31% at 3 years; OR 0.64; 95% CI, 0.46–0.90; $P = .01$) and DFS (41% vs 27% at 3 years; OR 0.63; 95% CI, 0.45–0.87; $P = .01$) were significantly superior with PB grafts.[103]

At MDACC, the graft source of choice for adult patients with MSD is PB (except certain diseases such as aplastic anemia and other bone marrow failure syndromes), and BM for patients with MUD except in those with highly advanced/refractory disease, prolonged cytopenias, myelofibrosis with splenomegaly, or other situations where rapid engraftment is necessary.

CHAPTER 19

Graft-Versus-Host Disease Prophylaxis

In a very broad sense, GVHD is an attack on recipient tissues by the donor's immune cells and most commonly involves the skin, GI tract, and liver in an acute setting. The pathophysiology of GVHD starts with the damage to host tissues from the preparative regimen, or even before, as a result of underlying disease itself or infections, resulting in substantial proinflammatory changes in endothelial and epithelial cells. The inflammatory cytokines then activate host antigen-presenting cells and upregulate adhesion molecules and several major and minor histocompatibility antigens, which leads to enhanced recognition by mature (infused) donor T-cells that secrete cytokines that mediate GVHD.[104] Approaches to reduce the risk of GVHD are targeted predominantly toward elimination or inhibition of donor T-cells, and include T-cell depletion (TCD) that can be done ex vivo (CD34+ selected or T-cell-depleted grafts) or in vivo (serotherapy with either antithymocyte globulin [ATG] or alemtuzumab), or by using post-transplantation immunosuppression with agents, such as methotrexate (MTX), calcineurin inhibitors (CNI, such as tacrolimus or cyclosporine), mycophenolate mofetil (MMF), sirolimus, or post-transplantation cyclophosphamide (PTCy).

Although the use of ex vivo TCD raises concerns about increased risk of graft failure[105] and relapse, at least in patients with CML,[106,107] it can reduce the risk of GVHD dramatically. In a study of 44 patients with AML who received TBI-based MAC followed by CD34-enriched, T-cell-depleted allografts from MSD, the incidence of aGVHD grade II–IV was about 23% without any post-transplantation GVHD prophylaxis.[108] The addition of in vivo TCD reduced the risk of aGVHD further, as shown in a study of 102 patients with MDS who received CD34-selected PB HCT after MAC with ATG. The cumulative incidence of grades II–IV aGVHD was about 10% at day 100 and about 16% at day 180. However, the use of T-cell-depleted grafts is plagued by slow and poor immune reconstitution that leads to significant risk of infections and consequent NRM.[109] To circumvent these issues, novel techniques of selective lymphocyte depletion such as CD3+/CD19+ and αβ T-cells/CD19 depletion are being evaluated.[110–112]

In vivo TCD is achieved with the use of serotherapy with either ATG[113,114] or alemtuzumab.[115,116] A variety of schedules and formulations of these have been tested for GVHD prophylaxis. Alemtuzumab is a humanized monoclonal antibody against CD52 that is expressed on a multitude of immune cells, including T-cells, B cells, natural killer cells, monocytes, macrophages, and some granulocytes and eosinophils. Antithymocyte globulin contains polyclonal antibodies generated in animals by inoculation with human thymocytes (developing T-cell progenitors that migrate from the BM to thymus for maturation). These antibodies bind to a variety of human T-cell receptors including CD2, CD3, CD4, CD8, CD25, CD45, and many HLA class I and II molecules, thus depleting lymphocytes from circulation. Two formulations approved by the FDA are equine ATG (ATGAM, Pfizer) and rabbit ATG (Thymoglobulin, Genzyme). Another rabbit ATG formulation is the ATG-Fresenius, which is used in many European studies and is not approved by the FDA. The immunosuppressive effects and doses of ATG vary significantly from one preparation to another.[117] In patients with severe aplastic anemia, immunosuppressive therapy with horse ATG (40 mg/kg/day for 4 days) plus cyclosporine as an alternative to HCT leads to superior survival than with rabbit ATG (3.5 mg/kg/day for 5 days) plus cyclosporine.[118] However, no such direct data about the superiority of one or the other formulation exist in the context of HCT. In contrast to horse ATG, rabbit ATG is more immunosuppressive and cytotoxic, depletes lymphocytes more efficiently, and induces the development of regulatory T-regulatory cells, which have added benefits for GVHD prevention.[118]

Therefore, rabbit ATG continues to be the preferred agent at many centers, including MDACC for GVHD prophylaxis, especially for patients with an unrelated donor. Serotherapy (ATG or alemtuzumab) is generally given before transplantation in conjunction with the conditioning regimens. However, because of long half-lives, their lymphodepleting effects last several days beyond the day of transplantation. This reduces the risk of GVHD by inhibiting donor T-cells, but also interferes with the recovery of donor-derived antiviral lymphocytes, leading to increased risk of cytomegalovirus and Epstein-Barr virus, adenovirus, and other viral reactivation, and may potentially interfere with the GVT effects. Because of the almost ubiquitous presence of CD52 on immune cells and significantly longer half-life, alemtuzumab leads to more intense immunosuppression, delayed immune reconstitution (with CD4 leukopenia lasting almost up to 3 years[119]), and higher risk of infections than with ATG.[120]

The history of using methotrexate (MTX) for GVHD prophylaxis dates back to the late 1950s when preclinical studies suggested that "mice which would normally succumb to a homograft reaction following lethal, total-body X irradiation and homologous marrow inoculation, may be spared if they are treated with folic acid antagonist, A-methopterin."[121] Thus, A-methopterin (methotrexate) became one of the earliest drugs used for GVHD prophylaxis.[122] It was used as a single agent dosed at 15 mg/m^2 on day +1, and 10 mg/m^2 on days +3, +6, and +11 and then weekly through day +102.[122] Subsequent adaptations included the addition of a CNI with a shorter course of methotrexate dosed at 15 mg/m^2 on day +1 and 10 mg/m^2 on days +3, +6, and +11,[123] or an even lower-dose regimen of 5 mg/m^2 on days +1, +3, +6, and +11 ("mini-methotrexate" regimen) used at MDACC.[124]

As of this writing, CNI is the most commonly used class of drugs for GVHD prophylaxis, generally in combination with either MTX or MMF. Both cyclosporine and tacrolimus bind to a cytoplasmic-receptor protein called immunophilin (cyclophilin and FKBP-12, respectively) and form a complex that binds to calcineurin and inhibits Ca2+-stimulated dephosphorylation of the cytosolic component of the nuclear factor of activated T-cells (NFAT). Upon T-cell receptor activation, calcineurin-induced dephosphorylation of NFAT is required to induce a number of cytokine genes, including interleukin-2 (IL-2). With the inhibition of dephosphorylation of NFAT by the calcineurin inhibitor/immunophilin complex, the activation of T-cells is thus inhibited.[125]

The combination of CNI and MTX is superior in reducing the risk of GVHD compared with either alone.[126,127] Which of the two CNIs (tacrolimus or cyclosporine) is superior was addressed in two large phase 3 randomized clinical trials.[123,128] One trial compared tacrolimus/methotrexate (Tac/MTX) with cyclosporine/MTX in patients who underwent MSD BMT. Patients in the cyclosporine arm had significantly higher incidences of grade II–IV aGVHD (44% vs 32%, respectively; $P = .01$) and extensive cGVHD ($P = .03$) than those in the tacrolimus arm, but with similar rates of grade III–IV aGVHD (17% vs 13%, respectively), overall cGVHD (50% and 56%, respectively), and relapse. Yet, patients in the cyclosporine arm also had a superior 2-year DFS (50% vs 40%; $P = .01$) and OS (57% vs 47%; $P = .02$) than the tacrolimus arm, respectively. This was likely related to a significantly higher proportion of patients with advanced disease in the tacrolimus arm (41% vs 29%; $P = .02$).[123] A subsequent phase 3 trial in patients undergoing MSD or MUD BMT also showed significantly higher risk of grade II–IV aGVHD in the cyclosporine versus the tacrolimus arm (48% vs 18%, respectively; $P < .0001$), but with no differences in cGVHD, relapse, or OS. However, one unexplained finding was that among recipients of MSD, relapse was noted to be significantly higher in the tacrolimus than in the cyclosporine group (31% vs 4%, respectively; $P = .01$).[128]

