Moreover, the post-thaw CD34+ viability, which defines the unit quality, is another important consideration.[6] A number of studies have shown the importance of post-thaw colony-forming unit dose for successful engraftment.[21,22] CB units with a low proportion of post thaw–viable CD34+ cells have been associated with very poor engraftment potential.[23]

The HLA-matching criteria between the CB units and the recipient have traditionally been less stringent compared with other donor sources. Therefore, although unrelated adult donors are selected to be closely matched to recipients at HLA-A, -B, -C, and -DRB1 by high-resolution testing,[24,25] CB units are selected using lower-resolution HLA typing (antigen-level) for HLA-A and -B and at the allele level for HLA-DRB1.[26] In a study of single CBT, Barker et al showed that recipients of 6/6 matched CB units had the lowest TRM regardless of the dose, followed by 5/6 matched CB units with TNC dose $>2.5 \times 10^7$/kg or 4/6 matched units with TNC dose $>5.0 \times 10^7$/kg, and 5/6 matched units with lower TNC dose ($<2.5 \times 10^7$/kg).[17,27] These findings support the notion that both TNC dose and HLA-matching level should be taken into account for CB unit selection.

Although the standard HLA-matching criteria do not require high-resolution typing at class I antigen in CBT, a study by the Center for International Blood and

Marrow Transplantation Research (CIBMTR) and the Eurocord reported better outcomes in single CBT after myeloablative conditioning (MAC) with improved allele-level matching for 4 HLA loci (-A, -B, -C, and -DRB1).[19] The investigators showed that the frequency of neutrophil recovery was lower for recipients of mismatches at 3–5 but not at 1–2 alleles compared with those of HLA-matched units. NRM was higher with units mismatched at 1–5 alleles compared with matched units. This retrospective study confirmed the clinical importance of selecting better HLA allele–matched units for single CBT, an observation already well described for BM and PB progenitor cell transplantation. Data from our institution have also demonstrated increased TRM with increasing HLA mismatch.[28] In contrast, other studies from the University of Minnesota,[29] Memorial Sloan Kettering Cancer Center,[30] and others[18,31] reported that a high degree of HLA mismatch did not adversely affect transplant outcomes. Further studies to establish the relative contribution of the TNC dose, the CD34+ dose, and the HLA match to the success of engraftment and survival post-CBT are warranted.

SINGLE VERSUS DOUBLE CBT

The relatively low number of progenitor cells in a single CB unit resulting in delayed hematopoietic recovery and engraftment failure limited the use of CBT in adults. Most adults do not have access to a single CB unit containing the recommended nucleated cell dose of 2.5×10^7 TNCs/kg.[32] To overcome the cell-dose limitation, investigators pioneered an approach where two partially HLA-matched CB units are used to augment the progenitor cell dose in circumstances in which a single unit was considered inadequate, and confirmed its feasibility.[32] A CIBMTR analysis investigated the relative risks and benefits of transplanting double CB units compared with an adequately dosed single CB unit. The investigators observed no differences in clinical outcomes after dCBT or adequately dosed single CBT. Both transplant approaches led to comparable outcomes with 78% (95% CI, 72–83) versus 81% (95% CI, 74–88; $P = .83$) probabilities of neutrophil engraftment by day 42, and 68% (95% CI, 62–74) versus 63% (95% CI, 53–72; $P = .34$) probabilities of platelet recovery at 6 months, respectively. There were no differences in grade III–IV acute GVHD ([18% (95% CI, 11%–26%) versus 14% (95% CI, 10–19%); $P = .64$]), 2-year probabilities of chronic GVHD (31% [95% CI, 26–37] versus 24% [95% CI, 15–34]; $P = .27$), TRM (hazard ratio [HR], 0.91; $P = .63$), risk of relapse (HR, 0.90; $P = .64$), and overall mortality (HR, 0.93; $P = .62$).[33] This and other studies[34] demonstrated the role of dCBT in extending the application of CBT to adults with inadequate single units. In addition, some other studies have suggested that dCBT may be associated with a reduced risk of relapse,[35–38] with one analysis proving that dCBT is more cost effective than single CBT.[39]

A unique feature after dCBT is evidence of mixed chimerism from both CB units observed during the initial post-transplant period.[40] In the early post-dCBT period (day +21), both CB units contribute to hematopoiesis in 40% to 50% of patients, but by day +100, one unit predominates in a vast majority.[41,42] Although the nonengrafting unit does not contribute to hematopoiesis, it may have a facilitatory effect on engraftment. In fact, an analysis of 129 dCBT recipients has shown that in patients receiving a low-dose dominant unit (defined as an infused viable CD34+ cell dose $<1.2 \times 10^5$/kg), a higher TNC dose in the nondominant unit is associated with improved neutrophil recovery.[43] The factors leading to unit dominance are not well-defined. It is however recognized that there is no association with the TNC or CD34+ cell doses, HLA match, gender match, ABO typing, or the order in which CB units are infused.[32,41,42,44,45] Moreover, there are no sufficient data to support interunit HLA matching when selecting double-unit grafts.[46] This current lack of evidence is a major limitation to dCBT, and identifying predictive factors for unit dominance would optimize CB-unit selection algorithms by allowing for the selection of two CB units with a high probability of long-term engraftment.

CONDITIONING REGIMENS

Myeloablative Conditioning Regimens

High-intensity MAC regimens are reserved for young and otherwise fit patients who can tolerate the associated regimen morbidity. Such regimens are associated with a low risk of relapse at the expense of a high TRM compared with reduced-intensity conditioning (RIC) regimens. One of the largest registry studies comparing single-unit CB (n = 165) with PB (n = 888) or BM (n = 472) transplants in adults with acute leukemia using MAC regimens from 2002 through 2006 showed promising outcomes with CBT. Total body irradiation (TBI) constituted part of the preparative regimen in about half of patients in the CB group and about two-thirds in the comparative groups. Despite a significantly higher number of patients with fully HLA-matched PB or BM grafts (70%) compared with CB grafts (6%), the rates of DFS and relapse were similar among the groups, whereas the risks of acute or chronic GVHD were significantly lower with CBT.

Also, TRM was similar with CBT compared with mismatched PB or BM grafts, but higher in contrast to fully matched PB (HR, 1.62 [95% CI, 1.18–2.23]; P = .0030) or BM transplants (HR, 1.69 [95% CI, 1.19–2.39]; P = .003). This was offset by a significantly lower incidence of chronic GVHD compared with fully matched PB (HR, 0.38 [95% CI, 0.27–0.53]; P = .001) or BM transplants (HR, 0.63 [95% CI, 0.44–0.90]; P = .01].[8] Therefore, in the absence of matched PB or BM donors, CBT potentially offers better outcomes compared with mismatched alternative donor transplants.

Similar encouraging results were noted in a study that compared 4–6/6 matched dCBT exclusively (using the MAC regimen including fludarabine 75 mg/m^2, cyclophosphamide 120 mg/kg, and TBI 1200–1320 cGy Flu/Cy/TBI) to 8/8 MRD or MUD, or 1 allele–MMUD donors.[11] This study also noted lower risk of relapse, higher NRM, lower GVHD, and comparable DFS after CBT compared with other groups. The risk of relapse was significantly lower after dCBT (15%, 95% CI, 9–22%) compared with MRD (43%, 95% CI, 35%–52%) or MUD (37%, 95% CI, 29%–46%) transplants. Higher NRM was noted after dCBT (34%, 95% CI, 25%–42%) compared with MRD (24%, 95% CI, 17%–39%) or MUD (14%, 95% CI, 9%–20%) transplants, which resulted in comparable 5-year DFS between CB (51%, 95% CI, 41%–59%), MRD (33%, 95% CI, 26%–41%), and MUD (48%, 95% CI, 40%–56%) transplants. The cumulative incidence of grade II–IV GVHD at day 100 after dCBT, MRD, and MUD was 60% (95% CI, 50%–70%), 65% (95% CI, 57%–73%), and 80% (95% CI, 70%–90%). The rate of chronic GVHD at 2 years was 26% (95% CI, 15%–35%), 47% (95% CI, 39%–55%), and 43% (95% CI, 34%–52%), respectively.[11]

In adults with high-risk acute lymphoblastic leukemia (ALL), CBT leads to similar OS, TRM, and relapse risk, with significantly lower risk of acute or chronic GVHD, compared with PB or BM transplants. This was demonstrated in a registry study that compared outcomes after single or double 4–6/6 matched CB (n = 116) and 7–8/8 matched PB (n = 546) or BM (n = 140) transplants after MAC regimens.[47] More than half of the patients in the CBT group received Flu/Cy/TBI as the conditioning regimen, and about 75% of the patients in the PB or BM groups received TBI/Cy-based regimens. There were no differences in the 3-year OS rates (44%, 44%, and 43%), relapse risk (22%, 25%, and 28%), or TRM (42%, 31%, and 39%) among the groups. However, the risk of acute grade II–IV GVHD (27%, 47%, and 41%) or grade III–IV acute GVHD (9%, 16%, 24%) was appreciably lower after CBT compared with 8/8-matched and 7/8-matched PB or BM transplants, respectively.[47]

The major concern with MAC regimens remains their associated toxicity, which was shown in more recent studies. A prospective multicenter study of high-dose myeloablative dCBT in adults with high-risk acute leukemia and MDS between 2007 and 2011 demonstrated 89% neutrophil engraftment at day 100, grade II–IV acute GVHD incidence at day 180 of 64%, and a 3-year incidence of chronic GVHD of 36%. At 3 years post-transplant, the TRM was 39% (95% CI, 26%–52%), and the 3-year relapse incidence was 11% (95% CI, 4%–21%). With a median follow-up of 37 months, the 3-year DFS was 50% (95% CI, 37%–63%). This study again shows the importance of CBT as an alternative therapy for high-risk acute leukemia/MDS in patients lacking a MUD with a low incidence of relapse. Yet the TRM risk remains high and strategies to ameliorate toxicities are warranted.[48]

Reduced-Intensity Conditioning Regimens

The advent of RIC regimens extended the utility of CBT to older patients and those with comorbid conditions that otherwise restrict the use of the MAC regimens. A majority of trials of MRD or MUD transplants used an arbitrary age definition of older than 55 to 60 years (to define "older patients") as a threshold of using a RIC regimen. However, age more than 40 to 45 years is generally chosen as a threshold for RIC in the CBT setting.

Barker et al reported that the RIC with fludarabine 200 mg/m^2, cyclophosphamide 50 mg/kg, and 2 Gy TBI (Flu/Cy/2 Gy TBI) was well tolerated, with rapid neutrophil recovery, a sustained donor engraftment rate of 94%, and a low incidence of TRM.[49] This regimen is associated with significantly better DFS compared with other RIC regimens (51% vs 28%, HR, 0.53; P = .0002).[50] Multiple studies supporting the use of RIC CBT in patients who would not be able to tolerate more intensive preparative regimens have subsequently been reported.[10,41,42,51–53]

A retrospective single-center study compared the outcomes in patients older than 55 years who underwent CB and MRD SCT with RIC (primarily of Flu/Cy/2 Gy TBI). There were no differences in TRM at 180 days (28%, 95% CI, 14%–41% vs 23%, 95% CI, 11%–36%), 3-year DFS (34%, 95% CI, 19%–48% vs 30%, 95% CI, 16%–44%), or 3-year OS (34%, 95% CI, 17%–50% vs 43%, 95% CI, 29%–58%) between the groups.[10] These findings were confirmed by a registry analysis of patients with acute leukemia comparing the outcomes after CB (n = 161), 8/8-matched (n = 313), and 7/8-matched PB (n = 111) transplant with

RIC regimens. Patients who underwent CBT after the Flu/Cy/2 Gy TBI regimen had comparable results with 8/8 HLA-matched PB donors. However, higher TRM and lower OS and DFS were observed in recipients of CBT if they were treated with alternative RIC regimens including busulfan plus melphalan, or cyclophosphamide with fludarabine and in vivo T-cell depletion with antithymocyte globulin (ATG).[53] Similar findings were reported by Eurocord and the EMBT in patients with lymphoid malignancies. When patients with CB units (n = 104) were compared with 8/8-matched PB MUD (n = 541) transplants, no difference was noted in NRM (29% vs 28%), PFS (41% vs 36%), or OS (56% vs 49%) at 3 years. Further, the risk of chronic GVHD was significantly lower in the CBT group (26% vs 52% at 3 years; $P = .0005$).[52]

More recently, intensification of the standard RIC regimen was investigated in a retrospective analysis of adult recipients of first dCBT comparing standard RIC regimen with an intensified regimen of fludarabine 150 mg/m^2, cyclophosphamide 50 mg/kg, thiotepa 10 mg/kg, and 400 cGy TBI (intensified RIC). The cumulative incidence of relapse was significantly lower with intensified RIC compared with standard RIC ($P = .0013$). TRM was comparable between the two groups ($P = .99$), whereas OS was significantly better after intensified RIC compared with standard RIC ($P = .03$); median OS was 17 months after standard RIC but was not reached after intensified RIC. Grade II–IV acute GVHD was significantly higher in the intensified RIC cohort compared with the standard RIC cohort ($P = .007$), whereas the incidence of grade III–IV acute GVHD, any chronic GVHD, and moderate-to-severe chronic GVHD was comparable between the two cohorts ($P = .20$, $P = .21$, and $P = .61$, respectively).[54] These studies support the use of CBT with RIC as a suitable alternative for patients who may benefit from RIC SCT and who do not have a suitable related or unrelated volunteer donor in the period in which transplantation is needed, with the possibility of intensifying the RIC regimen when appropriate in higher-risk patients (Table 20–2).

POST-TRANSPLANT COMPLICATIONS

Disease relapse is the most common cause of mortality after allogeneic SCT, whereas GVHD and infections are the two leading causes of NRM. Treatment options post-SCT relapse include withdrawal of immunosuppression, chemotherapy, or donor lymphocyte infusion (DLI). Although DLI is currently unavailable for CBT patients outside clinical trials, a study showed that in adults who have AML relapse after CB or MRD transplants, DLI in the latter group did not affect OS (19% CB vs 28% MRD at 1 year; $P = .36$), and patients with disease relapse had a poor prognosis independent of the donor source.[55]

In the CBT setting, infections are the leading cause of early 100-day NRM (27%), whereas GVHD contributes to most (20%) of the delayed NRM (beyond 100 days).[8] The reported probabilities of acute grade III–IV GVHD at day 100 (10%–40%), and chronic GVHD (25%–35%), TRM (20%–50%), risk of relapse (10%–50%), DFS (15%–60%), and OS (20%–70%) at 2 to 5 years vary, depending on conditioning regimens, study population, HLA matching, and other factors.[11–14,33,42,47,48,50,53,54] The rates of post-transplant complications are comparable after the use of dCBT and single CBT.[56]

Early infections (within 100 days) are primarily caused by neutropenia and mucosal damage caused by conditioning regimens. Delayed infections are related to the speed of cell-mediated immune reconstitution and use of immunosuppressants. Most early infections are bacterial; more than half of the invasive fungal infections and 45% of cytomegalovirus (CMV) occur beyond day +100.[57]

The heightened risk of infections in CBT is partly explained by the naïvety of CB T-cells, and delayed T-lymphocyte immune reconstitution and neutrophil engraftment in contrast to other donor sources.[8,11,53,58,59] Although significant B-cell recovery starts within 3 to 4 months and may approach normal numbers by 6 months after transplant, T-cell reconstitution is substantially prolonged.[59] The CD4+ and CD8+ T-cell counts are strikingly reduced after CBT, remain low for up to 6 months, and approach normal values by one year. The PB T-cells after CBT are more dysfunctional as compared with other types of allogeneic SCTs. Patients also do not recover thymic function after CBT in contrast to other allogeneic SCT recipients.[60]

A retrospective registry analysis from the CIBMTR comparing CB (n = 150) with matched (n = 367) or antigen-mismatched (n = 83) BM transplants reported higher risk of early (within 100 days) infection-related deaths after CBT compared with other groups (45%, 21%, and 24%, respectively; $P = .01$).[56] In another study, the risk of severe infection, especially bacterial infections in the first 100 days, was significantly higher after CBT in contrast to BM or PB graft (85% vs 69%; $P < .01$). The risk of infection-related mortality did not differ at day 100 or at 3 years. In a multivariate analysis of a CMV-seropositive recipient who received CBT, prolonged neutropenia beyond day 30 and low cell dose ($<2 \times 10^7$/kg) were the predictors for infection-related mortality.[57]

MD ANDERSON APPROACH TO CBT

At MDACC, patients with various hematologic malignancies who do not have a MRD or MUD but require SCT are considered for CBT, and a search for a CB unit is initiated (Fig. 20–1).

Unit Selection

Within the first days to weeks of the initial donor search, coordinators determine the likelihood of obtaining a suitably matched donor based on the patient's ancestry, the preliminary search results, and review of the HLA typing. If the likelihood of finding a matched donor is deemed to be low, we proceed with confirmatory HLA typing of CB units. Alternatively, we may delay typing of CB units if multiple 10/10 HLA-A, -B, -C, -DRB1, or -DQ allele–MUD are probable, or if the transplantation is not urgent. If an unrelated donor collection is delayed because of problems with donor health or availability, a prompt decision is made about whether to abandon the unrelated donor search in favor of CB.

To maximize the chance of identifying optimal CB unit(s), we conduct a global search while being aware that there is no global regulatory oversight of CB banking standards. It is important to know which banks are included in the NMDP consortium of banks, in the Netcord, and in the NMDP Cooperative Registries. We give equal consideration to domestic and international units as the primary units of the graft, whereas we prefer domestic units for backup.

Our current institutional policy is to use a double-unit graft in an effort to augment engraftment and reduce TRM. Given that either unit may engraft after a dCBT, each unit of a double-unit graft is equally important. We give a strong priority to HLA match over a pre-cryopreservation TNC threshold of ~2.0 × 10^7/kg for each unit of a double-unit graft. This approach gives strong priority to HLA match but augments the

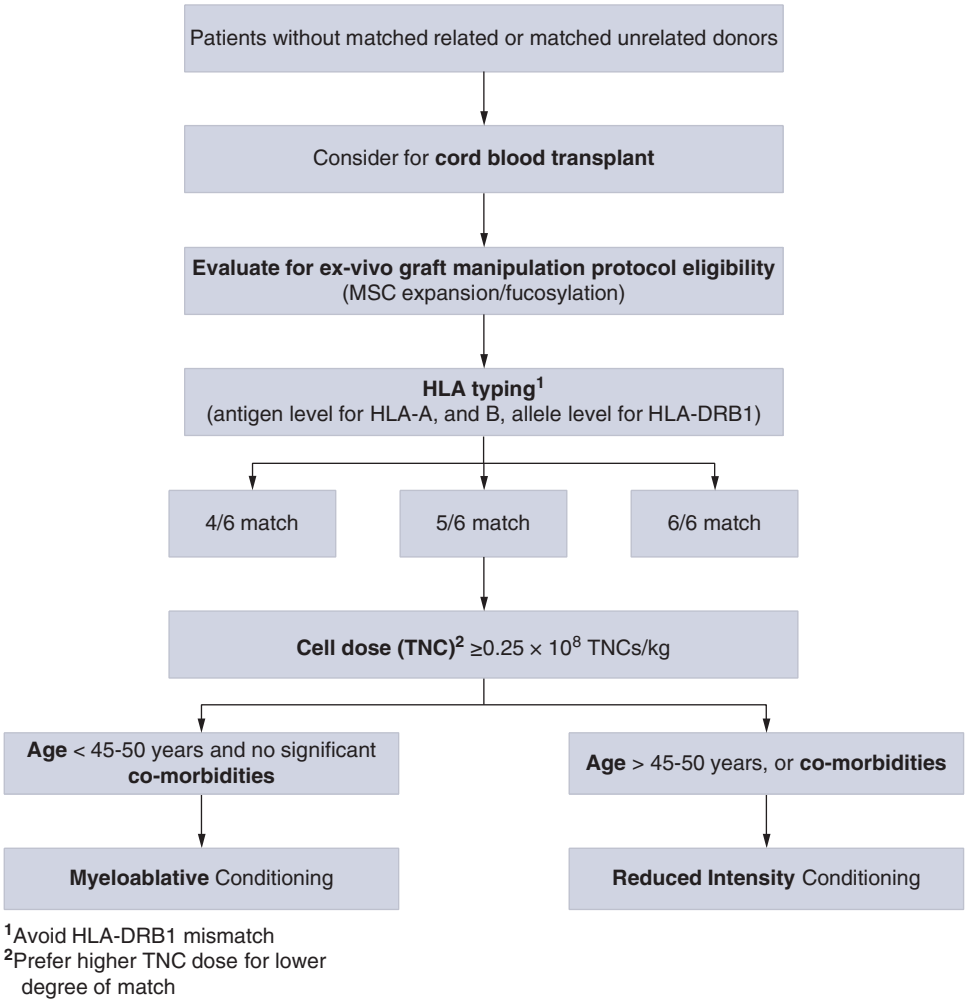

FIGURE 20–1 Approach to a patient for cord blood transplant.

chance of engraftment by infusing two units with at least an adequate dose in each.

We use novel ex vivo graft manipulation techniques pioneered at MDACC, such as ex vivo CB expansion with mesenchymal stromal cells (MSCs)[61] and ex vivo CB fucosylation.[62] With these techniques, remarkable improvement in engraftment is noted compared with historical controls. The median time to neutrophil engraftment is 15 days (range, 9–42) with MSC expansion[61] and 14 days (range, 12–28) with fucosylation, which is significantly faster than the 24 days (range, 12–52) noted in the CIBMTR controls, ($P \leq .001$).[62] Similarly, platelet engraftment is 42 days (range, 15–62) with MSC expansion and 33 days (range, 18–100) with fucosylation, compared with 49 days (range, 18–264) in the CIBMTR controls ($P = .03$).[61,62] We are investigating the impact of CB-unit killer cell immunotype receptor (KIR) genotype on transplant outcomes with an aim to integrate KIR information into a CB-unit selection algorithm.

Conditioning Regimens

We have investigated various MAC regimens for CBT, which include combinations of (1) melphalan, fludarabine, and thiotepa; (2) busulfan and fludarabine; (3) busulfan, clofarabine, fludarabine, and low-dose TBI given 9 days after chemotherapy; and (4) busulfan, clofarabine, fludarabine, and low-dose TBI given immediately after the chemotherapy.[63] The most favorable outcomes appear to be associated with the latest regimen, which is well tolerated and associated with prompt engraftment and effective disease control. This regimen consists of fludarabine 10 mg/m^2 per day (days –7 through –4), clofarabine 30 mg/m^2 per day (days –7 through –4), busulfan at a dose calculated to deliver a daily area under the curve of 4000 µmol/min for 4 days (days –7 through –4) based on an outpatient test dose of 32 mg/m^2, and 2 Gy TBI on day –3. Our preferred RIC regimen consists of fludarabine 40 mg/m^2 per day (days –5 through –2) and melphalan 140 mg/m^2 (day –2) in addition to the Flu/Cy/2 Gy TBI for patients older than 50 years and/or those who are not medically fit to tolerate the MAC regimen.

Prophylaxis

Prophylaxis against GVHD is provided with mycophenolate mofetil (MMF) and tacrolimus. We start MMF from day –3 at a dose of 15 mg/kg (maximum of 1 g orally twice daily) and continue it through day +100. Tacrolimus is started from day –2 and taper is started at day 180 in the absence of GVHD. We use rabbit ATG, 3 mg/kg infused over 2 days on days –4 and –3 in all patients. Patients taking azole antifungals require appropriate dose adjustments for adding tacrolimus. Other drug interactions and creatinine clearance need to be considered while calculating the dosage.

Filgrastrim is administered from day 0 until neutrophil engraftment and blood products are transfused as indicated. Standard infectious disease prophylaxis with antibacterial (levofloxacin), antiviral (valacyclovir), and antifungal (voriconazole, posaconazole, or caspofungin—the choice depending on risk factors) and against *Pneumocystis jiroveci* pneumonia (PCP) are also provided for all CBT patients. The surveillance for cytomegalovirus using quantitative polymerase chain reaction (or antigenemia assay if absolute neutrophil count is >1 × 10^9/L) is performed routinely, twice weekly for the first 100 days after CBT or longer if any complications are present. We routinely perform Epstein-Barr virus testing using quantitative polymerase chain reaction every 2 weeks from day +30 until day +100. Testing for other viruses including adenovirus, BK virus, respiratory syncytial virus, influenza, human herpesvirus 6, and parainfluenza is done as clinically indicated.

NOVEL STRATEGIES TO IMPROVE CBT OUTCOMES

Improving Cell Collection

Despite the availability of automated methods to increase the recovery of hematopoietic progenitor cells from banked CB units,[64] optimization of the number of cells collected remains a necessity. The BM environment where hematopoietic stem cells expand is very hypoxic, with oxygen levels as low as 1%–5%, and hypoxia is involved in stem cell regulation pathways.[65] The immediate exposure of collected CB cells to the high oxygen content of the ambient air grossly alters the numbers and function of stem and progenitor cells, a phenomenon referred to as "extra physiologic oxygen shock/stress (EPHOSS)."[66,67] Strategies to mitigate the oxygen shock have been investigated, such as the immediate collection and procession of the CB cells in the presence of cyclosporine A, which was shown to lead to an increase in the yield of hematopoietic stem cells.[66,67] However, this strategy necessitates more optimization and standardization. More recent in vivo studies showed that combinations of antioxidants and/or of epigenetic enzyme inhibitors allow for enhanced collection of mouse BM hematopoietic stem cells in ambient air,[68] although these procedures remain to be validated for human CB-unit collections. Research in this field is ongoing and aims to enhance the procedures used to collect CB for the best stem cell yield.

Improving Homing and Engraftment

To enhance the engraftment of hematopoietic stem cells after their administration, researchers have attempted to improve their capability to home to the BM. Different

methods have been tested, such as fucosylation of the CB progenitor cells[62,69,70]; the use of prostaglandin E2 derivatives[71] or dipeptidyl peptidase-4 (DPP4) inhibitors[72]; short-term treatment of cells with hyperthermia[73]; short-pulse glucocorticoid hormone stimulation[74]; inhibition of the negative epigenetic regulation by histone deacetylase 5 (HDAC5)[75]; the pharmacologic activation of nitric oxide signaling[76]; or a combination of strategies.[77] Many of these techniques have demonstrated significantly improved time to neutrophil engraftment (13–17 days) comparable with other donor types.

Ex Vivo Expansion

To increase CB cell dose, a variety of ex vivo expansion techniques have been developed, which yield significantly higher final numbers of TNC. These include coculturing the CB cells with cytokine support and or MSCs to simulate the BM "hematopoietic niche" ex vivo[61] or using nicotinamide analogs,[78–80] copper chelators (such as tetraethylenepentamine),[81,82] and targeting the *Notch* signaling pathway,[83] all of which block the differentiation of early progenitor cells leading to expansion of hematopoietic stem cells.