In contrast to CNI, sirolimus inhibits T-cell activation and proliferation downstream of IL-2. Although sirolimus also binds with an immunophilin (FKBP-12), the sirolimus/FKBP-12 complex does not affect calcineurin activity; rather it binds to and inhibits mammalian target of rapamycin (mTOR), which halts cell-cycle progression at the G1→S phase transition.[125] Studies also suggest that it promotes tolerance by expansion of CD4+CD25+FOXP3+ T-regulatory cells (Tregs) as well as dendritic cells.[129,130] Compared with Tac/MTX, the tacrolimus/sirolimus (Tac/Siro) combination has profound immunosuppressive effects, as suggested by higher Treg:Tcon ratio, and significantly lower absolute lymphocyte count, CD3+ cell, CD4+ cell, and conventional T-cell (Tcon) counts in the first 3 months after HCT, and delayed B-lymphocyte immune reconstitution.[131] Nevertheless, in the BMT-CTN randomized phase 3 clinical trial[132] comparing Tac/MTX with Tac/Siro in patients with MSD PB HCT, who received myeloablative TBI-based conditioning (Cy/TBI or TBI/etoposide), no differences were noted in the probability of day 114 grade II–IV aGVHD-free survival (67% vs 62%; $P = .38$), grades II–IV aGVHD (26% vs 34%; $P = .48$), cGVHD, DFS, or OS. Both tacrolimus and sirolimus were started at day −3 to maintain trough serum concentration of 5–10 ng/mL for tacrolimus and 3–12 ng/mL for sirolimus. Patients in the Tac/Siro arm experienced significantly higher incidence of elevation of creatinine, had a trend toward a higher risk of SOS/VOD (11% vs 5%; $P = .06$), and a higher incidence of thrombotic microangiopathy (TMA; 5% vs 1%; $P = .09$) than in the Tac/MTX arm. Also, of note, the

myeloablative Bu/Cy arm was stopped prematurely because of excessive risk of SOS,[132] which was seen in other studies as well.[133]

Another immunosuppressant commonly used with CNI is a purine metabolism inhibitor, MMF. It undergoes rapid metabolism to its active drug mycophenolic acid, which is a selective, reversible inhibitor of inosine monophosphate (IMP) dehydrogenase, an enzyme in the pathway of guanine nucleotide synthesis, critical for B and T lymphocyte proliferation. The combination of CNI/MMF is generally used in the setting of RIC or NMA HCT, and in those with MSD HCT,[134] but it may be a suboptimal approach in the setting of MAC and unrelated donor HCT.[135] It has also been used effectively with CNI or sirolimus in the setting of CBT[136,137] or haploidentical HCT with PTCy.[77]

Another novel approach to GVHD prophylaxis includes the use of the post-transplantation cytotoxic drug cyclophosphamide. The efficacy of cytotoxic drugs, including methotrexate, 6-mercaptopurine (6-MP), mechlorethamine, and cyclophosphamide to prevent GVHD was assessed as early as the 1960s.[138–140] In elegantly conducted experiments, Santos and Owen noted that cyclophosphamide, when given on days +2, +3, and +5 post-HCT, but not beyond day +7, significantly reduced the risk of GVHD.[139] However, because of concerns about its myelotoxicity when used after transplantation, its use as a GVHD prophylaxis strategy fell out of favor until late the 1990s/early 2000s, when this concept was revisited by investigators from the Johns Hopkins University in the setting of haploidentical HCT. Because of its unique pharmacology, cyclophosphamide can induce maximal immunosuppression without myeloablation, because it targets cells that express low levels of aldehyde dehydrogenase (such as B and T lymphocytes and natural killer cells), while sparing cells with a high level of this enzyme, such as the hematopoietic stem cells.[141] The safety and efficacy of using cyclophosphamide for prevention of both graft rejection and GVHD was demonstrated in a pivotal trial by O'Donnell et al,[142] where patients received T-cell-replete haploidentical BMT with NMA conditioning (Flu/TBI with or without Cy 14.5 mg/kg/day × 2 days pre-HCT), followed by single dose of Cy 50 mg/kg IV on day +3 post-HCT. Because CNI inhibits Cy-induced immunologic tolerance,[143] tacrolimus and MMF were added starting at day +4. Because the risk of graft failure and severe GVHD was still high (~60% at 6 months), the regimen was modified and patients received PTCy either on day +3 (50 mg/kg, n = 28) or on days +3 and +4 (50 mg/kg on each day, n = 40), followed by tacrolimus and MMF starting one day after PTCy.[77] Graft rejection occurred in 13%, and grades II–IV and III–IV aGVHD by day 200 were noted in 34% and 6% of patients, respectively. Although the risks of aGVHD, relapse, and NRM were similar among patients who received one or two doses of PTCy, the incidence of extensive cGVHD at one year was significantly lower in those who received two doses of PTCy than those who received a single dose (5% vs 25%, respectively; $P = .05$).[77]

The efficacy of PTCy was also tested in the setting of MSD or MUD HCT after RIC, in the BMT-CTN 1203 multicenter 1:1:1 randomized phase 2 clinical trial that evaluated three novel GVHD prophylaxis regimens—(1) PTCy/Tac/MMF (n = 92), (2) Tac/MTX with bortezomib (n = 89), and (3) Tac/MTX with maraviroc (n = 92).[144] Each study group was also compared separately with a contemporary control group of Tac/MTX (n = 224). Of these, the PTCy arm was found to be the most promising and led to statistically significant improvement in the primary end point (GVHD-free, relapse-free survival; GRFS: hazard ratio (HR) 0.72, 90% CI 0.54–0.94; $P = .044$) compared with controls. The incidence of grade II–IV aGVHD was not different among the arms, but that of grade III–IV was significantly lower only in the PTCy arm than in the controls (2% vs 13%; $P = .008$). Similarly, the risk of cGVHD (28% vs 38%; $P = .069$), and especially the cGVHD requiring immunosuppression (22% vs 37%; $P = .037$), were lower only in the PTCy arm. The risk of relapse, NRM, and DFS were similar among all groups, but viral infections appeared to be more common and occurred in about one-third of patients in the PTCy arm than other arms (20%–22%).[144]

MD ANDERSON CANCER CENTER APPROACH FOR GVHD PROPHYLAXIS

A combination of Tac/MTX is still considered the standard of care among recipients of sibling (without ATG) or unrelated (with ATG) donor HCT. However, PTCy/Tac/MMF, which is the standard for all haploidentical HCTs, is being used more commonly across all types of donor transplantations excluding CBT, where the standard is Tac/MMF with ATG. In the Tac/MTX regimen, tacrolimus is initiated on day –2, whereas it is started on day +5 in patients receiving PTCy. Tacrolimus is started at 0.015–0.03 mg/kg per day via continuous IV infusion with a target level of 7–12 ng/mL. In rare certain situations where tacrolimus cannot be used, cyclosporine is used to a target level of 300–400 ng/mL at least for the first 60 days post-HCT. Sirolimus is typically reserved for patients who are unable to tolerate tacrolimus, such as those with severe renal dysfunction or those with tacrolimus-related neurotoxicity. Methotrexate 5 mg/m^2 IV per dose is given on days +1, +3, +6, and +11. MMF is dosed at 15 mg/kg IV/by mouth every 8 hours (with a max of 1 g/dose).

POST-TRANSPLANTATION COMPLICATIONS

At least mild (grade I) toxicity related to the conditioning regimen will develop in almost all patients, whereas potentially life-threatening or fatal (grades III–IV) complications are relatively rare.[64,145] A detailed description of these complications is beyond the scope of this chapter. Some of the most commonly encountered nonhematologic toxicities include oral stomatitis (management reviewed by Keefe et al[146]), GI (nausea, vomiting, and diarrhea), and febrile neutropenia that occurs in more than 80% of patients, with documented infections noted in only about 25% to 50%[147,148] (management reviewed by the Infectious Diseases Society of America [IDSA][149] and the American Society for Blood and Marrow Transplantation [ASBMT][150]). Other regimen-related complications (besides GVHD) can be difficult to diagnose because similar presentation can be caused by several other factors. These include hepatic toxicities (drug-induced or infectious hepatitis or cholestatic disorders, iron overload, VOD/SOS; reviewed by Arai et al[151]); cardiovascular (hypertension, arrhythmias, cardiomyopathy, fluid volume overload; reviewed by Tichelli et al[152] and Blaes et al[153]); pulmonary (pulmonary edema, diffuse alveolar hemorrhage (DAH), idiopathic pneumonia syndrome; reviewed by Yen at al[154]); bladder (hemorrhagic cystitis,[155–158] which could be related to PTCy of infections such as BK virus and adenovirus); renal (acute or chronic kidney injury, thrombotic microangiopathy[159,160]); and CNS toxicity[161–163] (posterior reversible encephalopathy syndrome [PRES], seizures, hemorrhage, infections, encephalopathy), to name a few. The most common causes of death within the first 100 days of HCT are relapse of the underlying disease (20%–35%), infections (20%–30%), organ failure (20%–25%), and GVHD (~15%). The leading cause of death beyond 100 days of HCT is the relapse of the underlying disease (50%–60%), whereas infections (10%–15%), organ failure (~10%), GVHD (~15%), and others contribute to the rest (Fig. 19–4).

Infectious Disease Prophylaxis

We use fluoroquinolone (levofloxacin or ciprofloxacin) for antibacterial prophylaxis during the phase of neutropenia as recommended by the IDSA guidelines,[149] or cefpodoxime or azithromycin in case of quinolone allergies/contraindications. Patients also receive prophylaxis against *Candida* (per IDSA: fluconazole, itraconazole, voriconazole, posaconazole, or echinocandins are all acceptable options) and select patients (especially those with prior history of invasive mold infection, mismatched HCT, and those receiving in vivo TCD) also receive prophylaxis against invasive *Aspergillus* infections with either posaconazole[149] or voriconazole. Antifungal prophylaxis is generally continued until at least 2 months from when immunosuppression

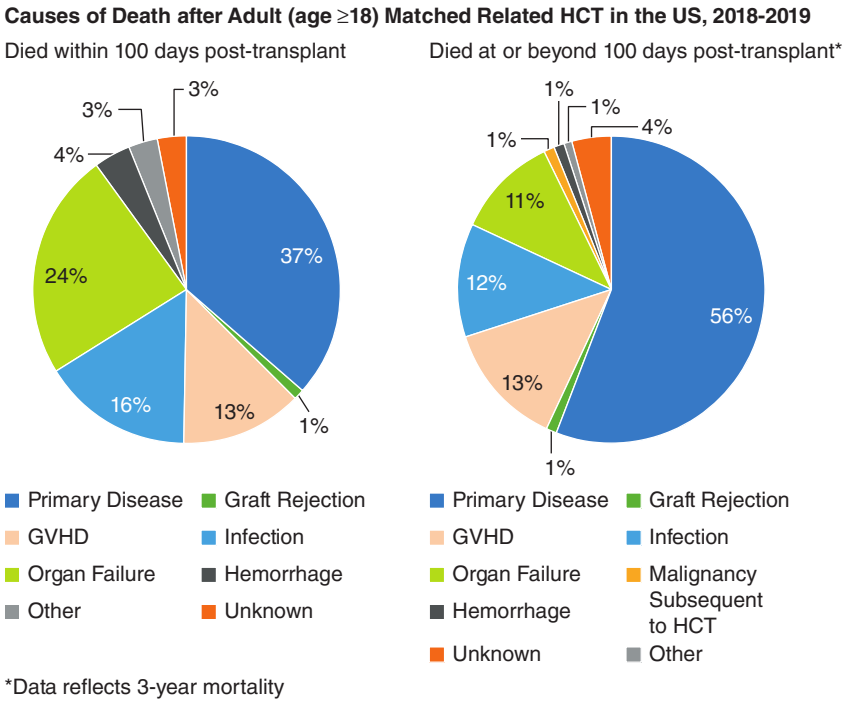

FIGURE 19–4 **Causes of death in matched sibling and unrelated donor HCT in 2016-2017 (Reproduced with permission from Phelan R, Arora M, Chen M: Current use and outcome of hematopoietic stem cell transplantation: CIBMTR US summary slides, 2020. https://www.cibmtr.org/ReferenceCenter/SlidesReports/SummarySlides/pages/index.aspx)**

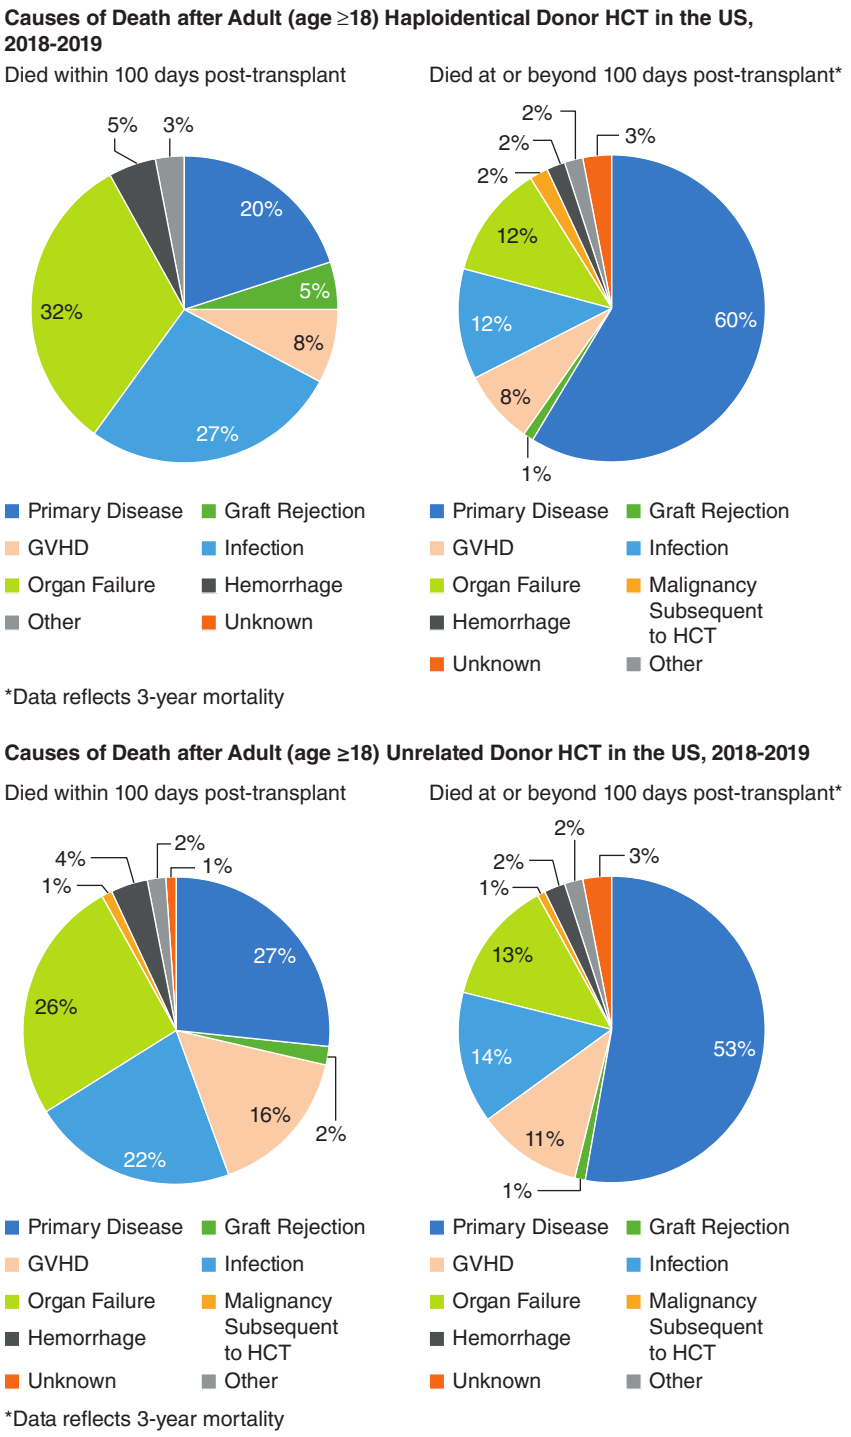

FIGURE 19–4 (*Cont.*)