Other approaches include the use of small molecules such as StemRegenin 1 (SR1) in combination with cytokines, which was investigated in a phase 1/2 study, leading to a 330-fold increase in CD34+ cells and engraftment in all 17 patients who underwent dCBT at a median of 15 days for neutrophils and 49 days for platelets, significantly faster than in patients treated with unmanipulated CB.[84] A more recent study investigated the use of UM171, a hematopoietic stem cell self-renewal agonist,[85] in a phase 1/2 study of 27 patients undergoing single CBT, which showed promising results. UM171 led to the successful expansion of 26 (96%) of 27 CB units. Among the 22 patients who received single UM171-expanded CBT, the median time to engraftment was 18 days, median time to platelet recovery was 42 days, and no graft failure occurred. At one year, the incidence of TRM was 5% and the incidence of relapse was 21%. Overall survival, progression-free survival, GVHD-free and relapse-free survival, and chronic GVHD-free relapse-free survival at 12 months were 90%, 74%, 64%, and 74%, respectively.[86]

Other small molecules such as antagonists of peroxisome proliferation-activated receptor (PPAR)-gamma,[87] structural analogs of SB20358 (p38-map kinase inhibitor),[88] and OAC1 that activates the pluripotent transcription factor Oct4[89] have been used to enhance cytokine-mediated ex vivo expansion of CB hematopoietic stem cells. DEK is a secreted nuclear protein that was demonstrated to enhance the ex vivo expansion of hematopoietic stem and progenitor cells when used as a purified recombinant protein and hence was shown to act as a hematopoietic cytokine with potential clinical applicability.[90] N6-methyladenosine (m6A) is the most abundant epigenetic modification on eukaryocytic messenger RNAs, has been implicated in the regulation of a wide range of biological processes, and is recognized by its reader YTH domain family members. A recent work showed that the knockdown of YTHDF2 results in increased numbers of hematopoietic stem cells from CD34+ CB cells and could be a promising strategy for clinical application in the ex vivo expansion of CB.[91,92]

Apart from augmenting the cell dose, ex vivo graft manipulation techniques are being increasingly explored, which has permitted the generation and clinical use of antiviral and antitumor adoptive immunotherapies, as well as cellular therapies for GVHD prevention.[93,94] A variety of "designer" CB lymphocytes can now be engineered and expanded ex vivo—for instance, T-cells with specific cytotoxicity against tumors and or viruses,[95–98] chimeric antigen receptor (CAR) T-cells,[99] NK cells,[100] CAR-NK cells,[101] and regulatory T-cells,[102] which are being tested in clinical trials.

In Vivo Enhancement

The means to enhance the efficacy of CBT by accelerating the renewal and differentiation of already transplanted CB cells have also been investigated. Such methods include the administration of growth factors and the use of DPP4 inhibitors such as sitagliptin before and after the engraftment process has started.[72,103,104] Other groups have investigated the use of hyperbaric oxygen for the recipient to enhance engraftment.[105,106]

Research to enhance the yield of collected CB, its ex vivo expansion, and engraftment is very active and continues to evolve to eventually help elucidate the optimal means for ex vivo CB expansion. However, guidelines such as those published by an international group of clinical investigators associated with the Cord Blood Association have now been published to standardize CB banking and procedures and provide guidance on means to enhance the efficiency of CBT (**Table 20–3**, **Fig. 20–2**).[107]

CONCLUSION

CB transplantation is an attractive option for patients who lack a matched PB or BM donor. We and other researchers and investigators continue to work on improving our understanding of the biology and regulation of the CB progenitor and stem cells. The outcomes of alternative donor transplantation with CBT

have significantly improved over the past decade, leading to survival and relapse rates comparable with those with other donor sources while offering the advantage of being logistically more practical and faster. To overcome the limitation of low cell doses in single CB units, dCBT has been adopted for many patients, and promising strategies to improve engraftment with ex vivo expansion or homing and to enhance immune reconstitution with the infusion of CB-derived NK cells and cytotoxic T lymphocytes with antiviral and antileukemic specificities have been investigated. The unmet need as of this writing remains instituting more prospective multicenter clinical trials to determine the efficacy of these promising technologies.

MD ANDERSON PRACTICE TIPS

- Within the first days to weeks after donor search is initiated, the likelihood of finding a matched donor is determined. If this likelihood is deemed to be low, we proceed with confirmatory HLA typing of CB units.
- Our current institutional policy is to use a double-unit graft in an effort to augment engraftment and reduce TRM. We give a strong priority to HLA match over a pre-cryopreservation TNC threshold of ~2.0 × 10^7/kg for each unit of a double-unit graft.
- We use novel ex vivo graft manipulation techniques pioneered at MDACC, such as ex vivo CB expansion with MSCs and ex vivo CB fucosylation.
- Our preferred MAC regimen consists of fludarabine 10 mg/m^2 per day (days –7 through –4), clofarabine 30 mg/m^2 per day (days –7 through –4), busulfan at a dose calculated to deliver a daily area under the curve of 4000 µmol/min for 4 days (days –7 through –4) based on an outpatient test dose of 32 mg/m^2, and 2 Gy TBI on day –3.
- Our preferred RIC regimen consists of fludarabine 40 mg/m^2/day (days –5 through –2) and melphalan 140 mg/m^2 (day –2) in addition to the Flu/Cy/2 Gy TBI for patients older than 50 years and/or those not medically fit to tolerate the MAC regimen.
- Prophylaxis against GVHD is provided with MMF and tacrolimus. We use rabbit ATG 3 mg/kg infused over 2 days on days –4 and –3 in all patients.
- Filgrastrim is administered from day 0 until neutrophil engraftment and blood products are transfused as indicated.
- Standard infectious disease prophylaxis with antibacterial (levofloxacin), antiviral (valacyclovir), and antifungal (voriconazole, posaconazole, or caspofungin—the choice depending on risk factors) and against PCP are also provided for all CBT patients.

Alternative Donor Transplants: Haploidentical Hematopoietic Stem Cell Transplantation

Samer A. Srour
Richard E. Champlin
Stefan O. Ciurea

KEY CONCEPTS

- Allogeneic stem cell transplantation (allo-SCT) remains the only curative intervention for a variety of high-risk hematologic malignancies. Haploidentical grafts from a first-degree related mismatched donor extends the applicability of this lifesaving treatment to a large proportion of patients who otherwise do not have a suitable human leukocyte antigen–matched donor.
- Breakthrough advances achieved over past decade in controlling the bidirectional alloreactivity and in graft engineering have led to a decreased incidence of complications, including graft-versus-host disease and nonrelapse mortality (NRM), without compromising the graft-versus-tumor effect.
- The use of haploidentical transplantation continues to increase with growing evidence for its effectiveness in several myeloid and lymphoid neoplasms. Haploidentical use has taken precedence compared with some other alternative donor sources given its immediate availability and cost-effectiveness.
- Fully matched related donors remain the preferred graft source for allo-SCT. However, several transplant registry studies in United States and Europe have confirmed comparable survival outcomes between matched unrelated and haploidentical transplants.
- The results of the large phase 3 randomized Bone and Marrow Transplant Clinical Trials Network multicenter clinical trials were reported recently confirming superiority of haploidentical transplant over double cord transplant in terms of improved overall survival and decreased NRM.
- Several factors are considered when choosing the best haploidentical donor. The donor-specific antibodies remain one of the most important factors to consider because the presence of antibodies is associated with a high risk of graft failure. Younger donors, male donors, fathers rather than mothers, and first-degree to second-degree donors are preferred graft sources for recipients of haploidentical transplants.

Haploidentical stem cell transplantation (HaploSCT) from a first-degree related mismatched haplotype donor (siblings, children, parents) extends the application of this lifesaving treatment to a large proportion of patients with high-risk hematologic malignancies who otherwise do not have a suitable human leukocyte antigen (HLA)–matched donor.[1] As the average family size continues to shrink, the likelihood of finding an HLA-matched related sibling donors continues to decrease.[2] Moreover, with aging of the United States population, finding a young healthy sibling donor becomes increasingly less likely. The use of matched unrelated donors (MUDs) is limited by a longer time to transplantation (median, 3–4 months), which makes it difficult to treat patients with more advanced disease in rapid need for a transplant. The ethnicity or race of the recipient can have great impact as well in identifying a suitable MUD because approximately 30%, 70%, and 90% of the white, Hispanic, and African American population do not have a MUD in the worldwide registries.[3] In contrast to unrelated donor grafts, haploidentical (or "half-matched") donors can be immediately available, and there are no costs associated with an unrelated donor search, graft acquisition, maintaining a registry, or coordinating logistics with distant donor centers. This is an especially valuable option for

nonwhite and mixed-race individuals who frequently have no available matched donors to proceed with transplantation.[3] This approach might also be particularly useful in developing countries that may not have the resources to procure unrelated donor transplants or maintain complex unrelated donor registries. Moreover, haploidentical donors offer the advantage of ad hoc availability to quickly collect donor cells for cellular therapy interventions after transplant. Over the recent decade, significant breakthrough advances in controlling alloreactivity have been made, and important steps have been taken toward graft engineering and posttransplant cellular therapy, approaches that may further change landscape of HaploSCT in the future. Improved haploidentical transplant outcomes represent a major advancement in transplantation, which has practically eliminated the limitation of donor availability for allogeneic stem cell transplantation (allo-SCT).

COMPLETE T-CELL DEPLETION: CONTROL OF GRAFT-VERSUS-HOST DISEASE BUT WITH A HIGH TREATMENT-RELATED MORTALITY RATE

Historically, the use of unmanipulated T-cell-replete HaploSCT grafts with conventional graft-versus-host disease (GVHD) prophylaxis in the late 1970s was associated with intense bidirectional alloreactivity and unacceptably high morbidity and mortality rates because of hyperacute GVHD and graft rejection.[4–6] This led in the 1980s to the development of complete ex vivo depletion of T-cells using CD34+-selected grafts. Complete T-cell depletion has been associated with much lower incidence of acute GVHD (aGVHD). However, this came at the expense of markedly delayed immune recovery after transplant and was associated with high nonrelapse mortality (NRM) from infections, higher disease relapse rates, given the decreased graft-versus-leukemia effect, and high rates of graft rejection.[7–9] Although graft rejection was partially overcome with "mega" doses of CD34+ cells (typically >10^7 CD34+ cells/kg) and a myeloablative conditioning regimen (including total body irradiation, cyclophosphamide, thiotepa), severe T-cell depletion of the graft delayed immune recovery led to an unacceptably high incidence of infectious complications and increased NRM in excess of 40%.[10] We have used this approach with our conditioning regimen (fludarabine, melphalan, and thiotepa) and showed that most patients died of NRM related to infectious complications.[11] Improved outcomes with selected α-β T-cell depletion has been subsequently adopted mostly in children with better results.[12] During the past decade, several advances have enabled investigators to selectively deplete alloreactive T-cells and successfully control GVHD rates while maintaining memory T-cells in the graft to accelerate immune recovery and prevent significant infectious complications post transplant. Table 21–1 summarizes the major contemporaneous approaches to HaploSCT. These advances have significantly improved the treatment outcomes of patients receiving haploidentical donor transplants, which are now comparable to matched transplants. In the following sections, we aim to summarize the recent developments with this type of transplant focusing on advances made at MD Anderson Cancer Center (MDACC).

TABLE 21–1 Current Approaches to Haploidentical Stem Cell Transplantation

Approach	Rationale	Stage of Clinical Development
High-dose posttransplantation cyclophosphamide	Eliminating the only the alloreactive T-cells. Rapid immune recovery with low infectious complications Acceptable rates of GVHD Lower cost	Phase II/III
Selective αβ T-cell depletion	Removing αβ T-cells that are most responsive for aGVHD Remaining γδ T-cells are thought to have an innate immune-like response capability without inducing GVHD	Phase I/II
Photodepletion	Ex vivo depletion of alloreactive T-cells with TH9402 that accumulates in activated T-cells	Phase I/II
Selective CD45RA+ T-cell depletion	Elimination of CD45RA+ naïve T-cells thought to play a major role in GVHD Preserves memory T-cells that are active against infections	Phase I

aGVHD, acute graft-versus-host disease; GVHD, graft-versus-host disease.

BALANCING GRAFT-VERSUS-HOST DISEASE, IMMUNE RECOVERY, AND THE CONCEPT OF SELECTIVE ALLODEPLETION: POSTTRANSPLANT CYCLOPHOSPHAMIDE

The introduction of high-dose posttransplant cyclophosphamide (PTCy) for GVHD prevention represented a major turning point for HaploSCT. The concept of inducing immune tolerance with PTCy was introduced by Berenbaum and Brown in 1963, who showed that the life of a skin allograft can be prolonged with the use of PTCy administered 1 to 3 days after the allograft.[13] Moreover, Mayumi et al demonstrated that microchimerism and robust tolerance to minor histocompatibility antigens can be achieved in mice receiving allogeneic splenic cells by intraperitoneal high-dose cyclophosphamide administered on days 2 or 3 posttransplant.[14] This concept found its best applicability in allogeneic transplantation, particularly in haploidentical transplantation, in which PTCy induces bidirectional immune tolerance by selectively eliminating the highly dividing alloreactive donor and recipient T-cells generated early after transplant in the setting of an HLA-mismatched transplant, which has led to decreased rates of GVHD and graft rejection.[15] Interestingly, preclinical and clinical studies have shown that stem cells are resistant to high-dose PTCy (because of high levels of aldehyde dehydrogenase present in these cells) and likewise the memory T-cells are spared, leading to excellent hematopoietic engraftment and a better immune reconstitution with relatively lower rates of infections.[16–18] Our group has demonstrated that this approach was superior to complete T-cell depletion approaches because of a significantly lower NRM and risk of infectious complications after transplant.[19]

We first used PTCy-based GVHD prophylaxis for HaploSCT in 2009 in a phase 2 clinical trial shortly after the first clinical trials in humans showed the safety of this approach.[17] Initial studies used a nonmyeloablative conditioning regimen with fludarabine, cyclophosphamide, and 2-Gy TBI, which was associated with a low incidence of grades 2 to 4 aGVHD and NRM at 1 year (35% and 15%, respectively); however, a remarkably high relapse rate of 51% at 1 year was observed particularly for patients with acute leukemia.[17] We hypothesized that a more intense but tolerable conditioning is needed, particularly for these patients; hence, we used our melphalan-based conditioning platform, previously used in T-cell-depleted HaploSCT,[11,19] which includes fludarabine 160 mg/m^2, melphalan 100 to 140 mg/m^2, and thiotepa 5 to 10 mg/kg (subsequently changed to 2-Gy TBI). Dose of thiotepa was decreased because of higher gastrointestinal toxicity in combination with melphalan, and melphalan dose was subsequently decreased for older patients and patients with lymphoma. Initial results were very promising and proved to be very effective in inducing remission in the great majority of patients with leukemia, including those with advanced disease.[11,19] The results of our phase 2 clinical trial in 60 patients, the majority with myeloid leukemias, showed 2-year progression-free survival (PFS) and overall survival (OS) rates of 53% and 55%, respectively, with 2-year NRM and relapse rates of 23% and 24%, respectively.[20] More recently, outcomes of 25 patients with lymphoma who underwent HaploSCT at our institution were reported with 3-year NRM, PFS, and OS of 31%, 49%, and 52%, respectively.[21] Patients with acute myeloid leukemia (AML) and lymphoma receiving haploidentical transplants had similar outcomes with other donor types, but older patients and those with lymphoma appeared to benefit from a reduced-intensity melphalan-based conditioning with lower doses of melphalan (100 mg/m^2),[21–23] with one exception— patients with Hodgkin lymphoma not in remission at transplant, who had better survival with the more intense regimen (140 mg/m^2).[24]

With HaploSCT outcomes significantly improved, we and others have subsequently compared transplant outcomes of patients treated with a haploidentical versus MUD, mismatched MUD, matched related donors, or cord transplants (Table 21–2).[20,25–27] All these single-institution studies uniformly showed at least comparable outcomes between patients treated with a haploidentical transplant with PTCy and those received HLA-matched donors or cord transplants with conventional GVHD prophylaxis and for mismatched MUD received PTCy-based GVHD prophylaxis.[20,25–27] In addition, the final results of the Bone and Marrow Transplant Clinical Trials Network (BMTCTN) phase 3 randomized trial comparing double cord transplant with HaploSCT were recently reported.[28] A total of 368 patients were enrolled, and with a an approximate median follow-up of 24 months, there were significantly better outcomes for HaploSCT in regards to OS (57% vs 46% for cord transplant; $P = .037$) and NRM (11% vs 18% for cord transplant; $P = .039$), albeit comparable PFS rates (41% for HaploSCT vs 35% for cord transplant; $P = .409$) and with no difference in relapse rates.[28] Several retrospective registry studies have been reported since confirming that haploidentical transplants have similar survival with MUD transplants (see Table 21–2).[29–34] Among the first and largest reports, that of Ciurea et al compared outcomes of patients with AML receiving HaploSCT with MUD transplants using the Center for International Blood and Marrow

[a]Two-year survival is reported.
[b]Haploidentical recipients were matched (1:2) with matched unrelated donor (MUD) control participants.
aGVHD, acute graft-versus-host disease; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; ATG, antithymocyte globulin; DLBCL, diffuse large B-cell lymphoma; GRFS, GVHD-free relapse-free survival; GVHD, graft-versus-host disease, Haplo, haploidentical stem cell transplantation; MAC, myeloablative conditioning; PFS, progression-free survival; RIC, reduced-intensity conditioning; TCD, T-cell depletion; TRM, transplant-related mortality.

Transplant Registry (CIBMTR) database.[29] Results of this retrospective analysis of 2174 patients showed similar 3-year OS between these two donor sources (45% for HaploSCT vs 50% for MUD with myeloablative conditioning; *P*= .38 and 46% vs 44% with reduced-intensity conditioning [RIC] for HaploSCT and MUD, respectively; *P* = .71). The incidence of grade 2 to 4 aGVHD was lower for haploidentical compared with MUD transplants (16% vs 33% for myeloablative and 19% vs 28% for RIC transplants), likely related to the use of PTCy and the predominant receipt of bone marrow graft in the haploidentical group.[29] Table 21–2 summarizes key findings from selected large transplant registry studies comparing HaploSCT versus MUD transplants in myeloid and lymphoid neoplasms. Based on these findings, we have proposed a prospective multicenter observational study comparing the two donor sources (BMTCTN 1702), which will help answer some of the questions not addressed to date in the retrospective studies.

GRAFT ENGINEERING

Several research strategies are being investigated to optimize the haploidentical graft, maximize the immune recovery, and minimize GVHD after transplant. A very promising approach is selective depletion of αβ T-cells that capable of eliciting GVHD while preserving in the graft the memory T-cells and γδ T

TABLE 21–3 Post transplant Cellular Therapies Aimed at Decreasing Disease Relapse in Haploidentical Hematopoietic Stem Cell Transplantation

Approach	Rationale	Pitfalls
Unmodified DLI	To fight disease relapse via harnessing graft-versus-malignancy effect	Limited experience in HaploSCT Potential for GVHD precipitation Not targeted to specific antigen(s)
Engineered donor lymphocytes with a safety suicide switch	To fight disease relapse via harnessing graft-versus-malignancy effect Safety switch allows T-cell suicide in case of GVHD development	Not targeted to specific antigen(s) Clinical efficacy not yet demonstrated
γ-δ DLI	Infusion of selected γ-δ T-cells No GVHD potential	Graft-versus-malignancy effect not yet demonstrated
CAR T-cells	T-cells engineered to recognize specific antigens (eg, CD19) that provide graft-versus-malignancy effect without GVHD	Clinical efficacy after HaploSCT not yet demonstrated
Infusion of ex vivo expanded NK cells	Potential graft-versus-malignancy effect without GVHD	Clinical efficacy demonstrated in a phase II study

CAR, chimeric antigen receptor; DLA, donor lymphocyte infusion; GVHD, graft-versus-host disease; HaploSCT, haploidentical hematopoietic stem cell transplantation; NK, natural killer.

cells.[12] γδ T-cells possess innate and adaptive immune responses, and similar to natural killer (NK) cells, can function without requiring antigen presentation by the HLA system, which makes them unlikely to generate GVHD.[35] Accordingly, methods to deplete αβ T-cells, leaving the γδ subsets intact, are being investigated with encouraging results especially in children.[36] Another approach involves depletion of naïve T-cells (CD45RA+) thought to play a major role in the development of GVHD in mouse models.[37–39] A phase 1 safety study testing safety of this approach in haploidentical donor transplants at MDACC has been completed, and preliminary results demonstrated excellent control of GVHD. Another approach to mitigate risks of complete T-cell depletion is administration of T-regulatory cells along with conventional T-cells to prevent GVHD; in a preliminary report, this approach was shown to reduce the risk of GVHD and leukemia relapse.[40] Future clinical trials will explore these approaches at MDACC because they may control GVHD and facilitate a rapid immune recovery without the need for posttransplant immunosuppression.

POSTTRANSPLANT CELLULAR THERAPY TO PREVENT DISEASE RELAPSE

With significant improvements in NRM, relapse remains the major cause of treatment failure, not only in HaploSCT patients but also in HLA-matched transplants. Several approaches are currently under investigation at our institution to prevent and treat disease relapse after transplant (Table 21–3).

Unmodified Donor Lymphocyte Infusion

The readily available haploidentical donors can be useful sources of lymphocytes for posttransplant donor lymphocyte infusion (DLI), which could be infused to prevent or treat early relapse. Although there is a theoretical higher risk of inducing severe aGVHD with the use of haploidentical DLI, the incidence of GVHD was not shown to be higher than in HLA-matched transplants,[41–43] possibly in part because of the tolerizing effect of PTCy. In one of the earliest reports, 40 patients with various hematologic malignancies received unmodified haploidentical DLI for relapsed disease after HaploSCT with PTCy-based GVHD prophylaxis.[41] Most patients received a dose of 1 ° 10^6/kg CD3+ T-cells. Acute GVHD developed in 25% of patients, and 15% of patients had grade III to IV aGVHD. Interestingly, most of these patients received cytoreductive therapy before the DLI infusion, and one third of patients achieved a complete response with a median duration of response of 12 months. Two more recent studies reported similar outcomes.[42,43] Because DLIs are expected to be more effective in patients with low tumor burden, such as patients with minimal residual disease,[44] preemptive DLI has been explored in the HaploSCT setting with encouraging results.[45,46] Prophylactic DLIs from haploidentical donors are also being explored for patients with high-risk of relapse after transplant.[47] These reports suggest that cellular

therapy with haploidentical DLI and other therapeutic cells can be applied safely after transplant, and future approaches should focus on improving the safety and efficacy of this therapeutic strategy.[48]

Modified Donor Lymphocyte Infusion Using T-Cells with a Safety Switch (Suicide Gene)

Improved control of GVHD posttransplant can be achieved by inserting a suicide gene in the haploidentical donor T-cells. If significant aGVHD develops, a "safety off switch" can be used to "turn off" these T-cells and avoid excessive aGVHD. This approach has so far been investigated to boost posttransplant immune recovery after T-cell-depleted haploidentical grafts. Ciceri et al infused DLI engineered T-cells to express *herpes simplex virus–thymidine kinase suicide gene* that can be triggered by ganciclovir to induce apoptosis.[49] This was used to boost posttransplant immune reconstitution by adding back T-cells after a complete or partial T-cell-depleted HaploSCT. Grade 1 to 4 aGVHD developed in 20% of the patients, and GVHD was successfully controlled by inducing the suicide gene with ganciclovir. However, ganciclovir may not be the ideal drug in this setting because it is commonly used after transplantation to control cytomegalovirus reactivation. Another approach developed by the Baylor group used modified DLIs engineered to express an inducible *caspase-9 transgene*.[50] This gene can be induced by a synthetic dimerizing drug leading to rapid cell death. GVHD, which occurred in four of the five HaploSCT patients after infusing the safety switch-modified T-cells, was rapidly reversed by administering the dimerizing drug.[50] Long-term outcomes were reported for 10 HaploSCT pediatric patients infused with same product, showing persistence of these modified cells for over 2 years and potentially contributing to opportunistic infection control and promoting endogenous T-cell recovery.[51] This approach could be explored in the future using preemptive DLI in patients who have advanced disease before transplant.

Chimeric Antigen Receptor T-Cells

Although DLI offers nonspecific antitumor activity, its effect is nontargeted. Recently, the introduction of chimeric antigen receptor (CAR) T-cells that can recognize a specific antigen on cancer cell surface has demonstrated excellent activity in CD19-expressing lymphoid malignancies. The Food and Drug Administration granted accelerated approval for treatment of relapsed or refractory B-cell acute lymphoblastic leukemia (ALL) and diffuse large B-cell lymphoma (DLBCL). In the initial pilot studies, Maude et al used autologous CARs against CD19 (CTL019) in 30 patients with relapsed refractory ALL and achieved complete remission in 90% of patients.[52] Subsequently, 75 patients were enrolled in a phase 2 clinical trial that confirmed an overall remission rate of 81% at 3 years, with 1-year PFS and OS rates of 50% and 76%, respectively.[53] Likewise, CD19 CAR T-cell therapy showed impressive results in patients with relapsed or refractoryDLBCL.[54,55] Our group has been exploring the use of CAR T-cells in the peritransplant setting to improve outcomes after autologous and allogeneic transplantation.[56,57] Results from the phase 1 clinical trial showed very encouraging outcomes, including in HaploSCT recipients ($n = 8$), with 1-year PFS and OS rates of 75% and 100%, respectively, and with no increased risk of GVHD.[56] These preliminary results suggested that allogeneic CAR T-cells can be safely given peritransplant without significant GVHD to decrease relapse posttransplant. Future studies should explore the use of CAR T-cells after allo-SCT for different diseases.

Natural Killer Cells and Killer Immunoglobulin-like Receptor Mismatch

NK cells are part of the innate immune system and normally are involved in identifying and killing tumor cells or virally infected cells. NK cells recognize and target "foreign" cells that lack one or more HLA class I alleles specific to the inhibitory receptors (killer immunoglobulin-like receptors [KIRs]).[58] NK cells, which target malignantly transformed or virally infected cells, do not contribute to the development of GVHD, making them ideal to use to decrease relapse in the posttransplant setting. Prior studies in T-cell-depleted haploidentical transplants showed a lower incidence of relapse when patients had a KIR-ligand mismatched (KIR-LM) donor.[59] Several studies suggest a lower risk of relapse with donors who possess specific activating *KIR* genes such as *KIR2DS1, KIR2DS2,* or the KIR "B" haplotype.[60–62] Although no definitive role for a KIR-LM donor has been confirmed to date, our group explored the use of high doses of ex vivo expanded and activated NK cells before and after transplant with very encouraging results. In a phase 1 dose-escalation stud,[63] using the mb-IL21 method as developed at MDACC,[64] 13 patients with high-risk myeloid malignancies were infused with mb-IL21–expanded donor NK cells on days -2, +7, and +28 of HaploSCT. The study demonstrated feasibility of infusing high doses of ex vivo expanded NK cells without significant toxicities or increased risk of GVHD and with notable low posttransplant relapse rates and incidence of viral infections.[63] Preliminary results from a subsequent phase 2 study confirmed the findings, and in a matched-pair analysis independently performed with a CIBMTR cohort, NK cell–treated patients showed a significantly lower relapse and improved PFS than patients who did not receive NK

cells.[65] Based on these data, a multicenter phase 2 study was initiated by the BMTCTN (BMTCTN 1803).

DONOR SELECTION FOR HAPLOIDENTICAL STEM CELL TRANSPLANTATION AND RISKS FROM DONOR-SPECIFIC ANTI–HUMAN LEUKOCYTE ANTIGEN ANTIBODIES

Unlike matched related donor transplants, in whom the number of matched donors is usually small, multiple donors are usually available to choose from in the HaploSCT. Several factors are considered when choosing the best donor.[66] One of the first and most important factors is to evaluate is the presence of donor-specific anti-HLA antibodies (DSAs).[67,68] Patients may develop antibodies against foreign HLA antigens, particularly parous women and multiply transfused patients. We have shown for the first time that patients with high levels of complement-fixing anti-HLA antibodies against donor HLA antigens are at high risk of engraftment failure.[68] Routine evaluation of all donors with HLA mismatches has now been incorporated into standard practice worldwide. Criteria to optimize donor selection to improve outcomes have been developed.[62,66,69] Patients with high DSAs should be avoided as donors but if not possible should be treated to decrease risk before transplant.[66] Younger donors, male donors, fathers rather than mothers, and first-degree to second-degree haploidentical donors are preferred for recipients of haploidentical transplants with PTCy.[66,67] In addition, ABO-matched or minor mismatched grafts are preferred to major ABO-mismatched grafts.[66] There is controversy whether patients should be selected based on NK cell alloreactivity; more studies are needed to clarify this aspect.[68]

CONCLUSIONS AND FUTURE DIRECTIONS

The field of HaploSCT has significantly grown over the past decade with the introduction of PTCy and novel methods of partial T-cell depletion. These newer techniques effectively control strong alloreactive reactions in HaploSCT and are associated with robust immune recovery, translating into fewer infectious complications and lower NRM. Data from several studies suggest that haploidentical transplants have similar outcomes to MUD transplants, but when faster transplantation is needed, haploidentical grafts may be preferred.[70] Because of these, the use of this type of transplant continues to expand worldwide. Prospective controlled clinical trials are needed to address important questions in different clinical settings and impact of donor choice and time to transplant on outcomes because approximately half of patients do not get to transplant in time. In addition, exploration of various cellular therapy interventions in the peritransplant setting, particularly NK cell therapy, represents a great opportunity to improve the graft-versus-malignancy effect and decrease relapse posttransplant, which is the next most important next step in improving transplant outcomes.