is discontinued. Antiviral prophylaxis against varicella zoster virus/herpes simplex virus is provided with valacyclovir. All cytomegalovirus-seropositive patients receive prophylaxis with letermovir 480 mg by mouth/IV daily starting on day +5, which is continued through day +100.[164] Another infection against which prophylaxis is routinely used is *Pneumocystis jiroveci* pneumonia (PJP). Although its incidence appears to be decreasing in the modern era (<1% of allogeneic HCT patients), it is still associated with high mortality.[165] Half of PJP infections occur between 2 and 9 months post-HCT, with the rest being distributed equally before and after this period.[165] For prophylaxis against PJP, we prefer trimethoprim/sulfamethoxazole over atovaquone, pentamidine, or dapsone because it provides additional coverage against *Toxoplasma gondii*, *Nocardia*, *Stenotrophomonas*, and other susceptible bacteria. Trimethoprim/sulfamethoxazole is used as a

double-strength tablet (800/160 mg) once daily three times per week, or a single-strength tablet (400/80 mg) once daily. For patients with contraindications, alternative regimens include pentamidine 4 mg/kg IV every 21 days (or 300 mg inhaled every 28 days), dapsone 100 mg orally daily, or atovaquone 1500 mg orally daily. Of these, only atovaquone has activity against toxoplasmosis. Prophylaxis against PJP is usually started about 3 to 4 weeks post-HCT and is continued for a minimum of 12 months, or at until 2 months after discontinuation of immunosuppression, whichever is later

In addition, to shorten the duration of severe neutropenia, all patients receive recombinant granulocyte colony-stimulating factor (G-CSF),which is continued through neutrophil engraftment—defined as the first of 3 consecutive days on which the absolute neutrophil count is greater than or equal to 0.5×10^9/L. Multiple phase 2/3 clinical trials demonstrated the safety and efficacy of G-CSF in reducing the period of severe neutropenia by about one week, which reduces the risks of infections and aids in earlier discharge from the hospital.[166]

Hepatic Veno-Occlusive Disease/Sinusoidal Obstruction Syndrome

The term VOD was used originally to describe a clinical syndrome of hepatomegaly, ascites, and jaundice, which was thought to be related to ingestion of certain toxic chemicals that led to fibrosis and occlusion of small hepatic venules. Description of its histologic findings can actually be traced back to reports from the 1920s describing it as "Senecio disease," related to ingestion of plants known as *Senecio ilicifolius* and *Senecio burchellii* that grew as weeds in wheat fields.[167] It has also been associated with pyrrolizidine alkaloids–induced liver toxicity.[168,169] At least in the context of HCT, when it was subsequently recognized that sinusoidal endothelial cells were the primary site of the toxic injury, the name was changed to SOS to adequately reflect its underlying pathophysiology.[170] Yet, both VOD and SOS continue to be used interchangeably, and will be referred to as VOD/SOS in this chapter.

Hepatic VOD/SOS is one of the most serious complications that can occur within the first few weeks of HCT, with an expected mortality exceeding 75% to 80%.[171] The reported incidence of VOD ranges from 0 to more than 60%, with a mean incidence of about 14% as reported by an analysis of 135 published studies.[171] The wide range in incidence across studies is likely related to the heterogeneity of the study population, type of transplantation, and conditioning regimen used. Risk factors include the use of MAC (especially high-dose TBI and oral or high-dose busulfan-based regimens), unrelated donor, HLA-mismatched donor, older age at HCT, poor performance status, females using norethisterone, advanced disease, genetic factors (GSTM1 polymorphism, C282Y allele, MTHFR 677CC/1298CC haplotype), prior history of liver disease/hepatitis, iron overload, abdominal or hepatic irradiation, and previous use of gemtuzumab ozogamicin or inotuzumab ozogamicin, to name a few.[172–175] The pathophysiology involves damage to endothelial cells and hepatocytes by high-dose conditioning, which leads to necrosis of hepatocytes in zone 3 of the liver acinus, engorgement of sinusoids with hepatocytes and red blood cells, and perivenular fibrosis, leading to obstruction of blood flow through hepatic capillaries and venules.[172–176]

The diagnosis of VOD is based purely on clinical presentation. Although radiographic findings and histology may help, they are never relied on primarily to make or exclude the diagnosis. Early initiation of treatment is crucial, because progressive disease, especially when associated with multiorgan failure, is almost universally fatal. Two most commonly used diagnostic criteria include the Seattle criteria, which was originally reported by McDonald et al in 1984[175] and subsequently revised in 1993 (the modified Seattle criteria),[173] and the Baltimore Criteria reported by Jones et al in 1987.[174] Most recently, the European Group for Blood and Marrow Transplantation (EBMT) criteria were reported in 2016[172] and include the classic VOD criteria based on the Baltimore Criteria that occurs within 21 days of HCT, and a distinct entity of late-onset VOD that can occur beyond 3 weeks, in which case hyperbilirubinemia is not mandatory for the diagnosis (Table 19–1). To grade the severity of VOD, the EBMT criteria categorize it as mild, moderate, severe, or very severe based on time to onset of VOD, degree and kinetics of hyperbilirubinemia, transaminases, weight gain, and renal function (Table 19–2).[172]

Treatment of VOD involves aggressive supportive care, with management of fluid and sodium balance with cautious use of diuretics, minimizing exposure to hepatotoxic agents, and pain/volume control with narcotics and paracentesis, or hemodialysis in patients with severe renal dysfunction or refractory fluid overload, and the use of defibrotide. Defibrotide is a "complex mixture of oligonucleotides derived from the controlled depolymerisation of porcine intestinal mucosal DNA."[177] The exact mechanism of its action is unclear but broadly involves two processes: (1) protection of endothelial cells and (2) restoration of the thrombotic-fibrinolytic balance as a result of its antithrombotic, profibrinolytic, and antiinflammatory properties.[177] In a multicenter phase 3 trial that included patients with VOD/SOS and advanced multiorgan failure (n = 102), defibrotide was given IV at 25 mg/kg per day in four divided doses (6.25 mg/kg IV every 6 hours), for a minimum of 21 days, and continued until

Table 19–1 Veno-Occlusive Disease (VOD)/Sinusoidal Obstruction Syndrome (SOS)

Seattle Criteria	Modified Seattle Criteria	Baltimore Criteria	EBMT Criteria	
Within **30 days** of HCT	Within **20 days** of HCT	Within **21 days** of HCT	Classical SOS/VOD in the first 21 days after HCT	Late-onset SOS/VOD >**21 days** after HCT
Any two of the following:	Any two of the following:			Classical VOD/SOS beyond day 21, OR
Hyperbilirubinemia (total serum bilirubin >2 mg/dL)	hyperbilirubinemia (total serum bilirubin >2 mg/dL)	hyperbilirubinemia ≥2 mg/dL **PLUS** at least 2 of 3 other findings	Bilirubin ≥2 mg/dL PLUS at least 2 of 3 other findings	Histologically proven SOS/VOD, OR
Hepatomegaly or right upper quadrant pain	Hepatomegaly or right upper quadrant pain	Hepatomegaly	Painful hepatomegaly	at least 2 of 3 other findings Bilirubin ≥2 mg/dL (or 34 µmol/L) Painful hepatomegaly Weight gain >5% Ascites
		Ascites	Ascites	
Sudden weight gain (>2% of baseline body weight)	Sudden weight gain (>2% of baseline body weight)	≥5% weight gain	>5% weight gain	AND Hemodynamic and/or ultrasound evidence of SOS/VOD

Table 19–2 EBMT Criteria for Severity Grading of Suspected SOS/VOD in Adults

	Mild[a]	Moderate[a]	Severe	Very Severe Multiorgan Dysfunction[b]
Time since first clinical symptoms of SOS/VOD[c]	>7 days	5–7 days	≤4 days	Any time
Bilirubin (mg/dL)	≥2 and <3	≥3 and <5	≥5 and <8	≥8
Bilirubin (µmol/L)	≥34 and <51	≥51 and <85	≥85 and <136	≥136
Bilirubin kinetics			Doubling within 48 hours	
Transaminases	≤2× normal	>2 and ≤5× normal	>5 and ≤8× normal	>8× normal
Weight increase	<5%	≥5% and <10%	≥5 % and <10%	≥10%
Renal function	<1.2× baseline at transplant	≥1.2 and <1.5× baseline at transplant	≥1.5 and <2× baseline at transplant	≥2× baseline at transplant or other signs of MOD/MOF

Patients belong to the category that fulfills two or more criteria. If patients fulfill two or more criteria in two different categories, they must be classified in the most severe category. Patient's weight increase ≥5% and <10% is considered by default as a criterion for severe SOS/VOD; however, if patients do not fulfill other criteria for severe SOS/VOD, weight increase ≥5 % and <10% is therefore considered a criterion for moderate SOS/VOD.
[a]In the case of the presence of two or more risk factors for SOS/VOD, patients should be in the upper grade.
[b]Patients with multiorgan dysfunction must be classified as very severe.
[c]Time from the date when the first signs/symptoms of SOS/VOD began to appear (retrospectively determined) and the date when the symptoms fulfilled SOS/VOD diagnostic criteria.

resolution of VOD/SOS or until patient discharge.[178] Treatment with defibrotide resulted in a significantly higher complete remission (CR) rate at day 100 (25% vs 12.5%; $P = .016$) and improved OS at day 100 (38% vs 25%; $P = .01$) than in historical controls, respectively. The incidence of adverse effects including DAH (12% and 16%) and GI bleeding (8% and 9%) were similar.[178] Despite similar rates of hemorrhagic complications, the EBMT guidelines suggest that patients treated with defibrotide should receive platelet transfusions to keep platelets above 30×10^9/L. Defibrotide has a short half-life (<2 hours), so it can

be held for about 2 hours before and after any invasive procedure that may be required.

Among several agents attempted for prophylaxis against VOD/SOS, including unfractionated heparin or low-molecular-weight heparin,[179] anti-thrombin III,[180] prostaglandin E1,[181,182] and pentoxifylline,[183,184] ursodeoxycholic acid (UDCA)[185] appears to be the most promising, with a very favorable toxicity profile. In a systematic review of four randomized clinical trials and two historically controlled studies, compared with no prophylaxis, UDCA was associated with significant reduction of VOD/SOS (relative risk [RR], 0.34; 95% CI, 0.17–0.66) and significant reduction in the risk of transplant-related mortality (RR, 0.58; 95% CI, 0.35–0.95), with no effect on aGVHD, relapse, or OS.[185] In a randomized trial comparing UDCA (n = 123) versus controls (n = 119),[186] UDCA was started at 12 mg/kg per day from a day before conditioning and continued until day +90 post-HCT. Use of UDCA was associated with significantly reduced risk of grade III–IV aGVHD; liver, GI, and severe skin GVHD, lower NRM (19% vs 34%), and improved survival (71% vs 55%) at 1 year.[186,187]

Similar to VOD/SOS, it has been hypothesized that many other complications in the early post-HCT period may have an endothelial origin as well. These complications include capillary leak syndrome, engraftment syndrome, transplant-associated microangiopathy (TMA), DAH, and idiopathic pneumonia syndrome.[188] Pathophysiology and management of these are reviewed elsewhere.[189]

ACUTE GRAFT-VERSUS-HOST DISEASE

Diagnosis and Classification

Although GVHD was traditionally classified as acute (aGVHD) or chronic (cGVHD) based on the timing of onset (before or after 100 days), the distinction is predominantly based on clinical presentation. The organs involved by aGVHD, in frequency of involvement, are skin (maculopapular rash), upper GI tract (anorexia, nausea, vomiting), lower GI tract (diarrhea, abdominal pain, bleeding), and liver (elevations of *total* serum bilirubin). Two most commonly used systems for staging and grading of aGVHD are (1) the modified Glucksberg GVHD staging system based on the 1994 Consensus Conference on Acute GVHD Grading held in Keystone,[190] and (2) the Mount Sinai Acute GVHD International Consortium (MAGIC) staging system reported by Harris et al in 2016 (Table 19–3).[191]

The differential diagnosis of skin rash post-HCT is broad and includes conditioning regimen-related rash, adverse drug-reaction, viral exanthema, cutaneous eruption of lymphocyte recovery, or GVHD. Therefore, skin biopsy is often performed to help with the diagnosis. Similar to clinical staging and grading, histopathologic findings are also graded based on the degree of injury noted by the pathologist. One histologic grading system reported by Lerner et al in 1974 ("Lerner grading system") includes changes of basal cell layer vacuolization often surrounded by lymphocytes, commonly called as satellitosis (grade I); grade II includes grade I changes plus focal spongiosis, single necrotic keratinocyte/dyskeratotic epidermal cell; grade III includes additional changes of formation of dermal-epidermal junction cleft; and grade IV is the complete loss of epidermis.[192] The utility of histologic confirmation for GVHD in confirming the diagnosis is controversial because many findings can also be seen in entities other than GVHD.[193–196] One study noted that 25% of GVHD and non-GVHD samples showed no basal vacuolization at all. Similarly, necrotic keratinocytes were noted in both GVHD and non-GVHD cases, although the GVHD cases trended to exhibit more necrotic keratinocytes. Further, more than half (55%) of the GVHD cases and about three-quarters (72%) of non-GVHD biopsies showed no or fewer than three necrotic keratinocytes per 4-mm biopsy.[195] Nevertheless, biopsies can be helpful in excluding other possibilities, especially infections, and confirming the diagnosis in the context of strong clinical suspicion.

In the GI tract, epithelial cell apoptosis (>1 per piece) in the crypts is the most important and the minimal pathologic criteria for histologic diagnosis of GVHD, as recommended by the GVHD consensus National Institutes of Health (NIH) Pathology Working Group—categorizing the findings as negative, possible, or likely GVHD.[197] Apart from this, there is no universally accepted grading system for histologic classification, and many are modified from what was originally described by Lerner et al in 1974.[192,198] One of these modified criteria and the one used at MDACC describes grade 1 histologic changes as the presence of increased apoptotic epithelial cells without crypt loss; grade 2: isolated crypt loss or micro-abscess; grade 3: 2 or more contiguous crypt loss; and grade 4: extensive crypt loss with mucosal denudation.[199] It is important to realize that histologic grade does not correlate well with clinical grade or prognosis, and even "mild" grade 1 histologic changes (which are the most common findings in a majority of biopsy specimens) are associated with significantly higher risk of NRM (HR = 2.7, $P = .02$) than those with negative findings.[199]

The histologic hallmark of acute liver GVHD is bile duct injury with evidence of nuclear enlargement and pleomorphism, cytoplasmic vacuolization, loss of nuclear polarity, and varying degrees of centrilobular cholestasis.

Table 19–3 Acute GVHD Staging & Grading[a]

Stage	Skin (Active Erythema Only)	Liver (Bilirubin)	Upper Gastrointestinal Tract	Lower Gastrointestinal Tract (Stool Output/Day)
0	No active (erythematous) GVHD rash	<2 mg/dL	No or intermittent nausea, vomiting, or anorexia	Adult: <500 mL/day or <3 episodes/day Child: <10 mL/kg/day or <4 episodes/day
1	Maculopapular rash <25% BSA	2–3 mg/dL	Persistent nausea, vomiting, or anorexia	Adult: 500–999 mL/day or 3–4 episodes/day Child: 10–19.9 mL/kg/day or 4–6 episodes/day
2	Maculopapular rash 25–50% BSA	3.1–6 mg/dL	—	Adult: 1000–1500 mL/day or 5–7 episodes/day Child: 20–30 mL/kg/day or 7–10 episodes/day
3	Maculopapular rash >50% BSA	6.1–15 mg/dL	—	Adult: >1500 mL/day or >7 episodes/day Child: >30 mL/kg/day or >10 episodes/day
4	Generalized erythroderma (>50% BSA) plus bullous formation and desquamation >5% BSA	>15 mg/dL	—	Severe abdominal pain with or without ileus, or grossly bloody stool (regardless of stool volume).