MD ANDERSON PRACTICE TIPS

- Haploidentical transplantation use at MDACC has increased significantly over past decade, and it is a preferred alternative donor source in the absence of a fully matched donor.
- There are no prospective randomized clinical trials comparing haploidentical with matched unrelated transplants. Haploidentical transplant is preferred over double cord transplant. MDACC is a lead in the ongoing multicenter BMTCTN prospective observational clinical trial comparing the outcomes of alternative donors in the absence of a fully matched sibling donor.
- The introduction of PTCy for GVHD prevention represented a major turning point for improving outcomes of haploidentical transplants. The concept was first adopted at MDACC in 2009, incorporated into our fludarabine–melphalan conditioning platform, and since has become our standard of care option.
- Incorporation of donor NK cell into haploidentical transplant for patients with high-risk myeloid malignancies has led to significantly deceased relapse and viral infections and improved survival outcome in our experience. A multicenter phase 2 study is initiated by the BMTCTN based on our data.
- The DSAs remain one of the most important factors to consider for best haploidentical donor because the presence of antibodies is associated with high risk of graft failure. Patients with high DSAs should be avoided as donors but if not possible should be treated to decrease risk before transplant.
- Prospective controlled clinical trials are a priority to address important questions in different clinical settings, impact of donor choice, and time to transplant on outcomes because approximately half of patients do not get to transplant in time.

Partow Kebriaei

KEY CONCEPTS

- The efficacy of allogeneic hematopoietic cell transplantation (HCT) is based on the graft-versus-tumor effect, by which the donor immune system achieves immunologic control of the tumor via the human leukocyte antigen (HLA) system.
- Three key barriers to successful HCT are relapse caused by failure of immunologic control of the underlying disease, graft-versus-host disease (GVHD), and infectious complications, and studies are underway to improve on these complications.
- Strategies to mitigate relapse include using prophylactic donor lymphocyte infusions, chimeric antigen receptor modified T-cells derived typically from the patient, and natural killer (NK) T-cells.
- In contrast to B and T lymphocytes, NK T-cells do not express rearranged, antigen-specific receptors and as a consequence have a low risk for GVHD, allowing the use of allogeneic NK cells. An allogeneic product is advantageous because it is readily available and furthermore uses healthy immune cells for product production.
- The pathogenesis of GVHD is complex and includes the differentiation of naïve donor T-cells into effector cells that attack host tissues. Increasing numbers of HLA mismatches are associated with higher incidence of GVHD and transplant-related mortality. Grades II to IV acute GVHD occur in 25% to 60% of cases with matched related donors and 45% to 70% of cases with matched unrelated donors. Recent improvements in GVHD include the approval of ruxolitinib for steroid-refractory acute GVHD and the use of posttransplant cyclophosphamide to decrease the incidence of GVHD.
- Viral infection is a major cause of death after HCT, resulting from cellular and humoral immune deficiency. Viral infections of particular relevance after HCT are cytomegalovirus, Epstein-Barr virus, the polyoma viruses BK and JC, adenovirus, and human herpesvirus 6. Pharmacotherapy for these infections has limited efficacy. Viral-specific T-cells directed against these infections is feasible to generate and effective.

The efficacy of allogeneic hematopoietic cell transplantation (HCT) in hematologic malignancies can in large part be attributed to a graft-versus-tumor (GVT) effect, by which the donor immune system achieves immunologic control of the tumor. As such, it is the prototype of cellular therapy. The human leukocyte antigen (HLA) system is fundamental to transplant biology. The HLAs are highly polymorphic proteins that have a key role in antigen presentation and immune regulation. Class I HLAs are expressed on the surfaces of all nucleated cells; class II are expressed on specialized antigen-presenting cells (APCs), such as macrophages, dendritic cells, and B cells.

Peptides derived from microbes are presented on class I HLAs to CD8+ T-cells and result in immunologic destruction of infected cells; class II HLAs are recognized by CD4+ T-cells. T-cell activation requires costimulatory signals from the APC, specifically CD80/86 binding to CD28 or LFA-3 binding to CD2.[1] Absence of a costimulatory signal results in T-cell anergy, which is a key mechanism of peripheral immune tolerance to self-antigen in normal immune

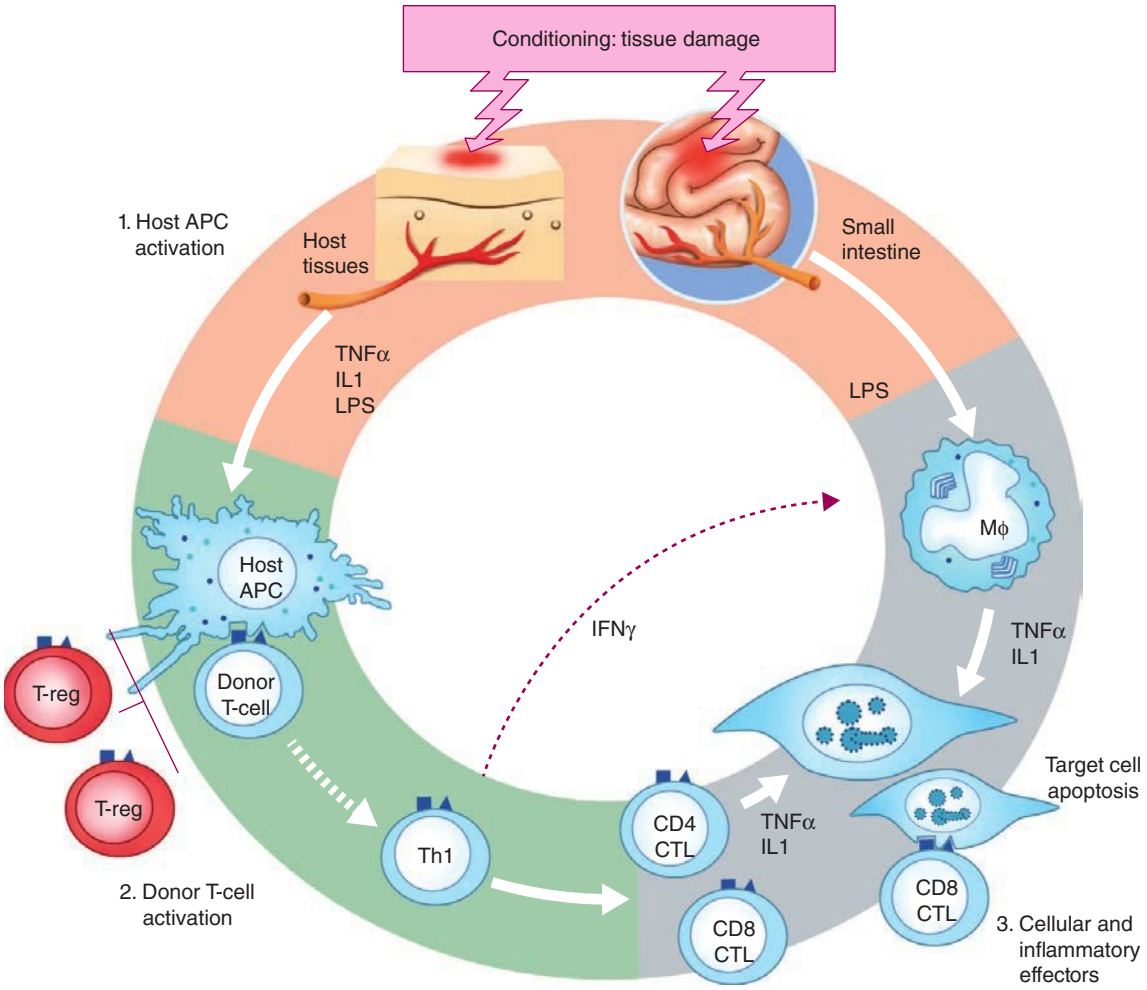

FIGURE 22–1 **Pathogenesis of graft-versus-host disease (GVHD). In phase I, chemotherapy or radiotherapy as part of transplant conditioning causes host tissue damage and release of inflammatory cytokines such as tumor necrosis factor α (TNF-α), interleukin (IL)-1, and IL-6, with resulting priming of host antigen-presenting cells (APCs). In phase II, host APCs activate mature donor cells, which subsequently proliferate and differentiate; release of additional effector molecules, such as TNF-α and IL-1, mediates further tissue damage. Lipopolysaccharide (LPS) that has leaked through damaged intestinal mucosa triggers additional TNF-α production. The TNF-α can damage tissue directly by inducing necrosis and apoptosis in the skin and gastrointestinal tract through either TNF receptors or the Fas pathway. TNF-α plays a direct role in intestinal GVHD damage, which further amplifies damage in the skin, liver, and lung in a "cytokine storm." The process culminates in death of host cells through CD8-positive cytotoxic T-cell-mediated apoptosis. regulation. Early after transplantation, there is a "cytokine storm"; release of proinflammatory cytokines, such as tumor necrosis factor α (TNF-α) and interleukin-6 (IL-6), is induced by tissue damage from the conditioning regimen, activating the host innate immune system (Fig. 22–1). Donor T-cells interact with host APCs and recognize foreign peptides; helper T-cells produce further cytokines, especially IL-2, and prime host APCs via CD40–CD40L interaction. Differentiation of naïve donor T-cells into effector cells subsequently occurs, resulting in immunologic attack on host tissues and the potential development of graft-versus-host disease (GVHD).[2] Increasing numbers of HLA mismatches are associated with higher incidence of GVHD and transplant-related mortality (TRM) rate.[3] However, even in a fully HLA matched HCT, GVHD still occurs because of donor T-cells directed against minor histocompatibility antigens (MiHAs), polymorphic peptides displayed on host HLA molecules.

There are three key barriers to successful HCT: relapse caused by failure of immunologic control of the underlying disease, GVHD, and infectious complications. Herein, we review these issues in greater detail with an emphasis on recent cellular therapeutic approaches to address these complications.

ENHANCING GRAFT-VERSUS-TUMOR EFFECT TO OVERCOME RELAPSE

Pathophysiology of the Graft-versus-Tumor Effect

The GVT effect occurs because of a predominantly T-cell-mediated immunologic attack on tumor cells. In HLA-identical transplants, GVT effect is mediated by naïve T-cells; for development of effector function, these must first be primed by host APCs. This requires the following: presentation of MiHAs or tumor-specific antigens on HLA; appropriate costimulatory molecules, including CD28, OX40, CD40L, and 41BB; and an appropriate "third signal," provided by IL-12, interferon g (IFN-g) or adjuvant.[4] Restraining influences limiting the degree of immune activation are present to protect the host from an excessive immune response and include expression of CTLA4 (which competes with CD28 for binding to CD80/86) and programmed cell death protein 1 (PD-1) and its interactions with its ligand PDL1, which limit T-cell activation and expansion during normal, pathogen-directed immune responses.

Soon after transplant, there are activation and expansion of MiHA-reactive T-cells followed by a decline, similar to that seen in pathogen-directed immune reactions. This may in part relate to the development of peripheral tolerance or anergy and to replacement of host hematopoiesis, with resulting loss of host APCs. For tumor-associated antigen presentation to continue, there must be cross presentation on donor APCs. In addition, the initial allogeneic response to MiHAs results in recruitment of T-cells targeting either tumor-associated antigens or nonpolymorphic genes, which are either overexpressed or aberrantly expressed by the tumor.[4]

Tumor Escape From Immunologic Destruction

Tumors use numerous mechanisms to escape immunologic destruction, including the following:

- Induction of regulatory T-cells
- Production of inhibitory cytokines
- Downregulation of costimulatory molecules and HLA class I
- Induction of co-inhibitory molecules
- Induction of myeloid-derived suppressor cells in the microenvironment that inhibit immune responses through multiple mechanisms.
- Invasion of immunologically privileged sites

Cellular therapeutic approaches are designed with the intent to abrogate these escape mechanisms.

Cellular Therapy to Induce Graft-Versus-Tumor Effect

Donor Lymphocyte Infusions

Donor lymphocyte infusion (DLI) may induce remissions in patients with molecular or overt low volume relapse of their malignancy and can reverse CD8+ T-cell exhaustion.[5] However, the likelihood of success varies significantly according to the underlying disease. Chronic myelogenous leukemia is most sensitive; follicular lymphoma (FL) and Hodgkin lymphoma (HL) are also highly responsive.[6,7] Responses to DLI in AML or myelodysplastic syndrome (MDS) are less frequent, and durability is often poor. Acute lymphoblastic leukemia (ALL) is the least responsive to DLI. Reported response rates are 60% to 73% in CML, 15% to 29% in AML, and 0% to 18% in ALL.[8] Limitations to DLI therapy include most notably, development of GVHD, which occurs in 40% to 60% of patients.[8] The GVHD rates may be reduced by reducing the T-cell dose; a dose–response relationship exists for both GVT and GVHD effects. Additionally, if there is insufficient residual donor hematopoiesis before DLI, eradication of host hematopoiesis by the infused lymphocytes can result in marrow aplasia; chimerism studies should therefore be performed before DLI to ensure adequate donor hematopoiesis.[9] Finally, responses to DLI may not be seen for up to 2 months.[8]

In efforts to enhance the response to DLI in AML, combination therapy with hypomethylating agents (HMAs) has been studied. Based on preclinical studies that azacitidine increases T-regulatory (T-reg) cells, suppressing GVHD while sparing GVT, Ghobadi and colleagues reported on a phase I trial testing three escalating doses of azacitidine (30 mg/m^2,45 mg/m^2, 75 mg/m^2) administered after DLI.[10] With a median follow-up period of 5.2 months, 6 of 8 treated patients responded, with no grades III or IV GVHD noted.[10] Schroeder and colleagues reviewed the outcomes of 36 patients with relapsed AML ($n = 29$) or MDS ($n = 7$) after HCT and treated with DLI and median two cycles of decitabine.[11] The median duration of complete remission (CR) was 10 months for the group, with acute and chronic GVHD rates of 19% and 5%, respectively; the 2-year survival rate was only 11%,[11] underscoring the limited impact of DLI, even with the addition of other agents.

Prophylactic Donor Lymphocyte Infusion in High-Risk Patients

The limited benefit of DLI in overt relapse after transplant has led investigators to study the potential of DLI for the prevention of relapse. In a study by Kothari and colleagues, 75 patients with high-risk hematologic malignancies underwent an alemtuzumab-based, T-cell-deplete transplant with matched related donors (MRDs $n = 46$) or matched unrelated donors (MUDs; $n = 29$) with planned early withdrawal of immune suppression (WOI) and DLI in efforts to decrease relapse.[12] Twenty-eight patients with MRDs were able to undergo early WOI, and 93% received at least one DLI; only seven patients with MUDs were able to undergo WOI and 57% received at least one DLI. The estimated 2-year progression-free survival (PFS) and overall survival (OS) rates for all patients were 41% and 51%, respectively; for patients who received at least one prophylactic DLI, 2-year PFS and OS were 57% and 67%. In addition, patients who received DLI had faster immune reconstitution and improved donor chimerism. This novel approach may be an effective strategy in patients undergoing MRD transplants.

In another study, low-dose azacitidine and DLI was tested in a prophylactic fashion in patients with AML ($n = 20$) or MDS ($n = 10$) deemed at high risk for relapse after allogeneic HCT.[13] The median number of azacitidine cycles was 5 (range, 1–12) with 33% completing the 12 intended cycles; 17 patients received 1-3 infusions of DLI. At a median follow-up period of 49 months (range, 27–63 months), the OS and disease-free survival (DFS) rates were 65.5% at 2 years; the rates for 2-year grades I to III acute GVHD and chronic GVHD were 31.5% and 53%, respectively, suggesting that this may be a reasonable strategy in high-risk patients.[13]

Cellular Therapy to Prevent Relapse: Chimeric Antigen Receptor T-Cells

Chimeric antigen receptor (CAR) T-cells have become one of the new and promising treatment modalities for hematologic malignancies. They are genetically modified T-cells, transfected with a viral vector or a plasmid coding for a chimeric receptor (Fig. 22–2). The extracellular portion of the receptor is a single-chain variable fragment (scFv) of an antibody, acting as the antigen recognition domain. First-generation constructs contained only the extracellular scFv domain coupled with an activating intracellular CD3 ζ component. because of limited in vivo proliferation and persistence of CAR T-cells, second-generation CAR includes an additional costimulatory domain (eg, CD28 or 4-1BB), resulting in improved CAR T proliferation and persistence in vivo, and third-generation CAR constructs have two costimulatory domains (eg, both CD28 and 4-1BB), with potential for even better expansion and longer persistence. This advantage for third-generation CAR was shown in a study in which both second- and third-generation CARs were infused simultaneously in the same patient.[14] Since second-generation CAR T-cells were approved by the Food and Drug Administration (FDA) in 2017, they are becoming more widely available and used as standard of care therapy for patients with relapsed or refractory B-cell non-Hodgkin lymphoma (NHL) or ALL. CAR T therapy induce high rates of responses, up to 74% in NHL and 90% in ALL, but are also associated

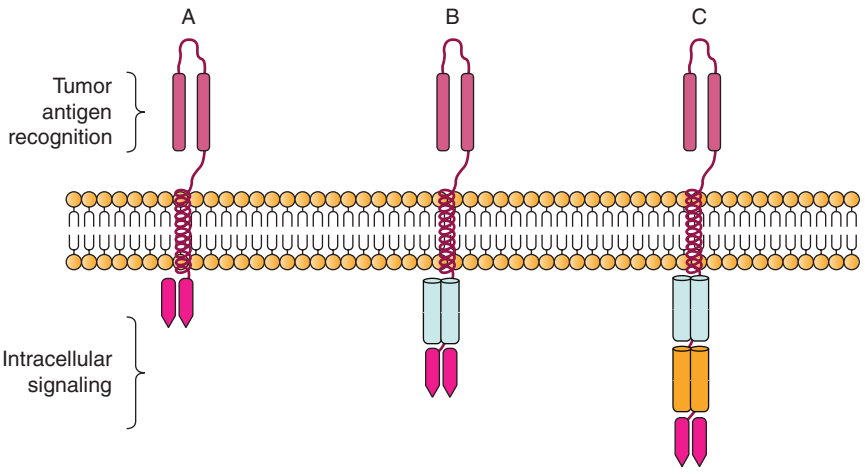

FIGURE 22–2 Schematic of chimeric antigen receptor (CAR) constructs. A. The first-generation CAR consists of an antigen recognition domain (usually a single-chain monoclonal antibody [scFv]) targeting a tumor-associated antigen), coupled via an extracellular hinge domain and transmembrane domain to an intracytoplasmic signaling domain, typically the CD3ζ chain. B. C. In second- and third-generation CAR constructs, the intracellular component includes costimulatory domains, typically 4-1BB, CD28, or both, that enhance persistence and proliferation.

with rates of serious toxicity in the form of cytokine release syndrome (CRS) of up to 44% and severe neurotoxicity of up to 42%.[15] With a longer follow-up period, up to 50% of ALL patients and 60% of NHL patients relapse, sometimes with an antigen-negative relapse.[16,17] In many ALL studies, despite a CR rate of 70% to 90% after CAR T therapy, more than half relapse within 1 year without consolidative allogeneic HCT.[18–25] Thus, studies are underway to investigate the ideal sequence for these therapies and if there is any benefit to combining with transplant.

Chimeric Antigen Receptor T-Cell Therapy Combined with Autologous Transplant

Several studies have looked at CAR T administration combined with autologous HCT for NHL. Sauter and colleagues reported on 15 patients with relapsed or refractory NHL who had positron emission tomography–positive disease before HCT and showed a 2-year PFS of 30% when CAR T-cells were administered on days 2 and 3 of the transplant.[26] Furthermore, 10 of 15 patients experienced high-grade neurotoxicity, perhaps because of the intense chemotherapy during the transplant. A study conducted at MD Anderson Cancer Center (MDACC) used the Sleeping Beauty transposon–transposase system (as opposed to a viral platform) to produce CD19 CAR T-cells, which were infused 2 days after autologous HCT in seven patients with relapsed or refractory B-cell NHL.[27] In this trial, the 5-year PFS and OS rates were 71% and 86%, respectively. Interestingly, 4 of 6 evaluable patients had persistence of the CAR T-cells at last follow-up, at a median of 4.5 years.

Current CAR T trials in multiple myeloma (MM) are mainly using the B-cell maturation antigen (BCMA) as the target and are usually enrolling relapsed or refractory patients who have had prior autologous transplant. However, one of the first trials used a CD19-directed CAR as an adjunct to a second transplant and compared each patient's PFS after the CAR T + HCT strategy to the previous PFS attained with transplant only.[28] The use of CD19, not usually present on mature plasma cells, was thought to target the myeloma-propagating cells. In this study, among 10 patients treated, only two had longer PFS after the CAR T + HCT versus transplant alone. Interestingly, these two patients eventually progressed with isolated extramedullary plasmacytomas, and the authors suggested this may hint at continuing bone marrow immune surveillance. Another trial reported on infusion of both CD19- and BCMA-directed CAR T-cells 14 to 20 days after HCT in nine patients.[29] The overall response (OR) rate was 100% with all patients achieving CR or very good partial response after CAR T-cell therapy, although response duration was not reported.

Chimeric Antigen Receptor T-Cell Therapy Combined with Allogeneic Transplant

Combining CAR T therapy with allogeneic HCT is also under investigation. The transplant preparative regimen may have a deleterious effect on any remaining circulating CAR T-cells and impair their immune surveillance. Furthermore, CAR T-cell therapy and its associated toxicity may impact transplant-related toxicities, such as increasing GVHD. Currently, the available data regarding the safety and possible benefit for allogeneic HCT after CAR T therapy comes from retrospective series, largely without preplanned consolidation with transplant (Table 22–1). The data in aggregate indicate that transplant consolidation may confers protection against relapse at the expense of greater TRM, thus not providing a survival benefit for all patients. Zhang et al reported on the outcomes of 52 adult patients with ALL who received treatment with either CD19 or CD22 autologous CAR T followed by planned allogeneic HCT with reduced-intensity conditioning therapy.[22] At 1 year, the relapse rate was 24.7%, TRM was very low at 2.2% without excess GVHD, and there was an excellent 1-year OS of 87.7%. More studies will need to be conducted with planned consolidation of allogeneic HCT after CAR T to confirm these highly encouraging results. Similarly, in children, data for consolidation with HCT after CAR T-cell therapy is mainly reported from retrospective studies without planned transplant consolidation.[30] A retrospective study of 15 pediatric or adolescent and young adult patients with relapsed or refractory B-cell ALL who went on to an allogeneic HCT after achieving an MRD-negative remission with CAR T-cells, reported OS of 80% at 24 months and relapse and TRM rates at 16% and 20%, respectively.[31] In this study, patients were treated with myeloablative conditioning regimens followed by either a CD34-selected T-cell-depleted allogeneic graft ($n = 9$) or unmanipulated graft ($n = 6$); TRM and OS were 0 and 100% versus 50% and 50% for the manipulated versus unmanipulated groups, respectively. This very small study hints at the possibility that a T-cell-replete graft may not be necessary if transplant is used as consolidation in this setting, sparing patients some degree of toxicity, such as GVHD. As we continue to investigate the role of CAR T therapy and its sequence in the treatment of different diseases and patient populations, we will be able to refine the role of transplant consolidation. The patient's disease characteristics, the CAR T construct, and the patient's response to therapy will help to delineate who may benefit from this approach. One such example of this approach was investigated by Summers and colleagues, in which patients with B-cell aplasia of less than 63 days after CAR T treatment were offered a transplant. Among 50 evaluable

allo-HCT, allogeneic hematopoietic cell transplantation; CAR, chimeric antigen receptor; CR, complete remission; EFS, event-free survival; LFS, leukemia-free survival; MRD, minimal residual disease; N/A, not applicable. OS, overall survival; TRM, transplant-related mortality.

patients, 15 had B-cell aplasia of less than 63 days, and nine of these patients proceeded to transplant. Among the transplanted patients, only two relapsed, and all six patients with early reconstitution of B cells who did not proceed to transplant relapsed.[32]

Chimeric Antigen Receptor T-Cell Therapy After Allogeneic Transplant

Finally, sequencing CAR after an allogeneic HCT allows the production of donor-derived CAR T-cells if the patient remains chimeric. This allows the use of healthy T-cells for CAR production and provides a strategy to address relapse in these patients. A report on 18 patients with relapsed CD19+ ALL after allo-HCT had 13 of 18 patients achieving a CR (72%) and 11 of these not requiring further therapy at a median follow-up period of 7 months.[33] Importantly, full donor chimerism was restored for the responding patients, and only two patients had GVHD that responded to therapy. In another trial of 20 patients with relapsed B-cell malignancies after allogeneic HCT who received CAR T infusion, eight of the patients had a CR or partial response.[34] These patients did not receive any lymphodepletion before CAR T infusion, and importantly, no patients developed GVHD, despite 70% of patients having had a prior history of GVHD with their transplant. Similar findings have been reported from smaller series, importantly all without excess rates of GVHD.[35,36] A recent report of donor-derived cytokine-induced killer T-cells engineered with the Sleeping Beauty transposon to express CD19 CAR showed responses in four of five patients with refractory ALL, with no GVHD reported after treatment.[37]

Although most donor-derived CAR T trials investigated the use of CAR T-cells as therapy for relapse after transplant, a few have studied CAR T-cells as prophylactic therapy. Kebriaei et al used a nonviral approach for the production of CD19-directed CAR T-cells using

the Sleeping Beauty transposon–transposase system to incorporate the vector into the genome; this construct was tested in phase 1 clinical trials in 26 patients with B-cell malignancies in combination with allogeneic (n = 19) or autologous (n = 7) transplant.[38] Six of seven patients who had an autologous HCT followed by CAR T were in remission after a median follow-up period of 25.5 months; 11 of 19 patients receiving an allogeneic HCT were in remission after a median follow-up period of 7.5 months, with reported 1-year PFS and OS rates of 53% and 63%, respectively.[38] In another small study of two patients using a similar strategy of prophylactic donor-derived CAR T-cells after allogeneic HCT, investigators reported prolonged CAR T persistence, absence of GVHD, and continued remission at a follow-up period of 1 year.[39]

NATURAL KILLER CELLS

Natural killer (NK) cells have a number of advantages over T-cell therapy in the treatment of patients with cancer. Unlike T and B lymphocytes, NK cells do not express rearranged, antigen-specific receptors and as a consequence have a low risk for GVHD. This allows the use of allogeneic NK cells, thus providing an off-the-shelf product that decreases the cost and delay to treatment seen with autologous CAR T therapy. Furthermore, there is evidence that autologous immune cells are dysfunctional in cancer,[40] and thus it might be ideal to use allogeneic cells.

NK effector function is dictated by an integration of activating and inhibitory signals received through germline-encoded receptors that can recognize ligands on their cellular targets. This interplay between receptors is complex because certain ligands, such as CD155, can bind to both activating and inhibitory receptors, and certain receptors can be either activating or inhibitory.[41]

NK cells serve an important role in cancer immune surveillance. One method that cancer cells use to evade T-cells is to downregulate their HLA class I molecules. Because HLA class I molecules are some of the strongest inhibitors of NK cells, the lack of these molecules consequentially leads to NK cell activation, thus providing a balance to T-cell surveillance.[41] NK cells can also be activated by ligands such as major histocompatibility complex class I polypeptide-related sequence A (MICA), MICB, and UL16 binding proteins (ULBPs) that are upregulated in cells that have DNA damage or are stressed or infected, including cancer cells. Finally, NK cells can be activated by binding to the Fc portion of antibodies through its CD16 receptor and thus are involved in the body's antibody-dependent cellular cytotoxicity immune defense. This is believed to be integral, for example, in the efficacy observed with the anti-CD38 antibody therapy daratumumab in multiple myeloma.[42] After being activated, NK cells can directly kill cancer cells via secretion of granzymes and perforins, and they can also modulate the surrounding microenvironment by secreting cytokines such as IFN-γ and TNF-α (Fig. 22–3).