Overall clinical grade (based on most severe target organ involvement):
- **Grade 0:** No stage 1–4 of any organ;
- **Grade I:** Stage 1–2 skin without liver, upper GI, or lower GI involvement;
- **Grade II:** Stage 3 rash and/or stage 1 liver and/or stage 1 upper GI and/or stage 1 lower GI;
- **Grade III:** Stage 2–3 liver and/or stage 2–3 lower GI, with stage 0–3 skin and/or stage 0–1 upper GI; and
- **Grade IV:** Stage 4 skin, liver, or lower GI involvement, with stage 0–1 upper GI.

[a]As per the Mount Sinai Acute GVHD International Consortium (MAGIC), reported by Harris et al.[191]
BSA, body surface area.

Other features such as portal or central vein endotheliitis, centrilobular necrosis, hepatocellular ballooning, and feathery degeneration are less common and may be noticed in advanced cases.[200] There is no universally accepted histologic grading system and we do not ascribe a histologic grade to patients with liver GVHD.

Because this is the most common error made by trainees and non-HCT physicians, it is worth emphasizing yet again that aGVHD staging and grading is based on the clinical presentation, not by histology, as noted in Table 19–3.

Treatment

Limited-stage isolated skin aGVHD (overall grade I, with <50% body surface area involvement) can be treated with topical or systemic corticosteroids or observation alone.[201] Although patients with disease managed by observation have a significantly lower risk of bacterial infections (12% vs 25%; $P = .04$) and less severe fungal infections, they also carry a significantly higher risk of progression to grade II–IV aGVHD than those treated with systemic corticosteroids 1 mg/kg per day (50% vs 33%, $P = .0005$).[201]

Any other aGVHD (grade II–IV) requires systemic treatment. Corticosteroids 2 mg/kg per day is the standard of care, which leads to responses in 40% to 60% of patients.[202,203] A randomized phase 3 trial compared the safety and efficacy of using prednisone 1 mg/kg per day versus 2 mg/kg per day among patients with grades II or higher GVHD.[204] The study found no significant differences in the risk of progression to grade III–IV aGVHD, cGVHD, NRM, relapse, or OS between the arms. However, a significantly higher proportion of patients treated with lower-dose prednisone required secondary systemic immunosuppressive therapy than in the standard-dose arm (41% vs 7%; $P = .001$). Furthermore, the use of lower-dose prednisone was not associated with any meaningful advantage, as suggested by similar risk of invasive infections, hyperglycemia, hypertension, degree of myopathy, and quality-of-life between the arms.[204] The addition of other immunosuppressants to corticosteroids, including MMF,[205,206] pentostatin,[206] denileukin diftitox,[206]

etanercept,[206] daclizumab,[207] anti–IL-2 receptor monoclonal antibody,[208] infliximab,[209] or ATG[210] have not shown additional benefits in multiple randomized trials.

Most recently, sirolimus was tested as a steroid-sparing strategy for patients with standard-risk GVHD (mostly skin ± upper GI GVHD).[211] In the BMT-CTN 1501 clinical trial, patients with standard-risk GVHD (per the Minnesota score[212] plus Ann Arbor biomarker score 1–2[213]) were randomly assigned to receive either sirolimus or prednisone (or prednisone dose equivalent) 2 mg/kg per day. The sirolimus level was kept therapeutic (10–14 ng/mL until aGVHD resolution, and then 5–10 ng/mL after resolution until at least day 56) with concurrent CNI (tacrolimus, 3–7 ng/mL or cyclosporine, 120–200 ng/mL). Overall response rates (ORRs) were comparable for sirolimus and corticosteroids at day 28 (65% vs 73%, respectively), with no differences in the risk of steroid-refractory aGVHD, cGVHD, serious infections, NRM, relapse, or OS. However, there was a higher proportion of nonresponders in the sirolimus arm by day 56 (with an ORR of 64% vs 79%, respectively), and the risk of TMA within 6 months was also significantly higher in the sirolimus than in the steroid arm (10% vs 1.5%, respectively).

Steroid-refractory aGVHD responds poorly to second-line therapies and is associated with increased mortality.[202] Multiple therapies have been tried with varying success, including extracorporeal phototherapy, MMF, methotrexate, basiliximab, daclizumab, inolimomab, denileukin diftitox, alemtuzumab, horse ATG, etanercept, infliximab, sirolimus, or pentostatin, to name a few (reviewed by Martin et al[202]). Other agents being tested include brentuximab vedotin,[214] α-1 antitrypsin,[215] mesenchymal stem cells,[216–218] and vedoluzumab[219] (specifically for lower GI tract GVHD). Among these, ruxolitinib became the first and only drug so far to have received FDA approval (May 2019) for steroid-resistant aGVHD based on the results of an open-label, single-arm, multicenter REACH1 clinical trial (n = 71).[220] The day 28 ORR in this study was 55% (complete response rate of 27%) and the median time to response was 7 (range, 6–49) days.[221]

CHRONIC GRAFT-VERSUS-HOST DISEASE

The pathophysiology of cGVHD is incompletely understood and involves complex interactions between the innate, humoral, and cell-mediated immunity, leading to fibrosis and other syndromes that resemble autoimmune or other immune-mediated disorders. A review by Zeiser and Blazer[222] highlights the key role of B-cell signaling, naïve T-cell differentiation into type 17 helper T (Th17) cells, and type 17 cytotoxic T (Tc17) cells, follicular helper T (Tfh) cells, and follicular regulatory T (Tfr) cells, and fibrosis-promoting factors in the pathophysiology of cGVHD.

Chronic GVHD typically presents insidiously, with a median time to onset of about 4 to 6 months, although about 5% to 10% of cases can present beyond the first year of transplantation. The diagnosis and staging of cGVHD is based on the 2014 NIH Chronic GVHD Diagnosis and Staging Consensus criteria.[223] As elaborated in Table 19–4, the signs and symptoms of cGVHD are consider either "diagnostic" (that establish the presence of cGVHD without need for further testing) or "distinctive" (not sufficient in isolation to establish an unequivocal diagnosis of cGVHD; these are not commonly seen in aGVHD). In certain cases, additional testing such as a biopsy is needed to make a diagnosis.

The common sites of involvement include skin/fascia (~75%–80%), mouth (50%–85%), eyes (20%–33%), liver (10%–50%), GI tract (20%–45%), lung (bronchiolitis obliterans, 5%–20%), muscles/joints, and genitalia.[224–227] At MDACC, patients benefit from comprehensive cGVHD care provided through a multidisciplinary team that includes a dermatologist, oral health specialist, physical therapist, and occupational therapist, who all generally evaluate patients jointly with a HCT physician. In addition, dedicated ophthalmologists and pulmonologists skilled in the diagnosis and management of ocular and lung cGVHD, respectively, are available on site.