Early NK cell recovery (within 30 days) after allogeneic stem cell transplant has been associated with reduced rates of both relapse and acute GVHD (aGVHD), with resultant improved survival.[43] This dual benefit makes allogeneic NK cells an attractive option for adoptive cellular therapy peritransplant. Adoptive transfer of NK cells has previously been limited by the small numbers of circulating NK cells (5%–15% of the total lymphocytes) and consequently the low numbers obtained in an apheresis procedure.[44] Thus, techniques that have been used to expand NK cells ex vivo from hematopoietic or induced pluripotent stem cell–derived NK cells[45] or to use an immortalized NK cell line.[46] At MDACC, we have developed a novel method to expand cord blood NK cells in vitro by using engineered K562 "feeder cells" with IL-2 and are able to obtain clinically relevant cell numbers.[47] Furthermore, cord blood NK cells appear to have higher expression of genes for cell cycle and replication than peripheral blood (PB) NK cells.[48]

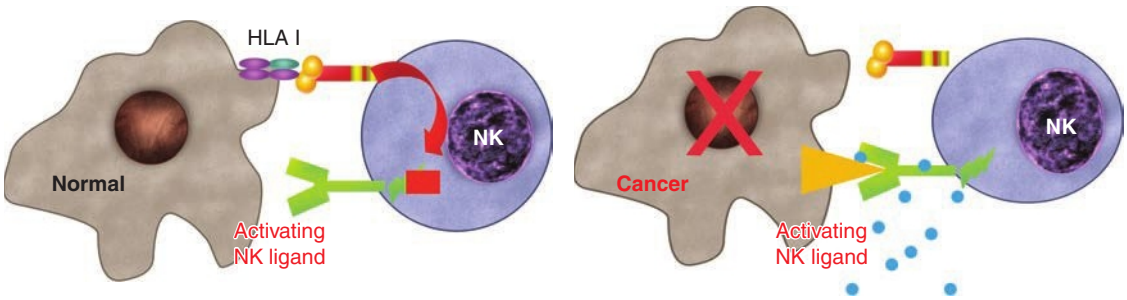

FIGURE 22–3 **Selective killing of transformed cells by natural killer (NK) cells. In normal cells, the inhibitory signals triggered by killer cell immunoglobulin-like receptor (KIR)–human leukocyte antigen (HLA) I molecule engagement overrides activating signals. In the context of cancer, expression of stress ligands for activating receptors, in conjunction with low expression of HLA I molecules, attenuates the triggering of inhibitory receptors and results in an activating signal.**

Optimizing Natural Killer Cell Efficacy

NK cells have a class of highly polymorphic receptors called killer cell immunoglobulin-like receptor (KIR) that can be divided into inhibitory and activating subtypes. The KIRs are inherited as haplotypes (KIR-A and KIR-B). The KIR-A haplotypes, found in one third of adults of European descent, have one activating receptor, but the KIR-B haplotypes have two or more. Transplantation in AML from a KIR-B haplotype donor is associated with lower relapse rates and superior survival.[49] Donor KIR2DS1 (an activating KIR) and recipient HLA-C type influence relapse risk. The KIR2DS1-associated reduction in the rate of AML relapse is restricted to donors with HLA-C1/C1 or C1/C2, in whom KIR2DS1-expressing NK cells are presumed to be "educated," and the benefit was eliminated in transplants from donors with HLA-C2/C2, in whom KIR2DS1-expressing NK cells are expected to be tolerized in the setting of self HLA-C2.[50] Selection of adult or cord blood donors for ex vivo NK cell expansion based on KIR genotype may therefore enhance NK cell efficacy.

Similar to T-cells, NK cells can be modified with a CAR to enhance their activation and specificity. This led to the first-in-human phase I/II trial of CAR-transduced NK cells at MDACC in which cord blood NK cells were modified to express a CAR against CD19 and to secrete IL-15 to support their in vivo proliferation and persistence.[51] In a heavily pretreated population of patients with B-cell malignancies who had received a median of four prior lines of therapy, 8 of 11 (73%) patients responded after only a single infusion, including patients with high-risk features such as Richter transformation or deletion 17p CLL. The infused CAR NK cells were detected as long as 1 year after treatment. The therapy was well tolerated, and the only grade 4 toxicity observed was neutropenia and leukopenia from the initial lymphodepleting chemotherapy. Unlike CAR T-cells, no CRS or neurotoxicity were observed, and there were no cases of GVHD. A phase II multicenter trial is planned.

Programmed Cell Death Protein 1 and Programmed Cell Death Protein Ligand 1 Antibodies

The interaction of PD-1 and PDL1 induces T-cell dysfunction, and manipulation of this pathway has offered a treatment strategy in a variety of malignancies. These therapies have been most extensively studies in metastatic solid tumors as monotherapy and in combination with the anti-CTLA4 antibody ipilimumab.[52] In one of the first studies in hematologic malignancies, 23 patients with refractory or relapsed HL received the PD-1–blocking antibody nivolumab with a reported overall response rate (ORR) of 87%[53]; these striking preliminary results were confirmed in larger trials[54] and led to the FDA approval of nivolumab for patients with relapsed HL.

The potential importance of immune checkpoints in AML has been demonstrated in preclinical studies,[55] and clinical studies are currently underway. Zeidner et al reported an ORR of 46% for patients with relapsed or refractory AML treated with high-dose cytarabine followed by pembrolizumab.[56]

REDUCING GRAFT-VERSUS-HOST DISEASE

Cellular Therapy for Treatment of Graft-versus-Host Disease

Grades II to IV aGVHD occur in 25% to 60% of MRDs and 45% to 70% of MUDs.[57] Corticosteroid-based therapy for grades II to IV aGVHD is unsatisfactory, with fewer than 50% of patients showing a durable complete response.[58] Increasing severity of aGVHD is associated with incremental TRM and inferior survival. Corticosteroid-refractory GVHD has a poor prognosis. Numerous additional agents have been studied in combination with corticosteroids or as second-line therapies and showed uniformly poor response rates and numerous complications, particularly viral reactivation.[58] Although mesenchymal stromal cells (MSCs) appear to show benefit in smaller, single-center trials for steroid-refractory GVHD,[59] there did not appear to be a clear benefit in the only phase 3 randomized controlled trial.[60] Some benefit was noted in post-hoc subset analyses of high-risk patients (day 28 OR, 58% MSC vs 37% placebo; $P = .03$) and pediatric patients (day 28, OR 64% MSC vs 23% placebo; $P = .05$), suggesting that MSCs may be a viable option for some patients. Further investigations are underway.[60]

T-Cell Depletion for Prevention of Graft-versus-Host Disease

A T-cell-replete transplant usually contains 1 to 5 × 10^7 T-cells/kg recipient weight.[61] T-cell depletion is the most potent method of preventing aGVHD but is associated with increased rates of graft rejection; delayed immune reconstitution; infectious complications, including Epstein-Barr virus (EBV)–driven post transplant lymphoproliferative disease (PTLD); and increased relapse risk.[62] T-cell depletion can be accomplished ex vivo immunologically (T-cell antibodies, positive CD34 selection) or by the use of physical separation (eg, density gradients) or in vivo by the use of anti-T-cell antibodies such as antithymocyte globulin (ATG) or alemtuzumab. In vivo T-cell depletion with

ATG reduces severe aGVHD and extensive cGVHD without increasing relapse but does not reduce TRM or improve survival,[62] likely because of increased infection risk. Alemtuzumab-based GVHD prophylaxis achieves low rates of severe aGVHD and extensive cGVHD but results in high rates of mixed chimerism and viral infections, particularly cytomegalovirus (CMV) reactivation.[63]

The alkylating agent cyclophosphamide is now being used more frequently as a method to eliminate cGVHD. Cyclophosphamide is metabolized by liver cytochrome P450 into phosphoramide mustard and acrolein and prevents cell division by crosslinking DNA strands. HSCs benefit from having a higher level of the enzyme aldehyde dehydrogenase, used to convert phosphoramide mustard into the inactive metabolite carboxycyclophosphamide. Administering cyclophosphamide a few days after transplant was first introduced into clinical practice on trials with haploidentical donor graft transplants at Johns Hopkins University[64] in an effort to reduce GVHD but has now extended across donor types as a mechanism to eliminate graft alloreactive CD4+ cells in donor grafts[65] and donor graft sources.[66] In a recent report of patients with AML or MDS who had checkpoint inhibitor therapy before proceeding with HCT, the use of posttransplant cyclophosphamide reduced severe acute GVHD and improved PFS.[67]

Adoptive Transfer of Regulatory T-Cells

The level of CD4+CD25+FOXP3+ T-reg cells in the graft and after HCT correlates inversely with aGVHD and cGVHD.[68] Therefore, adoptive transfer of T-reg cells could ameliorate GVHD. After sorting and expansion, adoptive transfer of T-reg cells has been shown in murine xenogenic GVHD models to prevent and treat GVHD, improving survival.[69]

Early-phase clinical trials have shown posttransplant adoptive transfer of T-reg cells to be safe, and they have been used for GVHD prevention, as well as treatment. In a study of 23 adult patients receiving double-unit cord blood–derived grafts, T-reg cells were administered for prevention of acute GVHD with a reduction in risk of grades II to IV aGVHD relative to historical control participants (43% vs 61%; $P = .05$) and, importantly, similar DFS rates.[70] A later report on 11 additional patients with higher dose levels showed very low incidence of 9% of acute GVHD and no patients with chronic GVHD at 1 year after transplant.[71] In a small case series with five patients receiving T-reg cells for as treatment for chronic GVHD, two patients had clinical improvement of symptoms, and three had a stable disease.[72] However, two of the patients developed skin cancers within 1 year of T-reg transfusion. Larger clinical trials are needed to validate these results and address safety issues as well as this therapy's impact on the graft-versus-leukemia effect.

Adoptive transfer of other immune-modulating cells, such as "veto" cells capable of inducing immune tolerance, are also being explored in preliminary clinical trials. These may also allow for more efficient "off-the-shelf" CAR T-cell therapy by inducing tolerance and preventing rejection of these allogeneic cells.[73]

PREVENTING AND TREATING INFECTION WITH VIRAL-SPECIFIC T-CELLS

Delayed recovery of cellular and humoral immunity results in morbidity and mortality from infection. Figure 22–4 shows the approximate time course of numeric recovery of immune cells after HCT; Figure 22–5 shows the time course of infections.

Viral infection is a major cause of death after HCT, resulting from cellular and humoral immune deficiency;

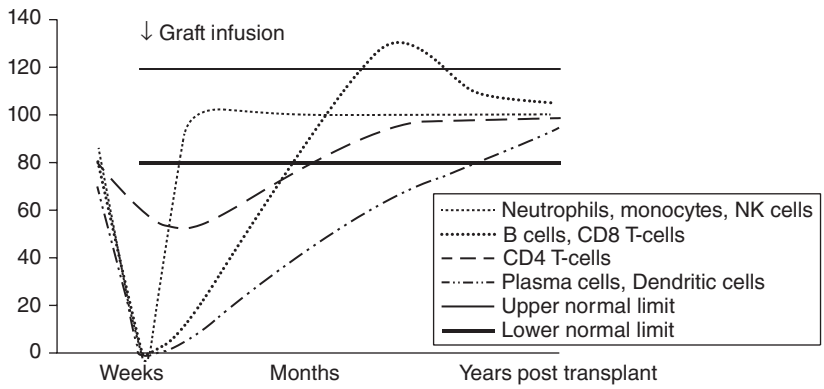

FIGURE 22–4 Time course of numeric cellular immune recovery posttransplant. (Reproduced with permission from Mackall C, Fry T, Gress R, et al. Background to hematopoietic cell transplantation, including post transplant immune recovery, *Bone Marrow Transplant* 2009 Oct;44(8):457-462.)

CHAPTER 22

risk factors include umbilical CB transplantation, T-cell depletion, and GVHD requiring systemic immunosuppression. Viral infections of particular relevance after HCT are CMV, EBV, the polyoma viruses BK and JC, adenovirus, and human herpesvirus 6 (HHV-6). Pharmacotherapy for these infections has limited efficacy and substantial toxicity Consequently, adoptive immunotherapy for the prevention and treatment of viral reactivation or infection after transplant is attractive.

Generation of viral-specific T-cells (VSTs)s is most straightforward from an immune-experienced adult donor who has viral-specific memory T-cells specific in the PB. The VSTs from such donors can be generated in two ways[74]:

1. T-cell co-culture, in the presence of specific cytokines, with an artificial APC modified to express the immune dominant antigens of the target virus and costimulatory molecules
2. Rapid selection strategies without ex vivo culture. These rely on the presence of sufficient numbers of VSTs in the donor PB and hence are limited to CMV and EBV.[75]

Generation of VSTs from immunologically naïve donors (eg, CB) is more challenging. However, multivirus-specific T-cells against EBV, CMV, and adenovirus can be generated from naïve CB cells by genetically modifying EBV lymphoblastoid cell lines transduced with an adenoviral vector expressing the CMVpp65 transgene.[76] These are highly active against virus despite recognition of noncanonical CMV and EBV epitopes,[76] and clinical results are encouraging.[77,78]

Third-party, banked VSTs from adult donors can also be used to treat viral reactivation in patients without an available adult donor or in whom rapid disease progression precludes waiting for generation of VSTs from their donor. Suitable lines (which are dependent on the recipient expressing immune dominant viral peptides on an HLA antigen shared by a donor VST line) are available in approximately 90% of patients and can be rapidly identified and made available. VSTs demonstrated high response rates in patients with refractory CMV, adenovirus, and EBV-related PTLD.[78–80]

In a recent review of 229 patients who received VST for viral infections occurring after transplant, the response rate was 91.3%.[81] Interestingly, despite the theoretical risk of inducing GVHD due to HLA mismatch, no severe cases of de novo aGVHD were seen in initial studies, and retreatment was successful in several cases despite initial immunologic rejection of the transferred cells.[78,79]

Treatment of Specific Infections with Viral-Specific T-Cells

Epstein-Barr Virus Reactivation and Posttransplant Lymphoproliferative Disorder

PTLD related to EBV occurs in the setting of severe transplant-related immunosuppression when the EBV-specific T-cell response is insufficient to control latent EBV infection within recipient or donor B cells. Risk factors for infection predominantly relate to the degree of immunosuppression in recipients of T-cell-depleted transplants. Patients typically present with high fever and lymphadenopathy with elevated serum lactate dehydrogenase levels. Initial therapy for EBV reactivation is reduction in immunosuppression. However, there are no randomized studies to guide the best therapy of established EBV-associated PTLD. In patients with frank PTLD, the largest study[82] showed a 70% complete response/complete response undefined rate with four weekly doses of rituximab monotherapy, but there were poor responses to subsequent treatment (chemotherapy, DLI, or both) in nonresponders. Chemotherapy is associated with greater toxicity in HCT recipients and may increase infection risk. Cellular therapy shows great promise in the management of EBV-related PTLD. Unmanipulated donor T-cell infusions can control established PTLD in approximately 70% of patients but can induce severe or fatal GVHD.[83] Therefore, when available, VSTs are preferred. The EBV-specific or polyvirus-specific cytotoxic T lymphocytes (CTLs) have proven successful in overt PTLD in 77.5% of patients, including patients with rituximab-refractory disease.[84] EBV CTLs have been administered in the prophylactic setting in more than 100 patients, and no patient has developed EBV-PTLD with up to 15-year follow-up.[75,85–91]

Cytomegalovirus Infection

Risk factors for CMV reactivation and disease after HCT include receiving umbilical CB grafts, T-cell-depleted grafts, T-cell antibody therapy for GVHD prophylaxis, or high-dose steroids.[92] In addition, CMV-seropositive patients with seronegative donors are at particularly high risk because of the lack of memory T-cells against CMV from the seronegative donor.[92] Although ganciclovir prophylaxis reduces the risk of CMV disease, it prolongs neutropenia, increases invasive bacterial and fungal infections, and does not improve survival.[92] Close monitoring for CMV reactivation in blood, followed by preemptive therapy with ganciclovir when assays in blood become positive, reduces the incidence of CMV disease. Overall, rates of CMV disease have declined from 30% to 35% to 8% to 10% with ganciclovir prophylaxis or preemptive therapy.[92] In 2017, letermovir, which targets the HCMV DNA terminase complex, was licensed for prophylaxis of HCMV infections in HCT recipients and has lowered the rate of reactivation. Use of letermovir is limited by emerging drug resistance and drug expense.[93] Gastrointestinal disease, pneumonia, and retinitis are the most common manifestations; pneumonia has a high mortality rate despite treatment with ganciclovir or foscarnet and CMV immunoglobulin.[92] Given the toxicity and expense associated with pharmacologic interventions and their imperfect efficacy, cellular therapy as treatment or prophylaxis of CMV in high-risk patients is attractive. In one study, 40 of 47 patients with CMV infection or disease refractory to antiviral therapy were treated with CMV CTLs and cleared the virus after one or two infusions. In another study, 110 patients received CMV CTLs as a prophylaxis 28 to 115 days after HCT. Reactivation of CMV in patients receiving CMV CTLs was 16% while reactivation in the control cohort was 66%. No statistically significant severe de novo GVHD has been reported after CMV CLT infusion.[94–99]

Adenovirus Infection

Adenovirus infection occurs in up to 21% of transplant recipients, with manifestations of adenovirus disease in 20% to 89% of infected patients.[100] Four clinically significant syndromes are seen: pneumonitis, nephritis, hemorrhagic colitis, and hemorrhagic cystitis. Disseminated disease with multiorgan failure also occurs and has a poor outcome despite antiviral therapy; most successfully treated cases are respiratory or urinary tract infections. Adenovirus-specific T-cells can now be generated from both CB[76,77] and adult donors,[77] with a high clinical response rate in cidofovir-refractory cases.[101] Donor-derived adenovirus-specific T-cells have been used recently in a high-risk pediatric trial with a 100% response rate with no serious toxicity noted.[91,102]

BK and JC Virus Infections

BK virus reactivation occurs in 5% to 68% of HCT recipients. It can cause severe hematuria, urinary obstruction, renal failure, and increased mortality. It is more frequent in patients with grades III and IV aGVHD and CB transplants.[103] Pharmacologic therapy is toxic and poorly efficacious. JC virus–associated progressive multifocal leukoencephalopathy (PML) occurs in immunosuppressed individuals and carries a grim prognosis with limited treatment options, although PD-1 inhibition does show some promise.[104,105] Because of the homology in immunogenic proteins between BK and JC, BK-0specific CTLs have been used in the treatment of patients with PML with

good response rates.[106] BKV CTLs have been included in multivirus-specific T-cell clinical trials with response rates approaching 100%.[91]

Human Herpes Virus 6 Infection

Infection with HHV-6 is virtually universal before age 2 years.[107] Reactivation occurs in more than 50% of allograft recipients and can result in encephalitis, delayed engraftment, and increased rate of GVHD, with increased mortality rates.[107] A response rate of 67% was reported in a clinical study in which HHV-6 was included in a multivirus-specific T-cell infusion.[91]

Multivirus Viral-Specific T-Cells

Some investigators have generated multiple-virus specific T-cells, with 2 ,3, 4, and 5 (EBV, CMV, adenovirus, BKV, and HHV-6) viruses included for use in both the prophylactic and treatment setting. Clinical studies have shown response rates from 67% to 100% with no increase in incidence of severe GVHD or other toxicity.[108,109]

CONCLUSION

Allogeneic HCT, initially performed in a twin patient with leukemia by Dr. E. Donnall Thomas in the late 1950s, was one of the first elegant demonstrations of the power of cellular therapy. Much has been learned since then, and our increased understanding of the immune system has translated into exciting new therapeutic approaches, especially relevant to transplantation and its complications, leading to continued better outcomes for patients.

MD ANDERSON PRACTICE TIPS

- Allogeneic HCT is curative for a subset of patients with hematologic malignancies.
- Adoptive infusion of CAR T-cells have shown remarkable efficacy for patients with refractory ALL and NHL; CAR T-cells in conjunction with transplant is under investigation.
- Infusion of allogeneic NK T-cells provide a readily available source of effective immunotherapy; trials are underway.
- The incorporation of post transplant cyclophosphamide has led to decreased rates of GVHD.
- Ruxolitinib is the first approved agent for steroid-refractory acute GVHD.
- VSTs can be very effective in patients with specific viral infections such as CMV, EBV, polyoma viruses BK and JC, adenovirus, and HHV-6.

Carl M. Gay

KEY CONCEPTS

- Small cell lung cancer (SCLC) is an aggressive malignancy for which outcomes remain poor. The majority of patients present with metastatic disease, and few patients are cured, even among those that present with early-stage disease. There is an urgent need for more effective therapies for this disease.
- For patients with stage I disease, surgical resection should be considered if mediastinal staging is negative. Adjuvant chemotherapy with four cycles of etoposide–cisplatin (EP) should be considered for all patients with surgically resected SCLC and no lymph node metastases found at the time of resection.
- Most patients with limited-stage disease are treated with concurrent chemoradiotherapy. Although carboplatin is frequently used in patients with extensive-stage disease, EP with twice-daily radiation therapy remains the standard of care in patients without contraindications to cisplatin.
- Numerous clinical trials have established the effectiveness of prophylactic cranial irradiation (PCI) in decreasing the incidence of intracranial disease, although its impact on survival has been variable. All patients with limited-stage disease who respond to treatment should receive PCI. The use of PCI in patients with extensive-stage disease remains controversial.
- First-line chemoimmunotherapy has recently been shown to improve survival in patients with extensive-stage disease. The development and understanding of biomarkers for response to immunotherapy is progressing and may improve outcomes for some patients.
- Treatment options are limited for patients with recurrent disease, and clinical trials are recommended when feasible. There are no approved targeted agents for SCLC despite a plethora of trials.

Small cell lung cancer (SCLC) is an aggressive bronchogenic carcinoma representing 14% of all lung cancers, accounting for approximately 30,000 new cases annually in the United States.[1] It is distinguished from non–small cell lung cancer (NSCLC) by its rapid doubling time and early metastatic dissemination. Regional lymph node involvement or distant metastasis is present in 90% or more of patients at diagnosis. Historically, SCLC has been staged as limited disease (LD), which is confined to the ipsilateral thorax of origin and regional nodes, versus extensive disease (ED). The recent International Association for the Study of Lung Cancer (IASLC) staging project and American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC), eighth edition, suggest use of the tumor, node, metastasis (TNM) system for the staging of SCLC.[2] Clinically, the limited- and extensive-stage classification is practical given that most patients present with advanced disease (stages III–IV) and are rarely candidates for resection or other definitive therapies.

Standard treatment for patients with LD (stages I–IIIB) includes both chemotherapy and radiation; chemotherapy is the mainstay of treatment for ED (stage IV). Although a dramatic response to initial therapy is usually observed, more than 95% of patients with ED and 80% to 90% of those with LD eventually have a relapse and die of their disease.

Despite extensive research, few substantive advances in the systemic treatment of patients with SCLC have been made for decades. However, molecular profiling and preclinical models of SCLC

have increased our understanding of the biology and genomic changes in the pathogenesis of SCLC. The use of immune checkpoint inhibitors has improved survival, and the translation of preclinical research to the clinic has brought promising data with targeted therapies, providing hope that further improvements in outcomes for patients are on the horizon.

EPIDEMIOLOGY

SCLC is uncommon in never smokers, who constitute only 3% to 5% of cases, and is commonly associated with intense tobacco exposure.[3,4] However, transformation to SCLC has been documented in never smokers with epidermal growth factor receptor (*EGFR*) mutation–positive adenocarcinoma of the lung, in the setting of resistance to tyrosine kinase inhibitors.[5] The original *EGFR* mutation is maintained in the SCLC, supporting the notion that the tumor evolved from transformation and is not a second primary cancer.

The incidence of SCLC has steadily declined, as illustrated by an analysis of the Surveillance, Epidemiology, and End Results (SEER) database,[1] in which the proportion of SCLCs decreased from 17% in 1986 to 13% in 2002. However, this decrease was accompanied by an increase in SCLC cases arising in women (28% in 1973 vs 50% in 2002), attributed to increasing tobacco use among women starting in the 1960s. The reduced incidence is primarily due to decreased smoking in men and may also be due in part to changes in the pathologic criteria leading to the classification of cases as large cell neuroendocrine carcinoma (LCNEC) that would have been previously classified as SCLC.

RISK FACTORS

Of all lung cancer subtypes, SCLC shows the strongest association with tobacco exposure, which represents the most important risk factor.[4] The risk is related to both duration (>40 years) and intensity of tobacco use (>30 cigarettes/day). This risk is lower in former smokers versus current smokers, although the risk in former smokers still exceeds that of nonsmokers.[4] Additional risk factors include exposure to asbestos, benzene, coal tar, and radon gas, usually as co-carcinogens with tobacco. Smoking cessation should be encouraged as primary prevention. Patients with LD who continue to smoke during or after chemoradiation experience increased toxicity, have a high risk of second lung cancers, and have shorter survival times than those who quit.[6]

NATURAL HISTORY

The natural history of SCLC was documented in the placebo arm of a randomized trial from the Veterans Administration Lung Cancer Study Group (VALSG) reported in 1969, testing the effect of three doses of intravenous (IV) cyclophosphamide.[7] In this trial, the median survival periods for patients in the placebo arm were 6 weeks for those with ED and 12 weeks for those with LD, based on the primitive staging studies that were available at that time. Because of the availability of modern staging techniques, outcomes in both groups would be likely better today. Cyclophosphamide increased the median survival by 75 days in both groups, tripling the survival time of patients with metastases and doubling that of patients with LD. This was the first observation foretelling the important role chemotherapy would come to play in management of patients with SCLC.

The use of effective combination chemotherapy and, in the case of patients with tumor amenable to definitive radiation, the use of multimodality treatment have improved survival of patients with SCLC.[1]

PROGNOSTIC FACTORS

The most important prognostic factor for SCLC is the stage because patients with LD have improved survival compared with those with ED.[8] Among patients with LD, good performance status (PS), age younger than 70 years, female gender, and normal lactate dehydrogenase (LDH) levels are predictive of a favorable outcome.[8] Among these patients, a small subgroup with very LD (no mediastinal involvement) was found to have a longer median survival time when treated with surgery.[9] In patients with ED, normal LDH, multidrug regimen treatment, and a single metastasis predicted better outcomes. Liver or cerebral metastases confer significantly shorter survival compared with bone, soft tissue, or bone marrow involvement.[10] Paraneoplastic syndromes (PNSs) may also predict outcome. Patients with the syndrome of ectopic corticotrophin (ACTH) secretion producing clinical Cushing syndrome have a dismal prognosis, with a low response to chemotherapy and poor control of hypercortisolism after treatment.[8] Lambert-Eaton myasthenic syndrome (LEMS), an autoimmune PNS, confers a more favorable prognosis, presumably because of immunity against the cancer.[11]

PATHOBIOLOGY

SCLC is defined by light microscopy as a malignant epithelial tumor consisting of small cells, with a round to fusiform shape, scant cytoplasm, finely granular

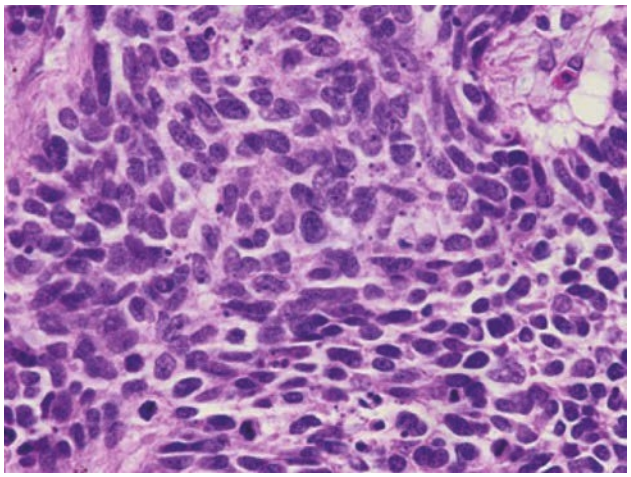

FIGURE 23–1 Light microscopic images of small cell lung cancer. Note the small, round, and spindle-shaped cells with hyperchromic nuclei and scant cytoplasm.

nuclear chromatin, and absent or inconspicuous nucleoli.[12] Nuclear molding and necrosis are frequent, and mitotic rates are high (Fig. 23–1). Tumors usually grow in diffuse sheets, but rosettes, peripheral palisading, organoid nesting, streams, ribbons, and rarely, tubules or ductules may be present. Typically, the diagnosis is made from small biopsies and cytology specimens because surgery is rarely performed. Because of significant crush artifact, biopsies are sometimes more problematic in diagnosis than cytology specimens.