It is crucial to recognize that the treatment of cGVHD that requires systemic immunosuppression generally lasts for at least one year, with the median duration of therapy being about 2 to 3 years, and about 15% of patients require treatment for more than 5 to 7 years.[226,228] Treatment generally includes corticosteroids (prednisone 0.5–1 mg/kg/day), which are tapered slowly at a rate that varies considerably from practice to practice. One approach is to taper the dose by approximately 25% every 2 weeks to reach an average dose of about 0.25 mg/kg per day (or 0.4–0.5 mg/kg every other day) within 3 months after starting treatment, followed by much smaller dose reductions toward the end of the taper, until the adrenal replacement dose is reached (roughly 0.10 mg/kg/day).[226] Despite lack of any randomized trial showing benefit, additional therapy is generally added to the corticosteroids with hopes to minimize toxicities from prolonged corticosteroid use.[229] Multiple agents have been tried as adjuncts to corticosteroids, including CNI, sirolimus, extracorporeal phototherapy, ultraviolet light therapy, ruxolitinib, ibrutinib, rituximab, imatinib, pentostatin, MMF, low-dose IL-2, bortezomib, thalidomide, pomalidomide, hydroxychloroquine, infliximab, and etanercept, to name a few.[224,226] Of these, ibrutinib is the first and only drug that received FDA approval (August 2017) for treatment of SR-cGVHD based on a single-arm study

Table 19–4 Signs and Symptoms of Chronic GVHD[a]

Organ or Site	Diagnostic (Sufficient to Establish the Diagnosis of Chronic GVHD)	Distinctive[b] (Seen in Chronic GVHD, But Insufficient Alone to Establish a Diagnosis)	Other Features or Unclassified Entities[c]	Common[d] (Seen with Both Acute and Chronic GVHD)
Skin	Poikiloderma Lichen planus–like features Sclerotic features Morphea-like features Lichen sclerosus–like features	Depigmentation Papulosquamous lesions	Sweat impairment Ichthyosis Keratosis pilaris Hypopigmentation Hyperpigmentation	Erythema Maculopapular rash Pruritus
Nails		Dystrophy Longitudinal ridging, splitting, or brittle features Onycholysis Pterygium unguis Nail loss (usually symmetric, affects most nails)		
Scalp and body hair		New onset of scarring or nonscarring scalp alopecia (after recovery from chemoradiotherapy) Loss of body hair Scaling	Thinning scalp hair, typically patchy, coarse, or dull (not explained by endocrine or other causes) Premature grey hair

The 2014 Diagnosis and Staging Working Group report, *Biol Blood Marrow Transplant* 2015 Mar;21(3):389-401.e1.

(n = 44) in that population.[225] The trial showed an ORR of 67% (21% complete and 65% partial responses), which was sustained for at least 20 weeks in a majority or patients. However, about one-third of patients had grade 3 or higher infections, about one-third required dose reductions because of toxicities, and about one-third discontinued treatment because of toxicities, most commonly fatigue or pneumonia.[225]

In addition to systemic treatment, skilled ancillary and supportive care are the keys to the management of cGVHD to target specific organs involved, such as oral mucosa (topical steroids, sialogogues), genital (topical steroids and dilators), ocular (artificial lubricant tears, punctal plugs, scleral lenses, or prosthetic replacement of the ocular surface ecosystem [PROSE] lenses), lungs (inhaled corticosteroids, pulmonary rehabilitation), and fascia/joint (physical/occupational therapy, stretching, casting, weight-bearing exercises, compression stockings for peripheral edema).[226]

RELAPSE

Role of Maintenance Therapy Post-Transplantation for Relapse Prevention

Multiple studies suggest a potential benefit of post-HCT maintenance in specific situations, such as in patients with FMS-like tyrosine kinase 3 (FLT3)/internal tandem duplication (ITD; FLT3/ITD), mutated AML, and Philadelphia chromosome–positive (Ph+ve) ALL/CML. The pivotal randomized, double-blind, placebo-controlled phase 2 multicenter (SORMAIN) trial[230] assessed the efficacy of sorafenib maintenance post-HCT but was terminated early because of slow accrual. Nevertheless, it did provide an indication of improved survival in patients who received maintenance. After a median follow-up of almost 42 months post-randomization, 2-year DFS was 53% versus 85% in the placebo versus sorafenib groups, respectively (HR 0.39, 95% CI, 0.18–0.85; P = .0135). Besides sorafenib,[230,231] many other oral FLT3/ITD inhibitors are being evaluated, including quizartinib,[232,233] midostaurin (RADIUS trial),[234] crenolanib,[235] and gilteritinib.[236,237] In patients with Ph+ acute or chronic leukemias, several tyrosine kinase inhibitors (TKIs), including imatinib[238–240] or newer-generation TKIs (dasatinib or ponatinib),[241] have been demonstrated to be safe for post-HCT maintenance.

Besides these targeted agents, there is no established role of maintenance post-HCT, although this has been an area of investigation in multiple trials, most commonly using DNA hypomethylating agents, eg, azacitidine or decitabine for AML/MDS.[242–244] The largest of these was a phase 3 randomized trial conducted at MDACC,[245] which assessed the efficacy of azacytidine (n = 93) versus observation (n = 94) in patients with AML/MDS. Azacytidine dose was 32 mg/m^2 per day given subcutaneously for 5 days, every 28 days for 12 cycles, with the first cycle started between days +42–100. About 93% of patients in the azacytidine arm started the maintenance at a median of about 2 months post-HCT, but about 75% could not complete the planned 12 cycles. The median number of cycles received was four; the most common reason for discontinuation was the relapse/death in about one-half of the patients (47%) followed by toxicity in about one-quarter (26%). The trial was stopped early because of slow accrual and showed no difference in DFS between the arms.[245] Many other clinical trials are underway at MDACC to assess the safety and efficacy of novel higher-potency hypomethylating agents (such as guadecitabine), novel combinations (such as azacytidine plus BCL-2 inhibitor venetoclax) for patients with high-risk myeloid malignancies, and bispecific monoclonal antibodies (such as blinatumomab[246]) for patients with ALL.

Treatment of Relapsed Disease

Although a small minority of "relapsed" disease post-HCT can be donor derived, a majority of relapses are the result of residual host malignant cells that survive the conditioning regimen and escape the GVT effect. This may be caused by loss or reduced expression of tumor-related antigens, loss of mismatched HLA haplotype leading to the development of mutant leukemic cells,[247,248] or development of tolerance in the donor-derived T-cells.[249] The management of relapsed disease post-HCT is complicated and depends on several factors, including time from HCT to relapse, several disease-related factors (impending relapse as assessed by the loss of donor myeloid chimerism, detection of new minimal/measurable residual disease, overt/proliferative relapse), and patient characteristics (performance status, comorbidities, presence or absence of GVHD, etc). Broadly, the options include withdrawal of immunosuppression (with close monitoring because of a high risk of GVHD), immunotherapy (DLI, chimeric antigen receptor cells, use of checkpoint inhibitors or other immunomodulatory drugs), chemotherapy, or subsequent HCT. The prognosis of relapsed leukemia post-HCT is dismal. A study by the CIBMTR in patients with relapsed AML showed that the median time to relapse after HCT was 7 months.[250] Of these, 29% of patients attained CR with subsequent treatment (chemotherapy, DLI, or second HCT), resulting in 1-year OS of 23%. Time to relapse after first HCT was the single most important predictor of survival. Three-year OS was 4% for patients whose disease relapsed within the first 6 months of first HCT, 12% for those whose disease relapsed between 6 and 12 months, 26% for those with disease relapse between 2

and 3 years, and 38% for those whose disease relapsed 3 or more years after first HCT.[250]

LATE COMPLICATIONS

Among long-term survivors of HCT, many patients experience delayed toxicities,[251] which could be a sequela of the conditioning regimen, GVHD, and/or its treatment. These include endocrine abnormalities such as hypothyroidism, hypogonadism, or growth hormone deficiency in younger patients, pulmonary toxicities such as restrictive or obstructive lung disease, cardiac toxicities such as hypertension, dyslipidemia, late infectious complications, impaired bone health (osteopenia, osteoporosis, or avascular necrosis) and secondary malignancies, to name a few.[252–255] The intensive treatment and prolonged recovery from allogeneic transplantation can also have profound psychosocial as well as financial implications for patients and their families. At MDACC, patients are routinely followed by a dedicated survivorship program to screen for and to address these late effects of HCT.

CONCLUSIONS

Allogeneic HCT remains an important therapeutic technique for the management of various malignant and nonmalignant disorders. Over the past decade, better disease risk stratification, identification of high-risk comorbidities, and advances in transplantation techniques, conditioning therapy, GVHD prophylaxis, and supportive care have advanced the field of transplantation immensely. With a wider use of alternative donors, no patient should now be denied transplantation for lack of a donor. Further, with an increasing use of RIC and innovative MAC regimens, older patients and those with high comorbidities can now be transplanted safely. Yet, relapse of the underlying disease, GVHD, and infections remain the Achilles heels that contribute to a vast majority of transplantation failure. Although tremendous strides have been made since that first human BMT performed in the late 1950s to now, we are yet to completely decipher the "Holy Grail" of transplantation—which is to maximize the GVT effect while minimizing the GVHD.