SCLC is a "small, round, blue cell tumor" using a hematoxylin and eosin stain, and the differential diagnosis includes other small, round, blue cell tumors, including lymphomas and small cell sarcomas. Histologically, identical tumors can arise in other organs (eg, nasopharynx, larynx, genitourinary or gastrointestinal tract, and cervix) and are termed extrapulmonary small cell carcinomas. Both pulmonary and extrapulmonary small cell carcinomas have similar biological features and clinical behavior, with high potential for widespread disease. However, malignant cells from extrapulmonary small cell carcinomas do not exhibit 3p deletions, which are common in SCLCs, indicating, at least in part, differences in carcinogenesis.[13]

Immunohistochemical (IHC) markers are valuable in differential diagnosis of SCLC. Positive pancytokeratin (AE1/AE3) staining helps to identify the tumor as a carcinoma rather than a lymphoma or sarcoma.[12] Neural cell adhesion molecule (CD56), chromogranin, and synaptophysin are the most useful markers. Whereas CD56 expression is detectable in approximately 90% to 100% of cases, SCLC may be negative for expression of neuroendocrine markers, such as chromogranin and synaptophysin.[14] SCLC is a primitive undifferentiated high-grade neuroendocrine tumor (NET) and does not typically express these proteins as intensely as low-grade, well-differentiated NETs do, such as carcinoids. In 10% of cases, all neuroendocrine marker results may be negative, and the diagnosis can still be established if the morphology is diagnostic. Thyroid transcriptase factor 1 (TTF-1) is expressed in 70% to 90% of SCLCs; however, this marker may also be expressed in extrapulmonary small cell carcinomas and thus does not reflect lung origin.[15] The expression of TTF-1 may reflect molecular differences that could help guide treatment.[16] The Ki-67 staining index, reflecting proliferation, is generally greater than 50% in SCLC and can be used to differentiate SCLC from lower-grade NETs.[17]

MOLECULAR FEATURES

SCLC is characterized by genomic alterations, biology, and clinical behavior that are distinct from the intermediate- and low-grade pulmonary NETs. Loss of function alterations in the tumor suppressors tumor protein 53 (*TP53*) and the retinoblastoma 1 (*RB1*) gene at 13q14 occur in virtually all patients with SCLC.[18,19] Haploinsufficiency caused by allele loss in multiple areas on chromosome 3p, including 3p21.3,3p12,3p14.2, and 3p24.4, leads to absent or lower expression of several tumor-suppressor genes in more than 90% of SCLCs and is an early event in tumorigenesis.[13]

In addition to near-ubiquitous *TP53* and *RB1* inactivation, genomic profiling of SCLC tumors revealed frequent (25%) inactivating mutations in *NOTCH* family genes (PMID:26168399). Along with *NOTCH* family mutations, additional mutually exclusive alterations are frequent among histone acetyltransferase genes such as CREB-binding protein (*CREBBP*) and E1A binding protein P300 (*EP300*), as well as several genes related to *TP53* and *RB1* (tumor protein 73 (*TP73*), retinoblastoma-like 1 (*RBL1*), and retinoblastoma-like 2 (*RBL2*) ((PMID:26168399)). Amplification of MYC family members (v-myc avian myelocytomatosis viral oncogene homolog, MYC, MYCL1, and MYCN) is detected in 20% of SCLCs.[18] Loss of phosphatase and tensin homolog (PTEN) is observed in 2% to 4% of tumors[20]; however, the phosphoinositide 3-kinase (PI3K) pathway alteration rate be overall higher and promote SCLC tumorigenesis in preclinical models.

Differential patterns of gene expression underlie significant inter-tumoral diversity among SCLC (PMID: 20926931). The neuroendocrine-high (previously *classic*) SCLC subtype, now referred to as SCLC-A, is driven largely by the expression of the transcription factor achaete-scute homolog 1 (*ASCL1*) and its transcriptional targets (PMID: 2985258,27452466). Meanwhile, neuroendocrine-low (previously *variant*) SCLC is composed of several unique subtypes, including a neuronal differentiation 1 (*NEUROD1*)-regulated subtype

TABLE 23-1 Representative List of Common or Potentially Targetable Genomic and Proteomic Alterations According to Percentage in Small Cell Lung Cancer

Gene	Mutation Frequency (Type of Mutation)
TP53	75%–90% Loss of function (mutation, LOH, deletion)
RB1	~100% Loss of function (mutation, LOH, deletion)
PTEN	~5% Loss of function (mutation, LOH, deletion)
MYC	18%–31% MYC family alterations overall Gain of function (amplification or transcriptional dysregulation)
SOX2	27% Gain of function (amplification)
FGFR1	<10% Gain of function (amplification, mutation)
CCNE1	<10% Gain of function (amplification)
EPHA7	<10% Gain of function (amplification)
PARP1	>50% (overexpression of protein target)

CCNE1, cyclin E1; EPHA7, ephrin receptor A; FGFR1, fibroblast growth factor receptor 1; MYC, v-myc avian myelocytomatosis viral oncogene homolog; PARP, poly(ADP-ripose) polymerase 1; PTEN, phosphatase and tensin homolog; RB1, retinoblastoma 1; SOX2, sex-determining region Y box 2; TP53, tumor protein 53.

(SCLC-N) and a subtype originating in pulmonary tuft cells driven by the expression of POU domain, class 2, transcription factor 3 (*POU2F3*, SCLC-P) (PMID: 29852 58,27452466,28089889,29945888).

At the protein level, increased expression of cKit, and its ligand stem cell factor, is detected in up to 80% to 90% of SCLC surgical specimens.[21] The BCL-2 family proteins exert an antiapoptotic effect and may be upregulated in 75% to 95% of SCLCs.[18] More comprehensive proteomic profiling by reverse phase protein array has identified differences in protein expression between SCLC or LCNEC and other NSCLC cancers, including the DNA repair protein poly(ADP-ribose) polymerase 1 (PARP1).[22]

Alterations in epigenetic regulation of the genome may be involved in SCLC biology. Sequencing of SCLC exomes has led to the identification of histone modification as a major feature. Mutations in CREBBP and EP300 are common in SCLC and may clustered around the histone acetyltransferase (HAT) domain, significantly impacting the activity of these genes, and supports a role for the loss of their function in SCLC.[23,24] Table 23–1 describes common genomic and proteomic alterations that occur in SCLC.

CLINICAL PRESENTATION

SCLC typically arises in the central airways and infiltrates the submucosa, with a tendency to narrow the bronchial lumen through extrinsic or endobronchial spread, in contrast to squamous cell carcinomas, in which polypoid luminal occlusion is common. Rapid intrathoracic tumor growth, lymphatic and distant spread, and manifestation of PNSs can cause severe and progressive symptoms that lead to diagnosis generally within 3 months from onset. Common clinical manifestations include cough, dyspnea, weight loss, and debility. Hemoptysis and postobstructive pneumonia are relatively uncommon because of the submucosal growth pattern of the tumor. Bulky involvement of mediastinal lymph nodes is a hallmark of SCLC, and syndromes resulting from mass effects are commonly seen, including superior vena cava syndrome, hoarseness (from recurrent laryngeal nerve compression), phrenic nerve palsy, dysphagia (from esophageal compression), and stridor (from tracheal compression). SCLC is the most common malignant cause of superior vena cava obstruction. Radiographically, a large hilar mass with bulky mediastinal adenopathy is commonly observed (Fig. 23–2), although occasional peripheral satellite nodules may be found.

Most patients (60%–70%) present with overt metastatic disease; common sites of metastasis include liver, adrenals, bone, bone marrow, and brain. Symptoms of metastatic disease can include bone or abdominal pain, headache, seizures, fatigue, and anorexia. Occasionally, patients may present with PNSs, such as syndrome of inappropriate antidiuretic hormone (SIADH) or LEMS.

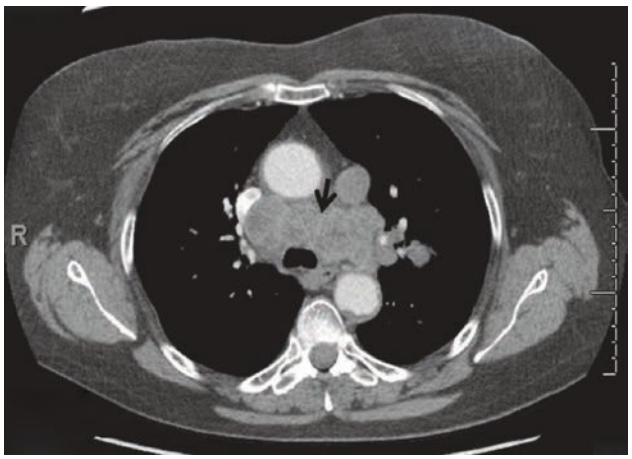

FIGURE 23–2 Bulky involvement of mediastinal adenopathy (*black arrow*) at computed tomography scan of chest in a patient with extensive-stage small cell lung cancer.

STAGING

The two-stage system originally proposed by the VALSG in the late 1950s and later modified by the IASLC is currently used for simplicity and practicality. LD is defined as a tumor confined to one hemithorax, with involvement of regional nodes, including contralateral mediastinal or ipsilateral supraclavicular nodes, that can be included in a single tolerable radiotherapy (RT) port (TNM stages I–IIIB). ED is defined as a tumor beyond the boundaries of LD, including distant metastases, malignant pericardial or pleural effusions, and contralateral supraclavicular and contralateral hilar node involvement (TNM stage IV, any T, any N, M1a/b). More recently, IASLC proposed changes to the TNM NSCLC staging system, mainly in T and M descriptors and stage groupings. These changes have been incorporated into the AJCC seventh and eighth editions, which recommend TNM staging for SCLC and NSCLC.[25] However, the two-stage system continues to be used in clinical practice because most patients present with advanced disease (stages III and IV) and are only rarely candidates for surgery. This system has prognostic significance and clinical implications because patients with LD are candidates for chemoradiation with curative intent, but patients with ED receive chemotherapy with or without immunotherapy and palliative radiation as clinically indicated. Approximately 30% to 40% of patients with SCLC present with LD; the remainder have ED.[1]

The initial clinical evaluation should include history and physical examination; chest radiography; pathology review; baseline laboratory tests, including complete blood cell count, a comprehensive metabolic profile, and LDH ;, computed tomography (CT) scans of the chest and abdomen with IV contrast; and brain magnetic resonance imaging (MRI) or CT scan with IV contrast. Brain MRI is more sensitive than CT in identifying metastases and is preferred. If LD is suspected, a positron emission tomography (PET)–CT scan may be indicated because it can identify distant disease and guide mediastinal evaluation. For most metastatic sites, a PET-CT scan is superior to other imaging modalities; however, it is inferior to MRI or CT of the brain for detection of brain metastases. Even though PET-CT may improve staging accuracy of SCLC, pathologic confirmation is still recommended for lesions depicted at PET-CT scan that may alter staging. If PET-CT scan is not available or is equivocal, bone imaging with a whole-body bone scan should be used to stage the skeleton.[26]

Staging should not focus only on symptomatic sites of disease or on altered laboratory data. For example, bone scans may be positive in up to 30% of asymptomatic patients without abnormal alkaline phosphatase levels. The goal of complete staging is to identify patients with LD who are candidates for definitive therapy. In the presence of obvious ED, staging may be clinically directed. Brain imaging should be obtained in all patients, given the morbidity of uncontrolled central nervous system (CNS) disease.[27] Imaging of the CNS reveals brain metastases in 10% to 15% of patients at diagnosis, with 30% of these individuals asymptomatic.

In patients with apparent stage I disease (T1-2N0), surgical resection should be considered if mediastinal staging results are negative[9] by conventional mediastinoscopy, transesophageal endoscopic ultrasound-guided fine-needle aspiration, endobronchial ultrasound-guided transbronchial needle aspiration, or video-assisted thoracoscopy. If a pleural effusion is present in a patient with otherwise LD, thoracentesis should be performed and fluid sent for cytology. If the fluid is exudative or if malignant cells are present, the patient should be considered to have ED (stage IV: M1a). Although most pleural effusions in lung cancer are related to the malignancy, there may be a few instances in which multiple cytopathological examinations are negative for malignancy and the pleural fluid is not an exudate. When these elements and clinical judgment indicate that a pleural effusion is not malignant, the effusion should be excluded as a staging element. Pericardial effusion is classified according to the same criteria.

Sampling of cerebrospinal fluid is indicated if leptomeningeal spread is suspected. Pulmonary function tests should be performed in patients who are candidates for definitive chemoradiation therapy. Severe anemia, nucleated red blood cells on peripheral smear, neutropenia, or thrombocytopenia, in the absence of other obvious causes are selection criteria for bone marrow aspiration and biopsy.[10,26] The presence of tumor cells in a marrow biopsy identifies ED. Treatment should be initiated as quickly as possible after diagnosis is confirmed, given the rapid rate of progression. If the patient is significantly symptomatic or the staging evaluation prolonged, staging should be completed while chemotherapy is started.

TREATMENT

Limited Disease

Patients with SCLC rarely survive more than a few months without treatment. The disease is highly responsive to both chemotherapy and radiation, and patients with LD are treated with curative intent. In LD, the overall response rates (RRs) to combined chemoradiation are typically 80% to 90%, including 50% to 60% complete RRs. Median overall survival (OS) is approximately 17 months, and the 5-year survival rate is approximately 12%.

Surgery

An autopsy series on patients who died from postoperative complications revealed that 90% of patients with SCLC had mediastinal metastasis within 30 days after surgical resection.[28] A randomized trial evaluating surgery versus thoracic RT (TRT) in patients with resectable disease revealed that the TRT group had significantly longer OS,[29] suggesting that even in absence of diagnosed metastases, surgery alone is an inadequate therapeutic strategy. However, surgery may play a role in multimodality therapy for patients (5%) with early T stage and without nodal involvement (T1-T2N0M0, very LD). A 5-year survival rate of 48% has been reported in patients with very LD when surgery was followed by adjuvant chemotherapy.[9] Adjuvant chemotherapy with four courses of etoposide–cisplatin (EP) should be considered for all patients with surgically resected SCLC. If nodal involvement is found at the time of surgery, chemoradiation and chemotherapy are recommended.

Combined Chemoradiation Therapy

Based on the results of a British Medical Research Council trial demonstrating surgery to be inferior to RT for the treatment of LD,[29] TRT became standard of care for local control for these patients. Although early studies indicated that RT could increase local control compared with chemotherapy alone, these studies did not consistently show significant survival benefits to combination therapy over chemotherapy.[30] Because of this controversy, randomized trials were performed. Two meta-analyses were performed that showed a significant 2-year survival benefit of 5.4% with the addition of RT to systemic chemotherapy for patients with LD.[30,31] Notably, the best outcomes from these older trials included concurrent as opposed to sequential approaches; in addition, the regimens used in this era were anthracycline- and alkylator-based therapies and were associated with excessive in-field toxicity when administered with concurrent radiation. The development of the EP regimen was critical to improving the tolerance and feasibility of concurrent chemoradiation. EP can be given at full dose with RT, leading to improved disease control.

An anthracycline-based regimen (cyclophosphamide, epirubicin, and vincristine [CEV]) was compared in a phase III trial with EP in patients with SCLC.[32] Patients received RT concurrently with the third cycle of chemotherapy, and prophylactic cranial irradiation (PCI) was administered to those who achieved complete remission (CR). The results showed that, in patients with LD, EP was superior to CEV for survival rates at 2 and 5 years (14% and 5% vs 6% and 2%, respectively; $P = .0001$), as well as median OS (14.5 vs 9.7 months; $P = .001$). In patients with ED, no survival difference was noted.

The addition of other chemotherapeutic agents to the EP regimen—either as a triplet with paclitaxel or alternating therapy with cyclophosphamide, doxorubicin, and vincristine—has also been studied, but to date a new standard in the treatment of LD has not emerged.[33,34]

Radiation Intensity

Based on the radiobiology of SCLC, the Intergroup (INT) trial 0096 studied accelerated hyperfractionated RT (AHRT) compared with conventional fractionation in a phase III trial.[35] More than 400 patients were randomized between the two arms. All patients received four cycles of EP, and TRT was administered concurrently, starting with the first cycle of chemotherapy. All patients received 45 Gy, either in once-daily 1.8-Gy fractions for 5 weeks or twice-daily 1.5-Gy fractions for 3 weeks. Patients in the twice-daily RT group had an improved median OS (23 vs 19 months) and 5-year survival (26% vs 16%), at the cost of increased weight loss and grade 3 esophagitis (27% vs 11%). Local failure rates were lower in the twice-daily RT arm, presumably the major reason for improved survival.

Intergroup trial 0096 convincingly showed an OS benefit to concurrent chemoradiation with hyperfractionation. However, because of concerns for side effects and the logistical difficulties involved in twice-daily treatment, the regimen was not widely adopted.[36] The control arm of the INT 0096 study used a relatively low total RT dose, and since the results of INT 0096 have become available, conventionally fractionated radiation in higher doses has also been studied. The Cancer and Leukemia Group B (CALGB) trial tested the regimen paclitaxel and topotecan for two cycles followed by TRT with 70 Gy in 35 daily fractions with concurrent carboplatin–etoposide (CE; total of three cycles) in a phase II study.[37] Median OS was 22.4 months, comparable to that found with AHRT in the INT 0096 study.

Another schedule of TRT tested was concomitant boost, in which patients received once-daily radiation through most of their course and then received hyperfractionated therapy at the end of treatment so that RT was accelerated without the need for twice-daily administration throughout the treatment course. The Radiation Therapy Oncology Group (RTOG) tested this approach in the phase II trial 0239. Patients received 61.2 Gy over 5 weeks, with twice-daily RT in the final 9 days.[38] RT started on day 1 of chemotherapy with four cycles of EP. The two-year survival rate was 37%, somewhat less than that found in both INT 0096 and the CALGB trial (2-year survival rates of 41% and 48%, respectively).

In the phase III CONVERT trial, patients were randomized to receive either 45-Gy RT in twice-daily fractions of 1.5 Gy over 19 days or 66-Gy RT in 33 once-daily fractions of 2 Gy over 45 days while receiving EP chemotherapy. The primary endpoint was OS, and there was no significant difference between the groups. Toxicities were similar between the groups, and twice-daily chemoradiotherapy continues to be the standard of care.[39]

Timing of Chemotherapy

Sequential, concurrent, and alternating chemotherapy have all been tested with TRT. Early studies did not show a survival benefit to concurrent chemotherapy, likely because of the increased toxicity when using cyclophosphamide- or doxorubicin-based chemotherapy. EP is better tolerated than these earlier regimens when administered concurrently with RT.

The National Cancer Institute of Canada reported a phase III trial of alternating CAV (cyclophosphamide, anthracycline, and vincristine)–EP with TRT in either the second or sixth cycle of chemotherapy.[40] The patients receiving early RT experienced improved OS (21.2 vs 16 months). The Japan Clinical Oncology Group compared RT (45 Gy in twice-daily 1.5-Gy fractions) starting with either the first cycle of EP or after completion of the chemotherapy course.[41] More myelosuppression was noted in the patients in the concurrent arm, but there was a significant reduction in risk of death for early concurrent therapy, with a hazard ratio (HR) of 0.70 (P = .02). Although not all trials have consistently shown a benefit for concurrent chemoradiation, the data strongly support this and its early integration in treatment when the regimen is EP. Furthermore, efficacy outcomes are consistently better with EP in the treatment of LD.

Given that SCLC is such a rapidly dividing malignancy, it has been hypothesized that accelerated proliferation of tumor clonogens can affect outcome and that treatment should be delivered in a condensed fashion.[42] A meta-analysis examined the impact of a novel parameter, time from the start of any treatment to the end of RT (SER), on OS in LD. A shorter SER was found to be a significant predictor of better outcome. For each week that the SER was lengthened, OS at 5 years showed an absolute decrease of almost 2%.[42] The data from INT 0096 had a strong influence on this result.

Carboplatin is frequently used in ED because of a more favorable toxicity profile, whereas cisplatin is preferred in patients with LD with curative intent. The efficacy of cisplatin versus carboplatin regimens in LD was evaluated in a meta-analysis of four trials,[43] which revealed no significant difference in terms of efficacy. Nevertheless, because of its use in trials for which the best 5-year survival rate has been observed in LD, EP should be given unless there is a significant contraindication to cisplatin use. Notably, the dose of cisplatin in INT 0096 was only 60 mg/m.[2] Figure 23–3 illustrates the treatment algorithm for management of limited-stage SCLC.

Extensive Disease

Systemic chemotherapy represents the primary therapeutic modality for patients with ED, although the addition of immunotherapy to first-line chemotherapy has been shown to improve survival.[44] Currently, TRT is used for symptom palliation; however, a potential role for radiation in patients with limited systemic disease and a good response to initial therapy has been suggested. Chemotherapy prolongs survival compared with best supportive care (BSC).[7] From the time of diagnosis, the median OS for patients with ED is 8 to 13 months, the 5-year survival rate is 1% to 2%, and the 2-year survival rate is 4% to 5%.[1] Figure 23–4 shows representative coronal PET-CT images in a patient with extensive-stage SCLC (ED).

Chemotherapy

In an early study, patients with SCLC had a highly significant improvement in survival with IV cyclophosphamide compared with placebo, increasing the median period survival from 12 weeks to almost 5 months.[7] As new cytotoxins became available, combination therapy was studied, and the CAV regimen became the standard of care for patients with ED. EP was initially evaluated in patients who had recurrent disease after or failed to respond to CAV, with RRs of 55%.[45] It was later evaluated as a first-line treatment in patients unable to tolerate CAV, demonstrating a median OS of 39 weeks in ED, with less toxicity.[46] In a phase III trial, the equivalent efficacy of EP and CAV was confirmed by randomizing 437 patients to receive four cycles of EP, six cycles of CAV, or alternation of these two regimens for 18 weeks (CAV/EP, three cycles each).[47] The RRs (61%, 51%, 59%, respectively) and median OS (8.6, 8.3, and 8.1 months, respectively) were equivalent across the arms. Myelosuppression was the dose-limiting toxicity, and four cycles of EP were better tolerated. Similar results were seen in a Japanese trial.[33]

Chemoimmunotherapy

The high mutation rate in SCLC led to the hypothesis that the addition of immunotherapy to chemotherapy could enhance the antitumor immune response. However, early trials of immune checkpoint inhibition did not improve outcomes. In a phase II study of 45

patients with ED who had a response or stable disease with induction chemotherapy received maintenance therapy with pembrolizumab, a monoclonal antibody directed at programmed cell death protein 1 (PD-1). The median PFS was 1.4 months (95% confidence interval [CI], 1.3–2.8), which was not improved compared with historical data. However, 13% of patients had PFS of at least 1 year, and 37% of patients had OS of at least 1 year, suggesting that an unknown subset of patients could have benefitted from this therapy.[48] Ipilimumab, a monoclonal antibody directed against CTLA-4 (cytotoxic T lymphocyte-associated antigen 4), was given in sequential combination with carboplatin–paclitaxel in a randomized phase II of 130 untreated patients with SCLC. There was improved PFS (HR, 0.64; $P = .03$) but not OS (median, 12.5 vs 9.1 months for the sequential combination vs chemotherapy alone; $P = .13$).[49] In a subsequent phase III study of more than 1110 patients with newly diagnosed ED, the regimen of EP plus ipilimumab was compared with EP plus placebo. The addition of ipilimumab did not improve the median OS, which was approximately 11 months in both treatment groups.[50]

More recently, the IMpower133 study combined atezolizumab with chemotherapy in newly diagnosed ED. In this double-blind, placebo-controlled, phase III trial, patients were randomly assigned to receive EP plus atezolizumab followed by maintenance atezolizumab compared with EP plus placebo followed by maintenance placebo. The median OS was 12.3 months in the atezolizumab group compared with 10.3 months in the placebo group (HR, 0.70, $P = 0.007$).[44] The results of this study represented the first significant improvement in OS for patients with ED in multiple decades, and this regimen is now the standard-of-care regimen for the first-line treatment of ED.

The therapeutic value of immunotherapy as shown in the IMpower133 study was confirmed in another recent phase III clinical trial, the CASPIAN study. In this study, patients were randomly assigned to receive durvalumab, an inhibitor of PD-L1, plus platinum–etoposide, durvalumab plus tremelimumab, an inhibitor of CTLA-4, plus platinum–etoposide or platinum–etoposide alone. At a median follow-up period of 14.2 months, the median OS was 13.0 months with durvalumab plus chemotherapy (95% CI, 11.5–14.8) and 10.3 months (95% CI, 9.3–11.2) with chemotherapy alone. Furthermore, the objective RR was higher with durvalumab plus chemotherapy (79% vs 70%), although there was no difference in the median duration of response.[51] This trial is ongoing, and results for the durvalumab plus tremelimumab plus chemotherapy group have not yet been reported. The impact of the addition of immune checkpoint inhibitors to conventional chemotherapy on the survival of patients with ED will be clarified as data mature. As the development and understanding of biomarkers for response to immunotherapy progress, outcomes may continue to improve for some patients.

Thoracic Radiation Therapy

Prospective trials have evaluated the role of consolidative TRT in patients with ED who initially respond to systemic chemotherapy. In a single-center study, 206 patients received three cycles of EP,[52] and complete responders at distant sites and those with intrathoracic partial remission (PR) or CR ($n = 109$) were randomized to thoracic AHRT (54 Gy, 36 fractions over 18 days) combined with CE or four additional cycles of EP. Patients with brain metastases, stable disease, progressive disease, or only PR outside the thorax were not randomized. The addition of TRT to chemotherapy improved median OS (17 vs 11 months; 5-year survival rate, 9% vs 4%, respectively; $P = .041$). There was a trend toward reduced local recurrence in the radiation arm but no difference in metastasis-free survival. Acute high-grade toxicity was higher in the chemotherapy arm.

In the phase III multicenter European CREST trial, patients with ED were initially treated with four to six cycles of platinum-based chemotherapy. Patients with any response were then randomized to TRT (30 Gy in 10 fractions) plus PCI ($n = 247$) or to PCI alone ($n = 248$).[53] The study did not meet the primary end point of 1-year survival improvement (33% with thoracic RT vs 28% without; $P = .07$). However, 2-year survival and PFS rates were significantly longer for those receiving TRT after prolonged follow-up (2-year OS, 13% vs 3%; $P = .004$; PFS, 24% vs 7%, respectively, at 6 months). The most common grade 3 toxicities in the TRT group compared with the control group were fatigue (4.5% vs 3.2%) and dyspnea (1.2% vs 1.6%). Patients most likely to benefit were those with residual disease in the thorax.

The RTOG 0937 phase II study (NCT 01055197) comparing PCI alone versus PCI with consolidative RT to residual locoregional and metastatic disease in patients with ED who responded to platinum-based chemotherapy was closed early due to excess grade 5 toxicity in the experimental arm. Currently, it is our practice to consider consolidative TRT in selected patients with ED with excellent control of extrathoracic disease, residual disease in the thorax, and retained PS after chemotherapy. Thoracic RT should be limited to palliative dosing and conventional fractionation, and concurrent chemotherapy should not be given.

Figure 23–5 demonstrates metabolic response on PET in a patient with ED and extensive bone metastases after four cycles of CE. Figure 23–6 shows the treatment algorithm for the management of extensive-stage SCLC.

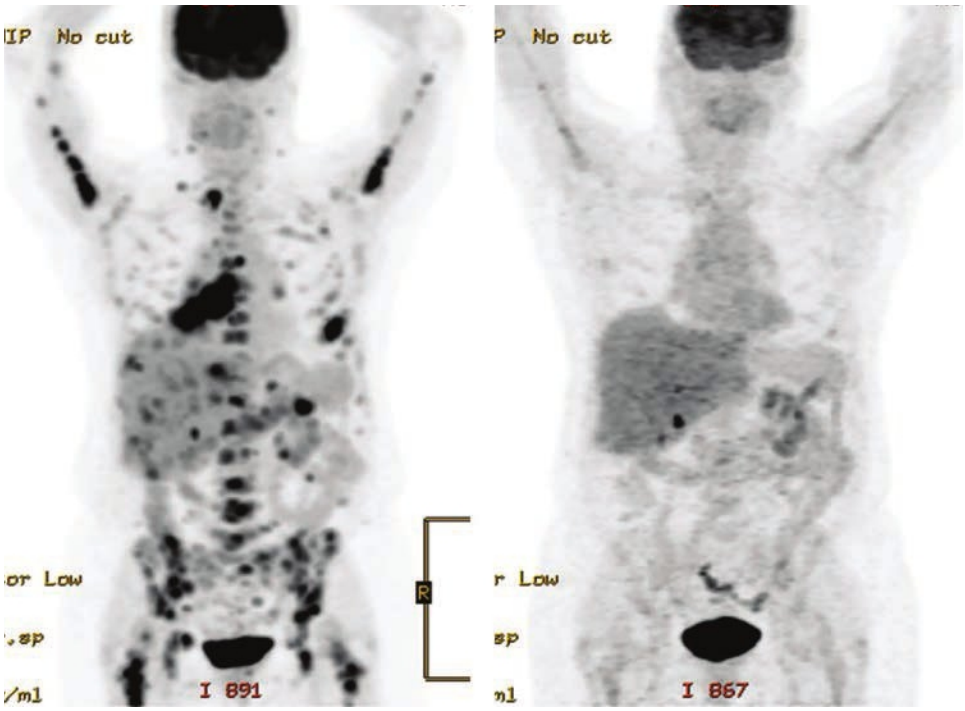

FIGURE 23–5 **Response of extensive-stage small cell lung cancer following treatment with platin–etoposide at positron emission tomography (PET)–computed tomography imaging. Baseline (A) and restaging coronal PET (B) images are shown.**

Recurrent Disease

Chemotherapy and Immunotherapy

Despite initial response to chemoradiation, approximately 11% of patients with LD and only 1% to 2% of those with ED are alive at 5 years, with the vast majority succumbing to recurrent SCLC.[1] Historically, recurrent disease is less responsive, and survival is limited, with the median survival period ranging from 2 to 6 months after relapse. The response to initial treatment and the time to relapse after induction chemotherapy are both important determinants of response to second-line chemotherapy. Patients with objective response to initial treatment and PFS at least 60 to 90 days after completion of induction chemotherapy are

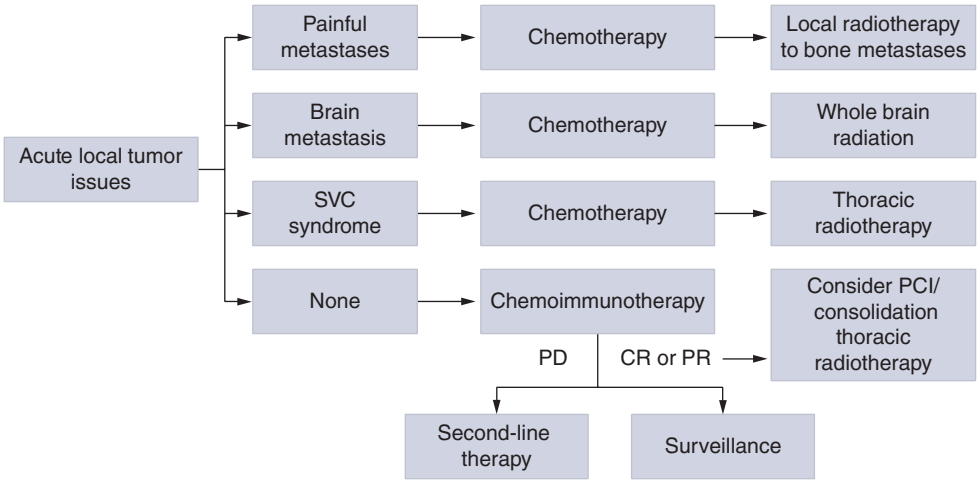

FIGURE 23–6 **Treatment algorithm for management of patients with extensive-stage small cell lung cancer. CR, complete remission; PCI, prophylactic cranial irradiation; PD, progressive disease; PR, partial remission; SVC, superior vena cava.**

more likely to respond to additional chemotherapy and are considered to have "sensitive" disease. Those who do not achieve disease regression with initial chemotherapy or with shorter duration of response after chemotherapy is discontinued are considered refractory.[54]

Reintroduction of the chemotherapy regimen used for induction has been a therapeutic strategy for relapse in patients with prolonged PFS after first-line therapy. The first evidence to support this was suggested in a series of six patients who had achieved a greater than 2-year remission after induction chemotherapy.[55] Five of these patients received some or all of the agents of their induction regimen, with four responses, lasting up to 18 months. Other studies also suggested responses when first-line therapy was reintroduced at relapse if patients had either a CR or a response longer than 34 weeks after induction.[56,57] In the modern era, when many patients receive just four courses of induction chemotherapy, retreatment with EP could be considered if initial response was dramatic and maintained PFS for 3 months or more.

Topotecan and irinotecan have been studied in recurrent disease. Topotecan is the only drug for which there are several randomized trials in this setting and is the only agent approved by the Food and Drug Administration (FDA) in the second-line setting for recurrent SCLC. Oral topotecan was found to have similar efficacy to IV topotecan, with less toxicity and ease of administration.[58] A phase III trial showed that IV topotecan had similar efficacy to the CAV regimen in patients with sensitive relapse, with an RR of 24% versus 18%, with a similar median TTP (13 vs 12 weeks) and OS (25 vs 24.7 weeks) for topotecan versus CAV, respectively.[54] The topotecan group had better symptom control, with less-severe neutropenia. The improvement in symptom control led to its FDA approval. In a phase III registration trial, oral topotecan was compared with BSC in patients who had relapsed 45 days or more after achieving a response to first-line therapy and were not candidates to receive IV topotecan.[59] Topotecan significantly improved OS (25.9 vs 13.9 weeks), including significant benefit in patients who relapsed 60 days or less after initial treatment, and was associated with a slower deterioration in quality of life. In a phase III trial, 304 patients with sensitive relapse were randomized to oral (2.3 mg/m^2 daily for 5 days) or IV (1.5 mg/m^2 daily for 5 days) topotecan every 3 weeks.[58] The RRs and the median and 1-year survival rates as well as the toxicity profiles were similar between the two arms (18% vs 22%, 33 vs 35 weeks, and 33% vs 29%, respectively). Topotecan is typically administered on days 1 to 5 of a 3-week cycle. Irinotecan has not been directly compared with topotecan, and phase III trials have not been performed; phase II studies suggested similar efficacy compared with topotecan in the recurrent setting.[60]

Temozolomide (TMZ) is a well-tolerated oral alkylating agent with an overall response rate (ORR) of 16% in a small phase II study.[61] In this study, the RRs were 23% in patients with platinum-sensitive disease, 13% in patients refractory to platinum, and 38% in brain metastases.

The CheckMate 032 study evaluated the efficacy and safety of nivolumab and nivolumab plus ipilimumab in patients with recurrent disease after the failure of platinum-based chemotherapy.[62] Patients were randomized to receive nivolumab or nivolumab plus ipilimumab for four cycles followed by nivolumab maintenance. The objective RR was 21.9% in patients receiving nivolumab plus ipilimumab compared with 11.6% with nivolumab alone. However, the median OS was similar between the two groups (5.7 months vs 4.7 months). This study has led to the inclusion of nivolumab with or without ipilimumab to the National Comprehensive Cancer Network SCLC Guidelines as an option for the treatment of recurrent, platinum-refractory disease. Furthermore, nivolumab monotherapy is FDA approved for use in the third-line setting. Pembrolizumab is also approved in the third-line setting based on the results of the KEYNOTE-158 study,[63] in which the ORR was 19%. Among patients that responded, the durations of response were greater than or equal to 18 months and 18 months in 56% and 63%, respectively.

BRAIN METASTASIS

The brain is a common site of metastasis in patients with SCLC, with 10% of patients presenting with brain involvement at diagnosis and an additional 40% to 50% developing CNS metastasis during the course of disease.

Whole-Brain Radiation Therapy

Whole-brain radiation therapy (WBRT) rapidly resolves symptoms of brain involvement from SCLC. RT with 30 Gy in 10 daily fractions has been shown equally effective as altered fractionation to a higher dose (54 Gy in 34 fractions) in the phase III trial RTOG 9104,[64] which evaluated these WBRT regimens in 429 patients with unresected brain metastases, including 39 patients with SCLC. Median OS was 4.5 months in both arms; the 1-year survival rate was also similar, at 19% with accelerated fractionation and 16% on the control arm.

Reirradiation of the CNS may be considered (20 Gy in 10 fractions) for symptom palliation in recurrent intracranial disease.[65] Stereotactic radiosurgery (SRS) represents a therapeutic option for progressive brain metastases following WBRT. The technique uses external irradiation beams that deliver a single high dose

of radiation to a small volume of tissue with minimal invasion of and injury to healthy tissue. SRS for brain metastases after WBRT from SCLC (fewer than four sites) is safe and achieves 1-year local control of 60% to 90%, especially in lesions smaller than 2 cm[66]; however, regional CNS recurrence risk approaches 60%.

Chemotherapy

In general, RRs to chemotherapy in brain metastases mirror those in extracranial disease sites, with higher rates in therapy-naïve patients. In a meta-analysis, a 36% RR in the CNS was revealed in the results of five trials in which 135 patients with brain metastases were treated after initial therapy with single-agent etoposide or carboplatin. Pooled data from another five studies conducted in 64 patients with brain metastases at diagnosis treated with various combination regimens showed a RR of 66%.[67]

In summary, for treatment-naïve patients who present with CNS involvement and are asymptomatic or minimally symptomatic, chemotherapy should be given initially, and if brain disease is controlled, WBRT may be given after completion of four cycles of chemotherapy. Brain irradiation should ultimately be administered given that it is associated with higher CR of brain metastases compared with chemotherapy alone. Symptomatic CNS involvement or progression of brain metastases during chemotherapy is an indication for WBRT. The approach of combining WBRT and induction chemotherapy must be considered in situations in which brain disease is bulky and symptomatic and there is also significant extracranial disease requiring urgent treatment. Myelosuppression is increased with concurrent modalities, and this should be expectantly managed. For patients who develop CNS involvement after initial chemotherapy, WBRT is indicated, and chemotherapy may have a palliative role in those who progress after receiving WBRT. Occasionally, previously irradiated patients with SCLC are candidates for SRS; however, the rate of brain failure is high.

PROPHYLACTIC CRANIAL IRRADIATION

Despite only 10% of patients with SCLC initially presenting with CNS involvement, there is a significant rate of occult brain disease in patients who lack neurologic symptoms; thus, staging of the brain is indicated in all patients. Approximately 15% to 20% of patients with LD SCLC who initially respond to therapy will develop brain metastases as the sole site of relapse, suggesting that brain radiation early in the treatment course might be curative in this group.[68] The risk of developing brain disease in patients alive at 2 years after diagnosis who did not receive PCI is between 50% and 80%.[68] PCI has been investigated as a means to control brain metastatic disease after chemotherapy before it becomes clinically evident, in an effort to prevent morbidity and mortality. Numerous clinical trials have established the effectiveness of PCI in decreasing the incidence of intracranial disease in patients who have responded to initial treatment for LD and ED, although its impact on survival has been variable.

Prophylactic Cranial Irradiation in Limited Disease

The PCI Overview Collaborative Group meta-analysis evaluated seven randomized trials comparing PCI (treatment group) versus no PCI (control group) in 987 patients with SCLC who achieved CR to initial therapy. Approximately 85% of the patients enrolled in both groups had LD. The PCI provided a 5.4% improvement in 3-year survival rate (15.3% vs 20.7% in control vs treatment group, respectively), increased disease-free survival (P <.001), and decreased the risk of developing brain disease (33% vs 59%, HR 0.46; P <.001).[68] A second meta-analysis evaluated 1547 patients from 12 randomized studies, five of whom required CR status for randomization.[69] The results of the second analysis confirmed the reduced rate of brain metastasis for all patients but improvement in OS only for patients in CR (HR, 0.82; 95% CI, 0.71–0.96). Based on these data, PCI became standard of care for patients with LD and disease control after chemoradiation.

Two large, randomized trials have investigated the effect of RT doses above 25 Gy. A multinational phase III trial randomized 720 patients with LD and CR after induction therapy to receive PCI at 25 Gy in 10 fractions or 36 Gy (18 fractions of 2 Gy each or 24 fractions of 1.5 Gy twice daily).[70] No significant differences were noted in the 2-year incidence rates of brain metastasis, and an increased mortality rate was noted with higher PCI doses (2-year survival rate 37% vs 42%; HR, 1.20). The phase II randomized RTOG 0212 study similarly showed no differences in the incidence of brain metastasis or OS benefit in patients with LD and CR after initial chemoradiation comparing PCI with 25 Gy to 36 Gy.[71]

Prophylactic Cranial Irradiation in Extensive Disease

An early European Organization for Research and Treatment of Cancer (EORTC) study suggested a benefit to PCI in ED, but this study had limitations in its design, and its conclusions were not supported

by a more recent study. The EORTC study randomized patients with ED with response to initial chemotherapy to either PCI (choice of three schedules) or observation.[72] Baseline imaging of the brain was required only for symptomatic patients. Overall, 286 patients were randomized. Patients in the PCI group had a lower risk of brain metastases (15% vs 40%; HR, 0.27; P <.001) and a longer median OS from time of randomization versus the observation group (6.7 vs 5.4 months, respectively). It is notable that more patients in the PCI group received second-line chemotherapy (68% vs 45%), possibly accounting for the OS improvement. Fatigue was significantly worse on the PCI arm in the first 24 weeks. Global health status and cognitive functioning were assessed only up to 9 months from randomization and were a mean of 8 points less (scale of 0–100) at 6 weeks and 3 months on the PCI arm.[73] These results are difficult to interpret given the lack of brain imaging at baseline and heterogeneity in both chemotherapy and PCI schedules. Furthermore, the 1.3-month OS improvement could be attributed to an imbalance in subsequent chemotherapy use, which is known to influence survival.

The more recent Japanese trial evaluated the efficacy of PCI versus observation in 224 patients with SCLC who had response to induction chemotherapy with either etoposide or irinotecan and cisplatin.[74] Before randomization, brain MRI was performed to rule out occult metastases, and patients on both arms were followed postrandomization with serial brain imaging. PCI was given as 25 Gy in 10 fractions. The accrual was stopped early for futility when analysis after 111 deaths revealed a trend toward shorter median survival with PCI (10.1 vs 15.1 months; HR, 1.38; P = .091). As expected, decreased incidence of brain metastases with PCI at 1 year (32% vs 58%; P <.001) was observed, and fewer patients treated with PCI required RT for symptomatic brain involvement (31% vs 80%). The high rate of brain metastases in both arms of this study (48% with PCI; 69% with observation) supports the need for MRI surveillance in all patients with ED.

In summary, PCI clearly decreased the incidence of symptomatic brain disease in SCLC, but the impact on OS in patients with ED was variable. It is reasonable to discuss PCI in patients with ED who have a CR or very good PR to initial treatment and good PS. The lack of definite survival benefit and the potential for at least short-term toxicity should be discussed. It should be used with caution in older adults and in patients with significant ischemic cerebrovascular disease because of a concern for increased acute and late brain toxicity. It is important to separate PCI from chemotherapy and to use radiation regimens that are safe in regard to late neurotoxic effects (e.g., 25 Gy in 10 daily fractions).

OLDER ADULT AND INFIRM PATIENTS

Approximately 25% of patients with SCLC are older than the age of 70 years. These patients have often been excluded from clinical trials because of concerns for greater toxicity because of lowered organ reserves, especially myelosuppression and frequently lowered functional status because of comorbidities. However, retrospective studies have shown that older adult patients with retained PS have improved outcomes with more aggressive treatment.[75] In a Canadian analysis, older adult patients 70 years of age or older who received four or more cycles of CAV or EP had a median survival time of 10.7 months; those patients who received three or fewer cycles had a median survival time of 3.9 months; and untreated patients survived a median time of 1.1 months.[76] Multivariate analysis showed that neither increasing age nor comorbidities was an adverse prognostic factor. This review reported that PS, stage, and treatment were the most important prognostic features. Additional studies have confirmed these conclusions, whereas only one retrospective Australian review reported that the complications from therapy adversely affected outcome in older adults.[77] In a retrospective cohort study examining the impact of chemotherapy on survival among patients 65 years and older with SCLC selected from the SEER database,[78]67% of the patients received chemotherapy, mainly EP or CE, which provided a 6.5-month improvement in median survival (P < .001), even in patients older than 80 years of age.

With regard to radiation tolerance in the case of LD, older adult patients have been reported to have increased toxicity. Analysis of the patients older than 70 years of age in the INT trial 0096 (EP with conventional TRT vs AHRT) showed that they experienced a higher rate of treatment-related death (older than 70 years vs 70 years or younger: 10% vs 1%, respectively).[79] However, the 5-year OS rate for older adult patients was 16%, similar to that in the control arm overall. Altered fractionation did not appear to benefit the older adult subgroup.

In summary, patients with good PS and no significant organ dysfunction should receive full-dose chemotherapy and RT. Their higher risk of treatment-related death implies a need for close monitoring and intense supportive care. Patients with severe comorbidities, a worse PS before diagnosis, or the very old may require a change in strategy from standard of care. A meta-analysis of randomized trials evaluating patients with "poor-risk" SCLC (generally ED) has shown a benefit of combination chemotherapy over single-agent oral etoposide.[80] These trials reported that IV combination regimens palliated symptoms better and improved median PFS and OS. Therefore, in patients with a poor

PS, initial treatment should be combination chemotherapy. EP is recommended over cyclophosphamide- or doxorubicin-based regimens in the older adult population because it is less myelosuppressive.[75] Several studies have evaluated the CE regimen in the older adult population.[81,82] With the exception of the trial reported by Samantas et al,[81] which used low doses of both agents, studies using CE have shown good RRs and tolerance in older adult patients.

In conclusion, carboplatin (area under the curve, 5) and etoposide (100 mg/m^2 for 3 days) can be recommended for most patients with SCLC considered "high risk" on the basis of age, comorbidities, or reduced functional status. The time of highest risk for treatment-related mortality is in the first cycle. Prophylactic use of bone marrow growth factors such as pegfilgrastim is recommended in this group when chemotherapy is given alone. The use of marrow growth factors is contraindicated during concurrent chemoradiation; thus, modest dose reduction and conventional fractionation should be considered. Continued research in this area, especially in the very old, is needed.

TARGETED AGENTS

There are no approved targeted agents for SCLC despite a plethora of trials over the past 15 years. Angiogenesis inhibitors, tyrosine kinase and other signal transduction inhibitors, and BH3 mimetics targeting apoptosis have not demonstrated substantial promise in early-phase trials, and none has been validated in phase III studies.[83–86] However, early experience with the Aurora A kinase inhibitor alisertib and inhibitors of poly(ADP-ribose) polymerase (PARP) showed promise.

Aurora A Kinase Inhibitors

Data in SCLC cell lines and xenografts indicate that expression of MYC is correlated with sensitivity to Aurora A kinase inhibition.[87] In a phase II study of alisertib (50 mg by mouth twice a day for 14 days every 21 days) in solid tumors, a partial RR of 15% was observed in 47 patients with relapsed SCLC.[88] In a randomized, double-blind, phase II study of alisertib plus paclitaxel as second-line treatment for SCLC, patients were randomized to alisertib plus paclitaxel or placebo plus paclitaxel. The median PFS was 3.3 months with alisertib plus paclitaxel compared with 2.17 months with placebo plus paclitaxel in the intent-to-treat population. However, among patients with cell cycle regular mutations, median PFS was improved to 3.68 months with the addition of alisertib compared with 1.80 months. In this group of patients, median OS was 7.2 months with alisertib plus paclitaxel and 4.5 months with placebo plus paclitaxel. Median PFS was also improved in patients with c-MYC expression.[89]

Poly(ADP-Ribose) Polymerase Inhibitors

Proteomic profiling of a large panel of SCLC cells showed high expression of PARP1 and other repair proteins. Several PARP inhibitors have shown single activity in in vitro and in vivo models of SCLC.[90] BMN-673 is the most potent PARP1/2 inhibitor, inducing synthetic lethality in tumors deficient in homologous recombination. In a phase I trial of BMN-673,2 of 11 patients with recurrent SCLC had PR. Veliparib, another PARP inhibitor, was studied in with TMZ in the second- or third-line setting in a randomized phase II study.[91] Patients were randomized to receive veliparib or placebo in combination with TMZ. There was no significant difference in the median PFS or OS between the groups. However, there was an improvement in the objective RR in patients receiving veliparib plus TMZ (39%) compared with placebo plus TMZ (14%). In patients who were positive for Schlafen-11 (SLFN11), a DNA/RNA helicase that regulates replication stress at sites of DNA damage, PFS was prolonged (5.7 months vs 3.6 months) as was OS (12.2 months vs 7.5 months) with veliparib plus TMZ. This study provided further evidence that a biomarker-driven selection of patients could improve outcomes in further clinical trials and suggested that SLFN11 may be predictive of response to PARP inhibitors.[92]

Delta-like Protein 3–Targeted Therapy

Delta-like protein 3 (DLL3) is a member of the NOTCH receptor ligand family and has been identified as a potential therapeutic target for SCLC and other high-grade neuroendocrine carcinomas. Rovalpituzumab tesirine is an antibody–drug conjugate targeting DLL3 that showed promising efficacy in a phase I clinical trial. The objective RRs were 18% in assessable patients and 38% in those with DLL3 expression in 50% or more of tumor cells.[93] Unfortunately, the phase III TRINITY showed only modest activity, including in patients with high DDL3 expression.[94] Furthermore, serious adverse events were seen in 63% of patients, and rovalpituzumab tesirine is unlikely to be tested further in SCLC.

PARANEOPLASTIC SYNDROMES

PNSs are a complex spectrum of symptoms secondary to hormones secreted from tumor cells not related to

their tissue or organ of origin or to immune-mediated tissue destruction through the production of autoantibodies against tumor cells. SCLC is one of the most common cancer types associated with such phenomena. Ectopic hormone production has been associated with ED and a poorer outcome, whereas the antibody-mediated PNSs are associated with more favorable outcomes.[8,11] It is critical to recognize the manifestations of PNSs because this may lead to the diagnosis of an underlying, previously unsuspected malignancy and be useful in monitoring the course of the underlying disease.

Endocrine Paraneoplastic Syndromes

Hyponatremia of malignancy occurs in 15% of patients with SCLC. This disorder is caused by ectopic production of antidiuretic hormone from tumor cells, resulting in the SIADH.[95] Fluid restriction, saline infusion with furosemide diuresis, hypertonic saline, and demeclocycline are options for acute management depending on the severity of symptoms. Chemotherapy should be started urgently.

The incidence of ectopic Cushing syndrome in SCLC is approximately 5%. Patients with SCLC with such a syndrome commonly present with signs and symptoms of rapid-onset hypercortisolism, including weight loss (83%), hypokalemia (87%), abnormal glucose tolerance (73%), and edema (58%) compared with the classic Cushingoid features of moon facies, central obesity, or hirsutism, which are more commonly seen in patients with carcinoid tumors.[95] This may be attributable to the slower growth rate of carcinoids, which causes a gradual, rather than acute, increase in ACTH levels. Patients with SCLC with Cushing syndrome have higher hydroxycorticosteroid (17-OHCS) and ACTH plasma levels than those seen in the Cushing disease of pituitary origin. These patients are immunosuppressed and at high risk for opportunistic infections from hypercortisolism; therefore, cortisol-suppressing agents, such as metyrapone or ketoconazole, are recommended before initiating myelosuppressive antineoplastic therapy. RT can also be used in these cases to palliate and temporize until hypercortisolism has been controlled. Endocrine syndromes parallel cancer control, subsiding with cytoreduction of tumor and recurring with progression.

Neurologic Paraneoplastic Syndromes

Neurologic PNS disorders occur as the result of onconeuronal antibodies recognizing tumor and neuronal cell antigens; thus, they are autoimmune in mechanism. LEMS, seen in 1% to 3% of patients with SCLC, is caused by autoantibodies directed against P/Q-type voltage-gated calcium channels on the tumor cells and at presynaptic nerve terminals. These antibodies impair acetylcholine release from the presynaptic motor terminal at the neuromuscular junction and cause transient cranial nerve palsies, upright presyncopal symptoms, proximal muscle weakness with lower extremity predominance, and depressed tendon reflexes.[11] The electromyographic findings of decreased baseline muscle action potential that increases with repeated stimulations are characteristic and allow for clear-cut diagnosis. LEMS represents a favorable prognostic factor presumably based on antitumor immunity.[11] Unfortunately, these patients frequently experience progressive neurologic decline despite tumor control with treatment because by the time neurologic symptoms and deficits emerge, permanent neuronal damage has occurred.

Additional paraneoplastic CNS disorders are associated with inflammation and neuronal loss. The most common syndromes in this group are paraneoplastic cerebellar degeneration, limbic encephalitis, opsoclonus-myoclonus, and diffuse encephalitis with multifocal neurologic symptoms.[95] It remains unclear whether these syndromes or the presence of antibodies can serve as predictive markers of tumor response or progression.

THE SPECTRUM OF NEUROENDOCRINE CARCINOMAS

Neuroendocrine carcinomas are a wide spectrum of diseases, including low-grade typical carcinoid (TC), intermediate-grade atypical carcinoid (AT), and high-grade neuroendocrine carcinomas (small cell carcinoma and LCNEC).[96] Carcinoid tumors are more often found in the gastrointestinal system than in the lungs. The behavior of these tumors is often dependent on grade of differentiation. The histopathological features of these tumors are identical regardless of their anatomic location; thus, the determination of a primary site often requires careful clinical evaluation.

Many of the same IHC markers are used to define NETs, regardless of primary site. Some IHC stains appear to be expressed in tumors in certain locations. For example, whereas TTF-1 is commonly positive in thoracic tumors, CDX2 is more commonly expressed in gastrointestinal tumors. On limited biopsies, definitive tumor grading may be challenging, especially in tumors of low and intermediate grade.