MD ANDERSON PRACTICE TIPS

- Whenever possible, allogeneic HCTs are performed in the context of clinical trials that are assessing novel conditioning regimens and GVHD prophylaxis strategies. Patients who are ineligible for clinical trials because of insurance issues or other reasons are discussed in HCT team meetings to formulate the standard of care plan.
- Most standard of care myeloablative conditioning regimens include busulfan and fludarabine (mostly using the fractionated approach), whereas fludarabine and melphalan are commonly used for reduced-intensity conditioning. Post-transplantation cyclophosphamide is being used more commonly in almost all types of HCT for GVHD prophylaxis, except CBT.
- Older and/or frail patients benefit from referral to the MDACC HCT "Enhanced Recovery program," which entails comprehensive assessment by a multidisciplinary team of HCT physicians, advanced care providers, nutritionists, physical and occupational therapists, pharmacists, rehabilitation physicians, and geriatricians to address frailty issues before HCT, with an aim to improve post-HCT outcomes.
- Allogeneic HCT patients are also assessed in a "survivorship clinic" around 3 months post-HCT for screening and counseling about long-term complications of HCT.
- Patients with GVHD benefit from care at dedicated GVHD multidisciplinary clinics that includes HCT physicians, dermatologists, oral health specialists, physical and occupational therapists, pulmonologists, and ophthalmologists.
- Patients are encouraged to participate in current clinical trials that are evaluating the use of strategies to reduce the relapse risk post-HCT.

20 Alternative Donor Transplants: Cord Blood Transplant

KEY CONCEPTS

- Cord blood is a valuable alternative donor source for stem cell transplant, offering a number of advantages: ease of collection, availability for urgent need, less stringent human leukocyte antigen (HLA)-matching requirement, and lower risk of graft-versus-host disease.
- Data are evolving about the difference in outcomes of stem cell transplant using different graft sources, but more recent data suggest that there is no survival advantage of a matched unrelated graft over cord blood.
- To overcome the limitation of low cell doses in single cord blood units, double cord blood transplant has been adopted for many patients.
- High-intensity myeloablative regimens are used in young and fit patients, whereas reduced-intensity regimens are used in older or unfit patients.
- Infections are the leading cause of early nonrelapse mortality after cord blood transplant, and graft-versus-host disease is the leading cause of late mortality.
- Novel strategies to improve cord blood transplant outcomes include improving cell collection, homing and engraftment, ex vivo expansion, and in vivo enhancement.

BACKGROUND

The number of allogeneic stem cell transplants (SCTs) performed in the United States has steadily increased, from more than 8000 per year in 2013 to 8839 in 2017 and an estimated 9028 transplants in 2018.[1] Donor identification has always been a challenge, and only 25% to 30% of patients who need allogeneic SCT have a matched-sibling donor available.[2] The National Marrow Donor Program (NMDP) and its cooperative international registries have more than 19 million volunteer donors, but the majority of them are White; other ethnicities are underrepresented in these large registries, which poses a significant challenge in finding donors for them.[3] Mismatched related (often haploidentical), cord blood (CB), or mismatched unrelated donors (MMUD) with either peripheral blood (PB) or bone marrow (BM) graft sources are potential options for patients in need of SCT but who lack a matched related (MRD) or unrelated donor (MUD).

Cord blood is a valuable alternative donor source for allogeneic SCT, offering many logistic advantages; CB units are easy to collect with little or no risk to the mother or newborn. CB units can be obtained rapidly for 80% to 95% of the patients 20 years or older across all races, and in almost 100% of younger patients.[4] This is particularly advantageous in cases where urgent transplant is needed. Owing to the rapid procurement of CB units, patients can receive CB transplantation (CBT) in 2 to 4 weeks from the initiation of search compared with 3 to 6 months for unrelated donor sources.[5] Further, CBT is associated with a low risk of infection transmission, requires less stringent human leukocyte antigen (HLA) matching criteria, and has a relatively lower risk of graft-versus-host disease (GVHD) with preserved graft-versus-malignancy effects.[6,7] However, it has been historically associated with a greater risk of graft rejection, delayed engraftment, and delayed immune reconstitution, leading to a heightened risk of infection or nonrelapse mortality (NRM).[8–11] Many

of the adverse outcomes noted after CBT are attributed to the naïvety of CB T lymphocytes, and the low numbers of total nucleated cells (TNCs) and CD34+ cells in the graft.

It is important to note, however, that the evolution of transplantation techniques and the optimization of practices of unrelated donor transplants including CBT in the past 2 decades have led to the improvement of outcomes and survival of CBT, as was shown in a recent large study from the European Society for Blood and Marrow Transplantation registry that included 106,188 patients between 2001 and 2015, among them more 3000 CBT recipients, demonstrating an improvement in the 3-year overall survival (OS) from 36% between the years 2006 and 2010 to 44% between the years 2010 and 2015, which owes primarily to a decrease in the incidence of relapse.[12] Comparison of outcomes between CBT, MUD, and MMUD was undertaken by a large, retrospective single-institution study in patients with acute leukemia or myelodysplastic syndrome (MDS) who received a first myeloablative SCT and showed that among patients with pretransplantation minimal residual disease, the probability of OS after receipt of a CBT was at least as favorable as that after receipt of a transplant from a MUD and was significantly higher than that after MMUD. Furthermore, the probability of relapse was lower in the CBT group than in either of the other groups.[13]

A recent prospective study also investigated the outcomes of MUD (91 transplants) and CBT (119 transplants) in adults with acute leukemia and MDS and demonstrated in multivariate analysis that the graft source was not a significant risk factor for OS, cumulative incidences of NRM and relapse, and disease-free survival (DFS). In adjusted analyses, MUD and CBT were shown to lead to similar OS, NRM, and relapse, again proving the importance of CB as an alternative source of transplant.[14] Moreover, the kinetics of immune reconstitution post-CBT might actually yield better outcomes after CBT. In a retrospective analysis of immune reconstitution kinetics after SCT from BM, PB, or CB, mature B cells and differentiated natural killer (NK) cells significantly increased after CBT.[15] A multivariate analysis showed that a higher CD16+ CD57– NK cell count correlates with a lower incidence of relapse, whereas higher CD20+ B-cell and CD8+ CD11b– T-cell counts are associated with lower NRM. This suggests that the collective contribution of graft source–specific and event-related immune reconstitution might yield better outcomes after CBT.[15] Similar results were observed in another recent study of immune recovery in 106 adults undergoing CBT, demonstrating a robust thymus-independent CD4+ T-cell recovery, which in turn is associated with reduced risk of mortality (**Table 20–1**).[16]

CELL DOSE, UNIT QUALITY, AND HLA MATCHING

The outcomes of CBT depend on the impact of cell dose and the degree of HLA match.[17] The TNC dose is a well-established parameter associated with successful engraftment and survival after CBT. However, the adequate TNC dose of a CB unit remains controversial. The randomized phase 3 trial BMT CTN 0501 defined a sufficient cryopreserved TNC dose in a single unit as $>2.5 \times 10^7$/kg.[18] On the other hand, in a large registry study of more than 1500 myeloablative single-unit CBTs, a TNC $<3.0 \times 10^7$/kg was found to be associated with an increased transplant-related mortality (TRM).[19] Moreover, an analysis of more than 1000 recipients of CBT from a single bank, the National Cord Blood Program of the New York Blood Center, suggested that a higher TNC dose is required to offset the effect of increasing HLA mismatch.[17] It is important to note that the CD34+ cell dose is a critical factor to be considered in unit selection along with the TNC dose. Purtill et al demonstrated the essential role that the dominant unit–infused viable CD34+ cell dose plays in determining the speed and success of neutrophil engraftment after double CBT (dCBT).[20] A dominant unit–infused viable CD34+ cell dose $<0.5 \times 10^5$/kg was associated with marked impairment of neutrophil engraftment.[20]