Pulmonary NETs comprise approximately 20% of all invasive lung malignancies. After SCLC, LCNEC accounts for 3% of resected lung cancers in surgical series, and TCs account for 1% to 2% of lung cancers. AT is the rarest lung NET because it comprises approximately 10% of all lung carcinoids, accounting

TABLE 23-2 Grading Criteria and Histologic Features of Pulmonary Neuroendocrine Tumors

Grade	Histology	Conventional Nomenclature
Low grade (well differentiated)	• < 3 mitotic figures × 10 hpf • Absent or only focal punctate necrosis • Absent or mild nuclear atypia	Carcinoid
Intermediate grade (moderately differentiated)	• 3–10 mitotic figures × 10 hpf • Comedonecrosis present • Moderate nuclear atypia	Atypical carcinoid
High grade, poorly differentiated (small cell carcinoma)	• >10 mitotic figures × 10 hpf • Necrosis present • Prominent nuclear atypia with or without positive NE markers	Small cell carcinoma
High grade, poorly differentiated (large cell neuroendocrine carcinoma)	• >10 mitotic figures × 10 hpf • Necrosis present • Prominent nuclear atypia with positive NE morphologic features and positive or negative NE markers	Large cell neuroendocrine carcinoma

hpf, high-power field; NE, neuroendocrine.
Data from Moran CA, Suster S, Coppola D, et al. Neuroendocrine carcinomas of the lung: a critical analysis, *Am J Clin Pathol.* 2009;131(2):206-221.

for 0.1% to 0.2% of invasive lung cancers. LCNEC has similar biology, behavior, and natural history to SCLC.[12] Table 23–2 shows the grading criteria and the histopathological features for pulmonary NETs.[97] The different types of NETs possess diverse epidemiologic, clinical, pathologic, and molecular features.[98]

Surgical resection is recommended for localized pulmonary NETs if pulmonary reserve is adequate. For surgically unfit patients or for exceptional low-grade cases, transbronchoscopic resection may be considered. Approximately 5% to 20% of bronchial TCs and 30% to 70% of ATs metastasize to lymph nodes; thus, a complete mediastinal lymph node sampling or dissection at the time of surgery is recommended. The 5-year survival rates of surgically resected pulmonary TCs and ATs range between 87% and 100% and 30% and 95%, respectively.[98] Patients with TCs are unlikely to benefit from adjuvant systemic therapy even if lymph node involvement is present. The ATs have higher recurrence rates; therefore, despite the lack of consensus, adjuvant EP with or without RT for patients with stage II or III may be considered.[99]

Because of the rarity of LCNEC, most of the data regarding treatment are retrospective in nature. In general, there is a worse prognosis for patients with resected LCNEC compared with those with stage-matched other NSCLC. Treatment recommendations for this entity are extrapolated from treatment paradigms for SCLC. For resected stage I and II LCNEC, four cycles of adjuvant EP are recommended. For locally advanced disease (stage III), concurrent chemoradiation or chemotherapy is recommended (one or two cycles of EP concurrent with RT followed by additional chemotherapy to complete a total of four courses). For stage IV disease, four to six cycles of EP and palliative RT, if clinically indicated, are recommended. PCI cannot be routinely recommended because of limited data on the incidence of brain metastases in patients with LCNEC.[96]

SUMMARY

SCLC is a very aggressive malignancy, affecting 30,000 or more individuals annually in the United States. Most patients present with widespread disease at diagnosis, and despite the initial high sensitivity to chemotherapy and RT, resistance emerges rapidly. Extensive research over the past few decades has not significantly impacted the therapeutic paradigm of SCLC. The standard of care for both LD and ED is etoposide–platin chemotherapy for a minimum of four courses. Early integration of concurrent TRT is indicated for LD. PCI can be offered to patients who have excellent disease control after initial therapy. Major advances in treatment will require greater understanding of the drivers of the pan-resistant phenotype that characterizes recurrent disease and development of therapy to which these cells will be vulnerable. Recent discoveries from bench research and early-phase clinical investigation fuel the hope that outcomes for patients with SCLC will continue to improve in the next decade.

MD ANDERSON PRACTICE TIPS

- Clinical trials should be considered for all patients with SCLC, especially after relapse.
- The use of PCI in extensive-stage patients with SCLC should be restricted to *highly selected* cases, such as patients with low burdens of metastatic disease; good PS; *and* a complete, or near-complete, metabolic response to frontline systemic therapy. All patients with extensive-stage disease should have surveillance brain imaging.
- Consider the use of the TMZ for patients with relapsed disease, which is a convenient (oral) agent with good tolerability and excellent blood–brain barrier penetration. In particular, this agent is useful for patients with a history of CNS metastases.
- Although both the IMpower133 and CASPIAN trials excluded use of consolidative thoracic irradiation after chemoimmunotherapy, we continue to deploy this treatment modality for appropriate patients treated with chemoimmunotherapy.
- As with all malignancies, but especially true in light of SCLC's poor prognosis, early establishment of realistic prognostic expectations and goals of care is critical.
- Although nivolumab and pembrolizumab are FDA approved for third-line treatment of relapsed SCLC, we do not recommend repeat use of immune checkpoint blockade in patients who failed frontline chemoimmunotherapy unless within a clinical trial. On the other hand, if a newly relapsed patient did not previously receive immunotherapy, off-label use of nivolumab or pembrolizumab even in the second line should be considered, in light of durable, albeit rare, responses.

Non–Small Cell Lung Cancer: General Principles, Management of Localized Disease, and Treatment of Metastatic Disease without Oncogene Drivers

Mehmet Altan
Joshua M Gulvin
George Simon
Bonnie Glisson

KEY CONCEPTS

- Lung cancer is the leading cause of cancer-related death in the United States. However, patients with early lung cancer have lower lung cancer–related mortality, and screening with low-dose computed tomography in high-risk groups correlates with a reduction in overall mortality.
- Multidisciplinary evaluation, including early integration of palliative care, for patients with locally advanced or metastatic non–small cell lung cancer (NSCLC), improves patient outcomes and quality of life.
- Immune checkpoint therapies, particularly therapies targeting the programmed cell death protein 1–programmed cell death ligand 1 pathway are now the standard (as a single agent or as a part of combination) therapy for first-line treatment of metastatic NSCLC that does not harbor targetable mutations and should be considered for all patients if there are no contraindications.

Lung cancer is the second most common cancer in women (after breast cancer) and in men (after prostate cancer) but is the most common cause of cancer-related death.[1] Every year, more than 1.7 million patients die of lung cancer worldwide.[2] About 70% of patients are diagnosed in advanced stages of disease, when the probability of cure is low. Over the years, lung cancer screening efforts and technological advancements in imaging studies have increased the detection of lung cancer in earlier stages; advances in minimally invasive techniques for diagnosis, radiation therapy, and multimodality approaches in locally advanced disease in non–small cell lung cancer (NSCLC) have improved clinical outcomes. Furthermore, in the metastatic setting, advances in targeted therapies in patients with actionable mutations and introduction of immune checkpoint inhibitors (ICIs) used as single agents or in combination have contributed to significant improvements in overall survival (OS). The eventual survival of a patient depends on factors such as presence or absence of comorbidities, stage, tumor characteristics, and performance status as discussed in this chapter.

Lung cancer is broadly divided into small cell lung cancer (SCLC) and NSCLC. Approximately 85% of lung cancers are NSCLC. This chapter describes the epidemiology, etiology, histology, prevention, and molecular biology of NSCLC. The multidisciplinary management of stages I to III is described followed by treatment of stage IV NSCLC without an oncogene driver. Chapter 25 focuses on treatment of patients with NSCLC with a targetable mutation. We will review current clinical knowledge in these areas, with an emphasis on our approach at the University of Texas MD Anderson Cancer Center (MDACC).

EPIDEMIOLOGY

Lung cancer is rarely diagnosed in people younger than 35 years old. Indeed, the median age for lung cancer in the United States in 70 years of age. Incidence and

death rates rise exponentially until age 75 years, when a plateau is reached. NSCLC accounts for the greatest number of deaths from cancer in both men and women over age 60 years.

The geographic, social, and temporal trends of the incidence of NSCLC are closely related to tobacco consumption. In developed Western countries, the incidence of NSCLC has been declining; however, it has been increasing in Asia, Eastern Europe, and developing countries.[3]

Worldwide, NSCLC is more common in men, and this difference has been attributed to higher tobacco consumption. In some regions, such as Eastern Europe and South America, there was an uptake of smoking by women in the 1980s, and these areas are currently experiencing a rise in NSCLC cases in women. In the United States, the incidence has been declining for both men and women as tobacco use declines; the male-to-female ratio from 2007 to 2011 was 1.4 to 1.[4]

ETIOLOGY

Smoking

The causal relationship between tobacco smoke and lung cancer was established in the 1950s in case-control and cohort studies. This led to the 1964 report of the US Surgeon General, concluding that smoking can cause lung cancer. Currently, it is estimated that 83% to 85% of lung cancers in the United States are caused by smoking. Nonsmokers who are exposed to secondhand smoke are also at an increased risk. There is a dose–response relationship between smoking and lung cancer risk, and smoking cessation leads to a significant risk reduction (Table 24–1).[5]

Tobacco smoke is a complex mixture of chemicals that includes multiple carcinogens, most important, the *N*-nitrosamines (nicotine-derived nitrosamino ketone and N′-nitrosonornicotine [NNN]) and polycyclic aromatic hydrocarbons [benzo(a)pyrene and dimethylbenz(a)anthracene]. They are activated through hydroxylation by the P450 enzyme system and exert their action through the formation of DNA adducts.

Smokeless tobacco is frequently advocated as a safer alternative. There has not been a clear association between smokeless tobacco and lung cancer; however, it increases the risk of head and neck, pancreatic, and gastric cancer. E-cigarettes deliver water vapor with scents and different amounts of nicotine, which is addictive and contains nitrosamines. They also contain high levels of propylene glycol and glycerin, and their long-term effects on health are unknown. Their use should not be recommended to nonsmokers, and use as part of a smoking cessation approach needs further study.[6]

Approximately 15% of cases of NSCLC occur in never smokers, corresponding to approximately 20,000 deaths annually. In addition to secondhand smoke exposure, several other agents have also been linked to the development of lung cancer (Table 24–2).

Asbestos

Asbestos exists in many natural forms. The silicate fiber has been implicated in carcinogenesis, is chemically inert, and can remain in a person's lungs for a lifetime. Epidemiologic studies have confirmed the association between asbestos exposure and certain lung diseases, such as pulmonary fibrosis, mesothelioma, and lung cancer.[7] Most exposure occurs in the workplace. When smoking is combined with asbestos exposure, the relative risk of lung cancer is strikingly increased.[7]

TABLE 24–1 Approximate 10-Year Risk of Developing Lung Cancer[a]

	Duration of Smoking					
	25 Years		40 Years		50 Years	
Age (years)	Quit (%)	Still Smoking (%)	Quit (%)	Still Smoking (%)	Quit (%)	Still Smoking (%)
One-Pack-Per-Day Smokers						
55	<1	1	3	5	NA	NA
65	<1	2	4	7	7	10
75	1	2	5	8	8	11
Two-Packs-Per-Day Smokers						
55	<1	2	4	7	NA	NA
65	1	3	6	9	10	14
75	2	3	7	10	11	15

[a]This table assumes that people who have quit smoking will continue to abstain for the next 10 years and those who are still smoking will keep smoking the same amount for the next 10 years.

Radon

Radon is a naturally occurring decay product of uranium. It is a colorless, odorless, chemically inert gas that can penetrate the earth's crust and accumulate in buildings. It emits heavy ionizing alpha particles, which may damage DNA. It was shown that many households in Europe, Canada, and the United States have some degree of radon radiation that may increase NSCLC risk among smokers and nonsmokers.[8]

Diet

The majority of studies that have examined vegetable consumption in relation to lung cancer have shown a protective effect,[9] but there are inherent biases in these population studies. There is also epidemiologic evidence that dietary intake of certain vitamins decreases lung cancer risk; however, trials of vitamin supplementation for cancer prevention have ultimately been unsuccessful (see later Chemoprevention section).

Other Factors

Environmental or industrial exposure to arsenic, chromium, chloromethyl ether, vinyl chloride, and polycyclic aromatic hydrocarbons increases lung cancer risk.[10] Preexisting lung disease such as tuberculosis, silicosis, pulmonary fibrosis, and chronic obstructive pulmonary disease are also associated with an increased lung cancer incidence even when correcting for the degree of cigarette consumption. This suggests that common pathways to these conditions, such as chronic inflammation, may drive the tumorigenic process.

Genetic Predisposition

Family history of lung cancer is associated with a two- to threefold increase in lung cancer risk, even after correction for smoking, and this risk seems to be inherited in a Mendelian co-dominant fashion.[11]

Many studies describe weak but consistent associations between some polymorphisms and lung cancer risk. The cytochrome P450 (CYP) family is responsible for the metabolism of tobacco smoke, and the polymorphism CYP1A1 $Ile^{462}Val$ is associated with a higher risk in Asians (odds ratio [OR], 1.61).[12] The glutathione *S*-transferase enzyme prevents oxidative damage, and the polymorphism GSTM1 increases risk in Asians (OR, 1.17).[13] Finally, individuals with impaired DNA repair capacity are at higher risk of developing lung cancer, even if they are nonsmokers, and the polymorphism $Lys^{751}Gln$ in the DNA-repairing enzyme ERCC2 is associated with lung cancer (OR, 1.15).[14]

Large genome-wide association studies (GWAS)[15] have identified three loci strongly associated with lung cancer risk in different populations: 15q25, 5p15, and 6p21. The 15q25 susceptibility region encodes three cholinergic nicotine receptor genes (*CHRNA3*, *CHRNA5*, *CHRNB4*), and alterations in those regions have been associated with a higher risk for nicotine dependence and higher smoking burden. In nonsmokers, they have also been associated with impaired healing of the respiratory mucosa, suggesting a higher sensitivity to toxin-induced airway damage. The 5p15 region encodes the *TERT* gene, responsible for telomerase function, which is altered in many cancers.[16]

PREVENTION OF LUNG CANCER

Smoking Cessation and Prevention

The most effective method of preventing lung cancer is reducing tobacco exposure, either through encouraging smoking cessation or preventing young people from starting to smoke. In the United States, campaigns to reduce smoking rates have been successful.

The estimated percentage of Americans who actively smoke decreased from 42.4% in 1965 to 25% in 1990 and to 18.1% in 2012.[17] However, former smokers retain an increased risk of lung cancer, and there are still a considerable number of smokers, highlighting the need for better education and prevention strategies, especially those targeted to youths.

Early Detection and Screening

Previous studies examined the role of chest radiography, with or without cytologic analysis of sputum, to screen for lung cancer, and none showed a clear benefit. Most of them were confounded by lead time, length time, and overdiagnosis biases.

Spiral computed tomography (CT)—also called helical CT or low-dose CT—is much more sensitive to detect early NSCLC than chest radiography. In 2011, the results of the National Lung Screening Trial were published.[18] In this trial, 53,454 current or former smokers ages 55 to 74 years old with at least a 30-pack-year smoking history and no symptoms that could be related to lung cancer were randomized to undergo yearly chest radiographs or low-dose CT for 3 years. After a median follow-up of 6.5 years, the low-dose CT group had a 20% reduction in the rate of lung cancer–specific mortality, from 309 to 247 per 100,000 person-years, as well as a 6.7% reduction in overall mortality. In the CT group, 39% of patients had suspicious lung nodules (vs 16% in the control arm), and the majority of these (96%) were considered false-positive results. Sensitivity and specificity of low-dose CT were 93.8% and 73.4%, respectively, compared with 73.5% and 91.3% for chest radiography. Cost-effectiveness analysis showed a median cost of $43,000 per quality-adjusted life-year gained for current smokers assigned to the low-dose CT group. Another trial that supported the surveillance with CT scans had been conducted in Belgium and the Netherlands (the NELSON study) looking at the 10-year impact of lung cancer screening using low-dose CT scan. In this study, A total of 13,195 male participants at high risk for lung cancer were randomly assigned to either the screening group (6583 men) or the control group (6612 men). CT screening performed at baseline, year 1, year 3, and year 5.5 or no screening. At 10 years of follow-up, the incidences of lung cancer were 5.58 cases per 1000 person-years in the screening group and 4.91 cases per 1000 person-years in the control group; lung cancer mortality was 2.5 deaths versus 3.3 deaths per 1000 person-years, respectively. The cumulative rate ratio for death from lung cancer at 10 years was 0.76 (95% confidence interval [CI], 0.61–0.94; P = .01) in the screening group compared with the control group. CT scanning decreased the mortality rate by 26% in high-risk men and up to 61% in high-risk women over a 10-year period.[19] Based on these results, the US Preventive Services Task Force currently recommends lung cancer screening with yearly low-dose CT for current or past smokers, age 55 to 80 years, with a smoking history of at least 30 pack-years. (In late 2020. this screening recommendation is expected to revise and to be extended to include adults ages 50 to 80 years who have a 20 pack-year smoking history and currently smoke or have quit within the past 15 years.[20]) Screening should be discontinued when a person has not smoked for 15 years.

Despite recent developments, low-dose CT screening still has significant limitations, including high false-positive ratios and the development of interval lung cancers, which can be aggressive. Positron emission tomography (PET)–CT scan, epigenetic markers, and cell-free tumor DNA are additional approaches under investigation, which are only recommended in the setting of a clinical trial.

Chemoprevention

Cigarette smoking has an effect of field cancerization, with the accumulation of genetic mutations and other premalignant changes throughout the lung and the aerodigestive tract lining. Patients treated and cured of early-stage lung cancer have a high risk of developing second primary tumors. Therefore, a series of chemoprevention trials has focused on smokers and survivors of lung and head and neck cancers.

Multiple studies evaluated supplementation with vitamins and oligo-elements, but none showed a benefit to supplementation, and several studies showed risk, with increased lung cancer incidence and mortality (Table 24–3).[21–27]

Given the potential connection between inflammation and tumorigenesis, phase II studies have used anti-inflammatory agents, such as celecoxib, and prostaglandin analogues, such as iloprost. These agents have been able to reduce proliferation and dysplasia of oral and bronchial epithelium in smokers and former smokers, but their benefit in cancer prevention remains to be proven. There are currently no proven agents for the chemoprevention of lung cancer.

HISTOLOGY AND MOLECULAR PATHOLOGY

NSCLCs include three major types: adenocarcinoma, squamous cell carcinoma (SCC), and large cell carcinoma.

The most current histologic classification of NSCLC was proposed by the International Association for the Study of Lung Cancer/American Thoracic

TABLE 24–3 Large Randomized Lung Cancer Chemoprevention Trials

Study	Intervention	Population	Size	Endpoint	Outcome
ATBC[21]	β-Carotene; α-tocopherol	Male smokers	29,133	Lung cancer incidence	Harmful
CARET[22]	β-Carotene; retinol	Current and former smokers	18,314	Lung cancer incidence	Harmful
Intergroup Lung Trial[23]	Isotretinoin	Resected NSCLC	1166	Second malignancies	Harmful
Euroscan[24]	Retinol, *N*-acetylcysteine	Resected NSCLC and head and neck cancer	2592	Second malignancies	Negative
ECOG 5597[25]	Selenium	Resected NSCLC	1772	Second malignancies	Negative
Physicians' Health Study II[26]	Vitamin C and vitamin E	Healthy male physicians	14,641	Cancer incidence	Negative
NORVIT and WENBIT[27]	Vitamin B_{12} and folic acid	Patients with ischemic heart disease	6845	Cancer incidence	Harmful

ATBC, The Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) Study; CARET, The Beta-Carotene and Retinol Efficacy Trial (CARET); ECOG, Eastern Cooperative Oncology Group; NORVIT, The Norwegian Vitamin (NORVIT) trial; NSCLC, non–small cell lung cancer; WENBIT, Western Norway B Vitamin Intervention Trial (WENBIT).

Society/European Respiratory Society in 2011[28] and uses immunohistochemistry (IHC) to identify subgroups with different molecular profiles and clinical behaviors (Tables 24–4 and 24–5). Adenocarcinomas usually stain positive for cytokeratin 7, thyroid transcription factor 1 (TTF-1), and Napsin A and are negative for cytokeratin 20. TTF-1 is a marker to determine if a tumor is arising from the lung or thyroid origin and is expected to be negative if adenocarcinoma is originating from other organ systems.[29] All carcinoids and most SCLCs stain positive for chromogranin and synaptophysin, whereas NSCLC is usually negative for these two markers. Mesothelioma is distinguished from adenocarcinoma by the presence of calretinin, WT-1, and cytokeratin 5/6 staining and the absence of carcinoembryonic antigen (CEA), B72.3, Ber-EP4, and MOC-31.[29,30]

Adenocarcinoma

Adenocarcinoma is the most common subtype of NSCLC in the United States, representing 40% of cases in men and 50% in women. It is predominant in nonsmokers, and its incidence has been rising. These tumors are classically peripheral and, on histologic examination, demonstrate gland formation, papillary structures, or mucin production (Fig. 24–1).

NSCLC is one of the cancer types with the highest mutation burden, with an average of 360 exonic mutations per sample.[31] However, the patterns of mutations are different for adenocarcinomas and SCCs.

About 75% of lung adenocarcinomas have alterations in driver genes that activate intracellular pathways leading to proliferation, cell survival, and oxidative stress response.[32] Up to 79% of those alterations are in the Receptor Tyrosine Kinase (RTK)–Rat sarcoma (RAS)–Rapidly Accelerated Fibrosarcoma (RAF) pathway, including mutations in the ErbB family member *EGFR* (ErbB1).The prevalence of *EGFR* mutations ranges from 5% to 10% in smokers to 40% to 50% in nonsmokers in the Western population.[33] The alterations are usually in the tyrosine kinase domain of the gene within exons 18 to 24, most specifically in the intracellular adenosine triphosphate (ATP)-binding domain.[33–35]

Frequencies of *EGFR*, *KRAS*, *ALK*, *ROS1*, and other driver genetic alterations commonly found in lung adenocarcinoma samples are listed in Table 24–6.[32,33,36–40] This is a rapidly changing landscape that is defining the many molecular subsets of this heterogeneous disease.

Squamous Cell Carcinoma

SCC is now the second most frequent histology, accounting for 30% of cases of NSCLC in men and 20% in women. This tumor arises most frequently in the proximal bronchi and has the stronger association with smoking than adenocarcinomas. Pathologically, it is characterized by visible keratinization, with prominent desmosomes and intercellular bridges (Fig. 24–2).

SCCs frequently have amplifications in chromosome 3q, which contains genes involved in squamous differentiation (*SOX2* and *TP53*) and cell proliferation (*PI3K*). About 81% to 90% of patients with SCCs have *TP53* mutations, and 47% have alterations in the PI3K–AKT–mTOR pathway, whereas only 26% of SCCs have activations of the RTK/RAS/RAF pathway.[31] Whereas the prevalence of *EGFR* mutations is 1% to 3%, 6% of patients have *EGFR* amplifications, and 1% to 6% have *KRAS* mutations.[31]

TABLE 24–4 The 2011 International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society Histologic Classification of Invasive Malignant Epithelial Tumors

Squamous cell carcinoma
Small cell carcinoma
Adenocarcinoma Lepidic predominant (formerly nonmucinous bronchoalveolar carcinoma pattern with >5 mm invasion) Acinar predominant Papillary predominant Micropapillary predominant Solid predominant with mucin production
Variants of invasive adenocarcinoma Invasive mucinous adenocarcinoma (formerly mucinous bronchoalveolar carcinoma) Colloid Fetal (low and high grade) Enteric
Large cell carcinoma Variants: large cell neuroendocrine; large cell neuroendocrine (NE) carcinoma (positive NE markers); large cell carcinoma with NE morphology (morphology suggestive of NE carcinoma but negative stains)
Adenosquamous carcinoma or NSCLC with squamous cell and adenocarcinoma patterns
Carcinomas with pleomorphic, sarcomatoid, or sarcomatous elements Carcinoma with spindle or giant cells Pleomorphic carcinoma Spindle cell carcinoma Giant cell carcinoma
Carcinosarcoma Blastoma (pulmonary blastoma) Others
Carcinoid tumor Typical carcinoid Atypical carcinoid
Carcinomas of salivary gland type Mucoepidermoid carcinoma Adenocystic carcinoma, others
Unclassified carcinoma

NSCLC, non–small cell lung cancer.

Large Cell Carcinoma

The least common subtype of NSCLC, large cell carcinoma, accounts for approximately 8% of all NSCLCs (Fig. 24–3). Refinements in histopathologic techniques have led to the diagnosis of adenocarcinoma or SCC in cases previously diagnosed as undifferentiated large cell carcinoma.

CLINICAL PRESENTATION

NSCLC is often asymptomatic at diagnosis and may be found incidentally on imaging performed for other reasons. If symptoms are present, they are often related to the specific locations of tumor masses and the occurrence of paraneoplastic syndromes. The symptoms of centrally located lesions include cough, hemoptysis, wheezing, stridor, dyspnea, and postobstructive pneumonia. Peripheral lesions can cause pain because of pleural or chest wall invasion, cough, or restrictive dyspnea. Loss of appetite, loss of weight, and bone pain are other common systemic symptoms.

The involvement of thoracic and cervical structures can also lead to classical clinical presentations:

- **Pancoast syndrome:** shoulder pain radiating to the arm in an ulnar distribution caused by invasion of the eighth cervical and first thoracic nerves in the superior sulcus
- **Horner syndrome:** enophthalmos, ptosis, miosis, and ipsilateral dyshidrosis caused by involvement of the paravertebral sympathetic nerves, typically from a superior sulcus tumor
- **Hoarseness:** compression or invasion of the left recurrent laryngeal nerve as it passes through the aortopulmonary window by metastatic adenopathy
- **Elevation of the hemidiaphragm:** involvement of phrenic nerve from mediastinal adenopathy
- **Superior vena cava syndrome:** swelling of the face and arm and superficial venous engorgement caused by compression of the superior vena cava either directly by the primary tumor or by metastatic adenopathy

The production of hormones or hormone-like substances can lead to paraneoplastic syndromes:

- **Cancer cachexia:** The most common paraneoplastic syndrome, characterized by weight loss, impaired immune function, and weakness that are not completely explained by poor oral intake. The exact mechanism for development of cachexia is unknown, but tumor-elaborated cytokines have been implicated.
- **Hypercalcemia:** The second most common paraneoplastic syndrome in NSCLC, hypercalcemia is caused by ectopic production of a parathyroid hormone–related protein or bone metastases. Ectopic secretion is more common in the squamous cell subtype.
- **Hypertrophic pulmonary osteoarthropathy:** Arthropathy and clubbing of the fingers and toes with evidence of periostitis of the long bones (Fig. 24–4). Its cause is unknown, and it is more common in adenocarcinomas and large cell carcinoma.

NSCLC is frequently metastatic at diagnosis, and symptoms secondary to metastases are common. The most common sites for metastases are intrathoracic nodes, pleura, contralateral lung, liver, adrenal glands, bone, and brain.

TABLE 24–5 Adenocarcinoma Histologic Subtypes and Molecular and Radiologic Associations

Predominant Histologic Subtype	Molecular Features	Computed Tomography Scan Appearance	Relative Risk of Recurrence After Resection
Lepidic	TTF-1 positive: 100% *EGFR* amplification: 20%–50% *EGFR* mutation (nonsmokers): 10%–30% *KRAS* mutations (smokers): 10% *BRAF* mutations: 5%	Ground glass or solid nodule	1.0
Papillary	TTF-1 positive: 90%–100% *EGFR* amplification: 20%–60% *EGFR* mutation: 10%–30% *KRAS* mutations: 3% *BRAF* mutations: 5% *ERBB2* mutations: 3% *P53* mutations: 30%	Solid nodule	2.7 (95% CI, 1.1–6.8)
Acinar	TTF-1 positive or negative *EGFR* amplification: 10% *EGFR* mutation (nonsmokers): <10% *KRAS* mutation (smokers): 20% *P53* mutation: 40% *EML4/ALK* translocation: >5%	Solid nodule	2.3 (95% CI, 0.9–5.7)
Micropapillary	*EGFR* mutation: 20% *KRAS* mutation: 33% *BRAF* mutation: 20%	Unknown	4.4 (95% CI, 1.8–11.2)
Solid	TTF-1 positive: 70% MUC1 positive *EGFR* amplification: 20%–50% *EGFR* mutation (nonsmokers): 10%–30% *KRAS* mutation (smokers): 10%-30% *EML4/ALK* translocations: >5% *P53* mutations: 50% *LRP1B* mutations *INHBA* mutations	Solid nodule	5.7 (95% CI, 2.2–14.7)
Invasive mucinous adenocarcinoma	TTF-1 negative (0%–33% positive) No *EGFR* mutation *KRAS* mutation: 80%–100% MUC5, MUC6, MUC2, CK20 positive	Consolidation; air bronchograms	Unknown

CI, confidence interval; TTF-1, thyroid transcription factor 1.

DIAGNOSIS

Solitary Pulmonary Nodule

A solitary pulmonary nodule is a single asymptomatic mass that is surrounded by lung tissue, is well circumscribed, measures less than 3 cm, and does not show evidence of mediastinal or hilar adenopathy. The differential diagnosis includes primary cancer, metastatic cancer, infection, benign tumors (eg, hamartomas), vascular abnormalities, and inflammation (eg, granulomatous disease). The American College of Chest Physicians and National Comprehensive Cancer Network (NCCN) have issued guidelines on the evaluation of solitary lung nodules, based on their size, the clinical probability of malignancy, and the patient's surgical risk41 (Table 24–7 and Fig. 24–5).

TABLE 24–6 Common Driver Genes Altered in Lung Adenocarcinoma

Name	Alteration	Main Effects	Incidence
KRAS mutations	Multiple; usually in codons 12 and 13; most common, G12D (nonsmokers) and G12C (smokers)	Activation of RAS–RAF–MEK–ERK pathway	30%–35% (mostly in smokers)[33]
EGFR mutations	Several alterations in the ATP-binding domain of the receptor	Activation of RAS/RAF/MEK and PI3K–AKT–mTOR pathways	10%–15% (40%–50% in nonsmokers)[36]
BRAF mutations	~50% are the V600E mutation also described in other cancers	Activation of RAS–RAF–MEK–ERK pathway	7%–10%[32]
MET mutations	Exon 14 skipping; can occur with or without *MET* amplification	Activation of MET	7%[32]
PIK3CA	Many activating mutations	AKT, TSC, and mTOR	7%[32]
EML4/ALK and other *ALK* translocations	Inversion within chromosome 2p	Constitutively activates the anaplastic lymphoma kinase (*ALK*) gene leading to downstream activation of RAS and PI3K	1%–4%[37,38]
ROS1 fusions	Multiple rearrangements of the *ROS1* gene with different genes	Related to the ALK protein, also activates RAS and PIK3CA	1%–2%[37]
RET fusions	Multiple rearrangements of the *RET* gene with different genes	Activation of the *RET* proto-oncogene and RAS pathway	1%[39]
ERBB2 (*HER2*) mutations	Various mutations; in ~50% of cases co-occurrence with *HER2* amplification	Activation of RAS–RAF–MEK and PI3K–AKT–mTOR pathways	2%–4%[40]

AKT, Protein kinase B (PKB); ERK: extracellular signal-regulated kinase; MEK, Mitogen-activated protein kinase kinase; mTOR, mammalian target of rapamycin; PI3K, phosphoinositide 3-kinase; RAS, Rat sarcoma; RAF, Rapidly Accelerated Fibrosarcoma; TSC, Tuberous Sclerosis Complex.

A detailed description of the management of solitary pulmonary nodules is beyond the scope of this book chapter. Readers referred to the updated Fleischner Society guidelines (2017)[42] and the NCCN guidelines.[43]

Pulmonary Mass

Lesions that are large (>3 cm), multiple, or with enlarged hilar, mediastinal, and/or supraclavicular lymph nodes should undergo complete lung cancer staging and a

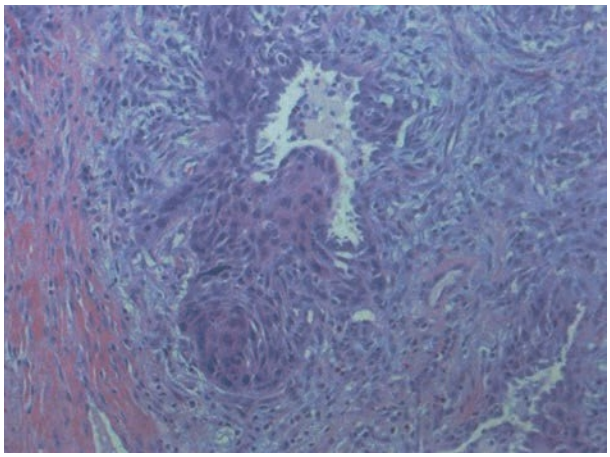

FIGURE 24–2 Squamous cell carcinoma. Photomicrograph of squamous cell carcinoma of the lung stained with hematoxylin and eosin. (Used with permission from Cesar Moran, MD.)

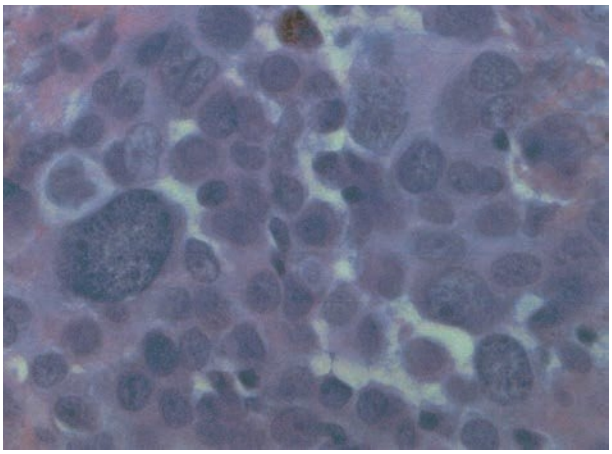

FIGURE 24–3 Large cell carcinoma. Photomicrograph of large cell carcinoma of the lung stained with hematoxylin and eosin. (Used with permission from Cesar Moran, MD.)

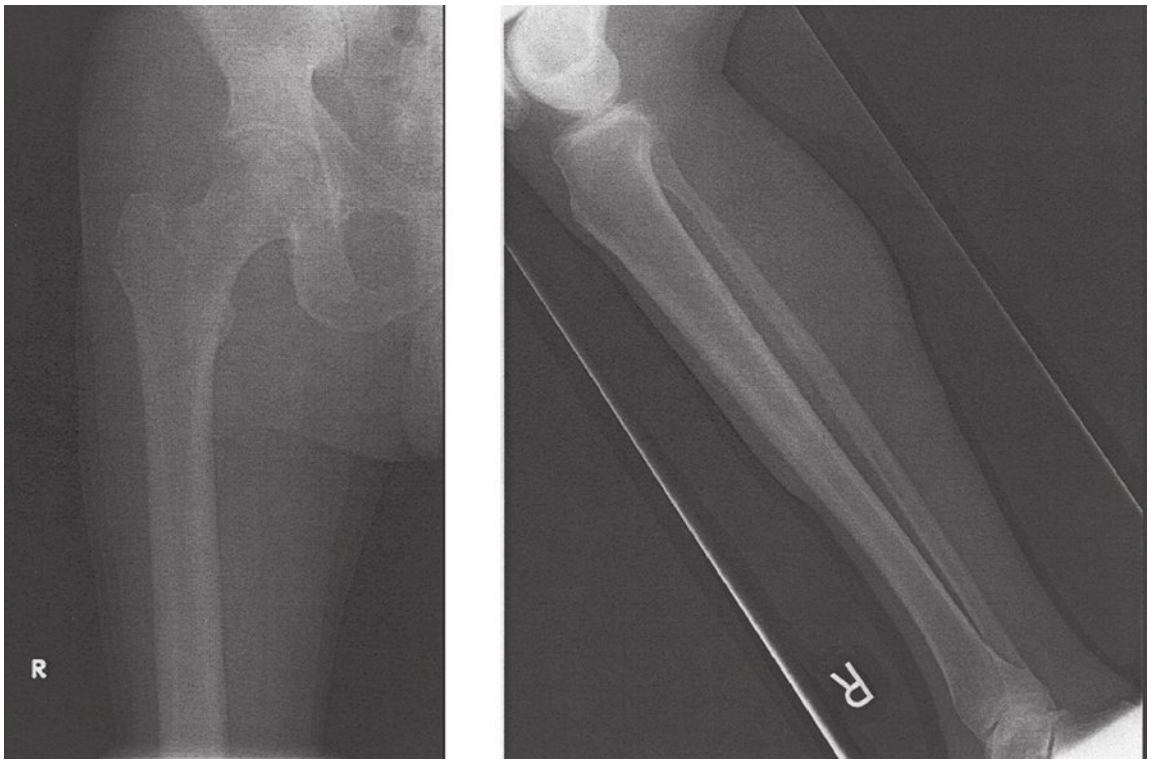

FIGURE 24–4 Hypertrophic pulmonary osteoarthropathy (HPO). This 62-year-old man with non–small cell lung cancer reported a 1-month history of finger clubbing and arthritic lower extremity pain. Plain radiographs of the lower extremities show a periosteal reaction in both femora as well as in bilateral tibias and fibulas that is consistent with HPO.

TABLE 24–7 Clinical Probability of Malignancy of Solitary Lung Nodules

	Low Probability (<5%)	Intermediate Probability (6%–65%)	High Probability (>65%)
Patient	Young, low smoking burden, no previous history of cancer	Mixture of low- and high-probability features	Older, heavy smoker, previous cancer
Nodule (CT scan)	Small, regular margins, non–upper lobe location, enhancement <15 HU in the contrast phase	Mixture of low- and high-probability features	Large, irregular or spiculated, upper lobe location; enhancement >15 HU in the contrast phase
FDG-PET results	Low or moderate clinical probability with low PET probability	Weak or moderate PET activity	Intense hypermetabolic nodule
Nonsurgical biopsy results (bronchoscopy or transthoracic biopsy)	Specific benign diagnostic	Nondiagnostic	Suspicious for malignancy
Behavior on CT surveillance	Progressive decrease in size or resolution; no growth over ≥2 years (solid nodules) or over ≥3 years (semisolid nodules)	NA	Clear evidence of growth

CT, computed tomography; FDG-PET, ^{18}F-fluorodeoxyglucose–positron emission tomography; NA, not applicable.

nonsurgical biopsy. Fiberoptic bronchoscopy is appropriate for central lesions and is able to establish the diagnosis in 97% of cases. For peripheral lesions, the diagnostic yield of bronchoscopy is only 55%, and percutaneous transthoracic biopsies can be considered. Because of the tissue requirements for IHC and molecular marker testing of lung cancers, at MDACC, we usually perform an image-guided core-needle

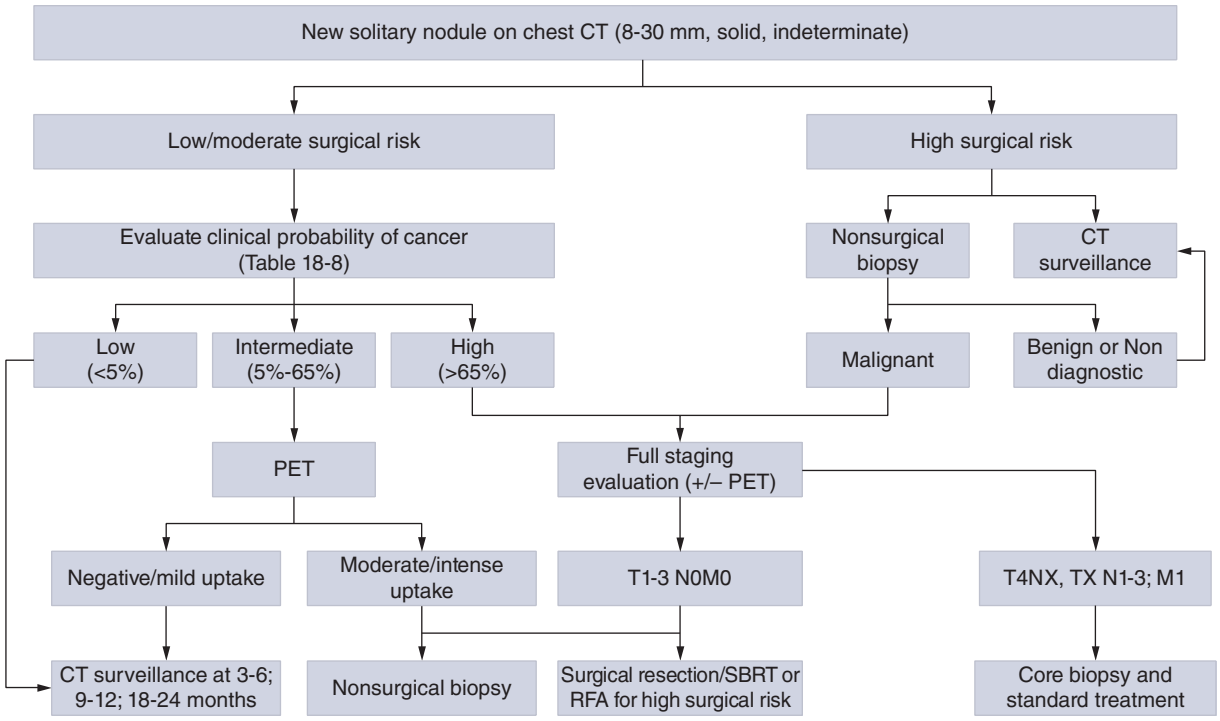

FIGURE 24–5 Management algorithm for individuals with solitary nodules (8–30 mm). biopsy. Mediastinoscopy or bronchoscopic endobronchial ultrasound (EBUS) can be used to obtain biopsy samples from mediastinal and hilar nodes.

Staging

After the histologic diagnosis of NSCLC has been established, the extent of disease must be determined. The stage of disease dictates therapy and prognosis (Tables 24–8 and 24–9). All patients must undergo a complete history and physical examination, PET-CT, a complete blood count, and blood chemistry tests that assess renal and hepatic function, electrolytes, and calcium levels. All patients with stage II to IV disease should have evaluation of the brain, with magnetic resonance imaging (MRI) if possible. Central nervous system imaging may also be considered for patients with stage I disease. For stage I to IV NSCLC,[18]F-fluorodeoxyglucose (FDG)-PET should be performed to evaluate mediastinal nodes and for distant metastases. Because the involvement of mediastinal lymph nodes will influence surgical decisions (see the Treatment section), the presence of FDG-avid mediastinal lymph nodes in a PET-CT scan should be confirmed with either mediastinoscopy or EBUS. In the setting of a normal-appearing mediastinum on PET-CT, invasive mediastinal assessment should also be encouraged as a part of the initial evaluation in the preoperative setting and preradiation settings (stages I–III) In one series, occult N2 disease was found in 20% of patients with T1 to T2 NSCLC, node negative by PET-CT.[44]

After completion of the staging evaluation, the disease is assigned a TNM stage as outlined in Tables 24–8, 24–9. The eighth edition TNM staging a was adopted in 2017.[45]

Key T Descriptors (Fig. 24–6)

Primary Tumor

T1 disease: T1 tumors are divided into T1a (≤1 cm), T1b (>1 to ≤2 cm), and T1c (>2 to ≤3 cm).

T2 disease: T2a is larger than 3 cm to 4 cm, and T2b is larger than 4 cm but not larger than 5 cm. Or it is a tumor with any of the following features. involvement of the mainstem bronchus, regardless of the distance from the carina; visceral pleura involvement; and partial or total atelectasis that extends to the hilar region either involving part of the lung or the entire lung.

T3 disease: T3 is larger than 5 to 7 cm. Or the tumor directly invades any of the following: chest wall, phrenic nerve, parietal pericardium, or associated spate tumor nodule(s) in the same node as the primary.

TABLE 24–8 Definitions for Tumor (T), Node (N), and Metastasis (M) Descriptors (Stage Grouping for the TNM Classification for Lung Cancer)

Descriptor	Subgroup	Definition
T		Primary tumor
Tx		Primary tumor cannot be assessed or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0		No evidence of primary tumor
Tis		Carcinoma in situ
T1		Tumor ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (ie, not in the main bronchus)[a]
	T1mi	Minimally invasive adenocarcinoma[b]
	T1a	Tumor ≤1 cm in greatest dimension[a]
	T1b	Tumor >1 cm but not >2 cm in greatest dimension[a]
	T1c	Tumor >2 cm but not >3 cm in greatest dimension[a]
T2		Tumor >3 cm but not >5 cm or tumor with any of the following features[c] • Involves main bronchus regardless of distance to the carina but without involving the carina • Invades the visceral pleura • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region, either involving part of the lung or the entire lung
	T2a	Tumor >3 cm but not >4 cm in greatest dimension
	T2b	Tumor >4 cm but not >5 cm in greatest dimension
T3		Tumor >5 cm but not >7 cm in greatest dimension or one that directly invades any of the following: chest wall (including superior sulcus tumors), phrenic nerve, or parietal pericardium; or associated separate tumor nodule(s) in the same lobe as the primary
T4		Tumor >7 cm or one that invades any of the following: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina; separate tumor nodule(s) in a different ipsilateral lobe to that of the primary
N		Regional lymph nodes
Nx		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N1		Metastasis in ipsilateral peribronchial or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2		Metastasis in ipsilateral mediastinal or subcarinal lymph node(s)
N3		Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M		Distant metastasis
M0		No distant metastasis
M1		Distant metastasis
	M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural or pericardial nodules or malignant pleural or pericardial effusion[d]
	M1b	Single extrathoracic metastasis in a single organ[e]
	M1c	Multiple extrathoracic metastasis in one or several organs

[a]The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified as T1a.
[b]Solitary adenocarcinoma (≤3 cm), with a predominantly lepidic pattern and ≤5 mm invasion in the greatest dimension in any one focus.
[c]T2 tumors with these features are classified T2a if ≤4 cm or if size cannot be determined and T2b if >4 cm but not >5 cm.
[d]Most pleural (pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple microscopic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. When these elements and clinical judgement dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging descriptor.
[e]This includes involvement of a single distant (nonregional) node.

Reproduced with permission from Goldstraw P, Chansky K, Crowley J, et al: The IASLC Lung Cancer Staging Project: Proposals for Revision of the TNM Stage Groupings in the Forthcoming (Eighth) Edition of the TNM Classification for Lung Cancer, *J Thorac Oncol* 2016 Jan;11(1):39-51.

T4 disease: T4 is larger than 7 cm. Or the tumor that invades any of the following: diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina or it is a separate tumor nodule(s) in a different ipsilateral lobe to that of the primary.

Regional Lymph Nodes (Fig. 24–7):

N0: no nodal metastases

N1: metastasis in ipsilateral peribronchial or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension

N2: metastasis in ipsilateral mediastinal or subcarinal nodal disease

N3: metastasis in contralateral mediastinal, contralateral hilar, ipsilateral, or contralateral scalene or supraclavicular lymph node(s)

Distant Metastasis (Fig. 24–8)

M1a: metastatic disease confined to the chest is classified as M1a, which includes contralateral lung nodule(s) (notably, nodules in the ipsilateral lung are classified as T3 disease if they are in the same lobe as the primary or T4 disease if they are in a different lobe as the primary), malignant pleural or pericardial effusions, or pleural or pericardial nodules. MIa disease is grouped as stage IVA disease.

M1b: a solitary metastasis outside the chest. M1b disease is grouped as stage IVA.

M1c: multiple metastases outside the chest in one or several organs. M1c disease is grouped as stage IVB. Please see Table 24–10 for stage groupings and prognosis by stage.[45]

Clinical staging has inherent inaccuracies and therefore typically underestimates the true extent of disease. In patients who undergo surgical tumor resection, surgical or pathologic staging should be done to predict recurrence and to evaluate the need for adjuvant therapy. Patients' 5-year survival rates by tumor stage per American Joint Committee on Cancer (AJCC) eighth edition are shown in Table 24–10.

TREATMENT

Stage I and II Disease

Surgery

Surgery is standard treatment for stage I and II NSCLC if there are no contraindications (Figs. 24–9 and 24–10). For patients who cannot be safely operated on or refuse surgery, radiation therapy can be considered.

The extent of lung resection is dictated by the size and location of the tumor. The entire tumor must be removed, with margins negative for cancer. Wedge resection and segmentectomy are associated with higher rates of local recurrence than lobectomy and pneumonectomy and are not considered standard of

care, although they may be an option for patients who cannot tolerate a larger surgery due to poor pulmonary function.[46] All patients should also undergo complete ipsilateral mediastinal lymph node dissection or systematic mediastinal sampling for accurate pathologic staging.[47]

Any patient who is being considered for surgery must undergo pulmonary function tests to assess the ability to withstand pulmonary resection. Split-lung function studies can further help to predict lung function after the planned resection. There is no single accepted value, criterion, or cutoff for pulmonary resection. Published criteria that have been shown to predict high risk for lung resection include estimated posttreatment forced vital capacity less than 2 L, forced expiratory volume in 1 second less than 1 L, and diffusing capacity of the lungs for carbon dioxide less than 40% to 60%.[48]

Radiation Therapy

For patients with early-stage lung cancer who cannot undergo surgery because of poor pulmonary reserve or medical comorbidities, stereotactic radiosurgery (SRS) is a reasonable and even a desirable option with local control rates of 90% and a cancer-specific survival rate of 88% at 3 years.[49]

There is controversy regarding whether SRS should be considered in patients who are candidates for surgery and who have small primary tumors and no lymph node involvement. Retrospective series suggest that outcomes with radiation may be similar to those

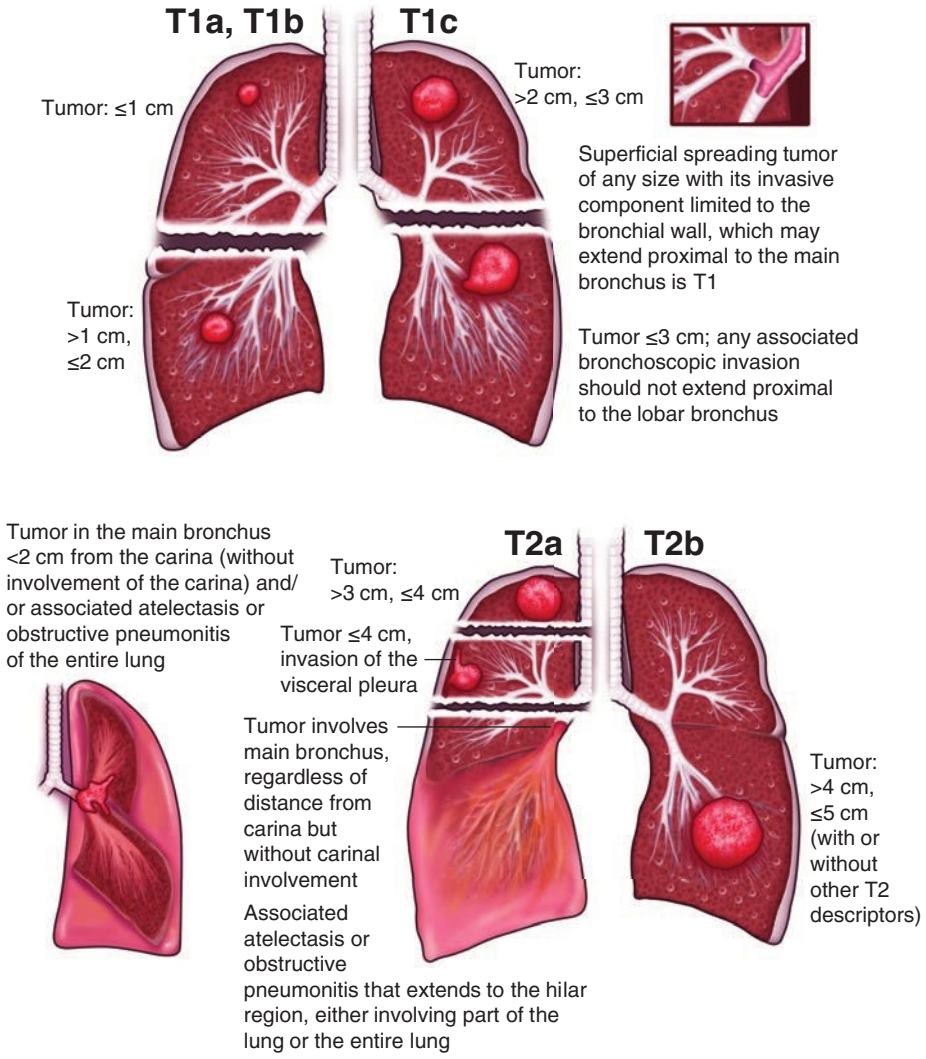

FIGURE 24–6 Lung cancer staging for tumor (T). SVC, superior vena cava.

(*Continued*)

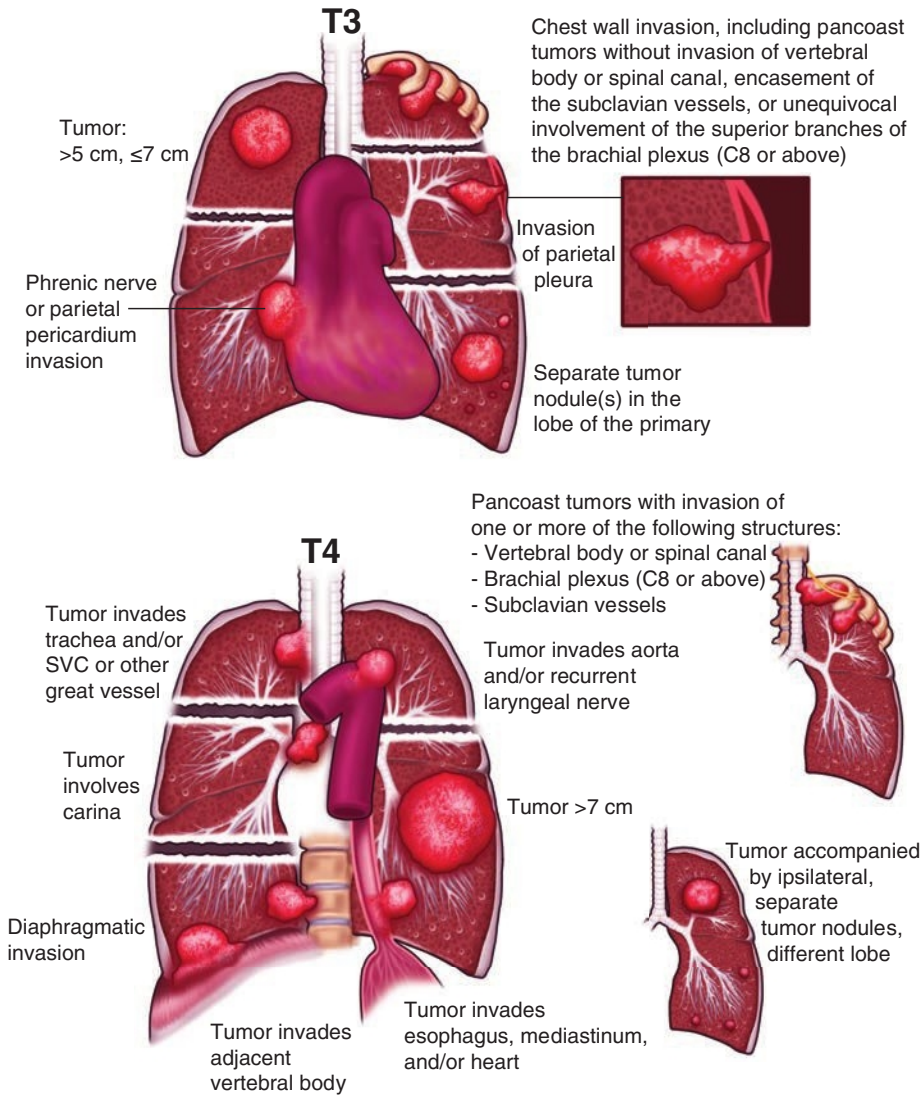

FIGURE 24–6 (*Continued*)

of surgery.[49] Surgery, however, remains the standard of care for patients who can tolerate it.

Concurrent chemotherapy and radiotherapy are recommended for patients who are medically inoperable with stage II (node-positive) and stage III NSCLC.[50–53]

Adjuvant Chemotherapy

Even after complete resection, rates of recurrence of NSCLC are high, prompting the study of adjuvant chemotherapy in this disease. The potential benefit of adjuvant chemotherapy is the eradication of micrometastatic disease before it becomes clinically evident, thus potentially increasing cure rates. For patients with completely resected stage II or III NSCLC, multiple meta-analyses demonstrate that adjuvant platinum-based chemotherapy is associated with an absolute benefit in 5-year survival rate of about 5%.[54] In a pooled analysis of five largest trials of cisplatin-based chemotherapy in patients with completely resected NSCLC showed that this benefit is greater with increasing stage, with a hazard ratio (HR) for stage II of 0.83; (95% CI, 0.73–0.95) and HR for stage III of 0.83; (95% CI, 0.72–0.94).[55] Thus, adjuvant chemotherapy should be offered to all patients with good performance status, with completely resected stage II and III NSCLC (Table 24–11).[55–60] For patients with no lymph node involvement and a primary tumor smaller than 4 cm, adjuvant chemotherapy is not recommended. For node-negative tumors larger than 4 cm, the Cancer and Leukemia Group B 9633 trial suggested a benefit of adjuvant platinum-based chemotherapy, and it should be considered particularly in the setting of high-risk factors such as vascular invasion, visceral

Data from Goldstraw P, Chansky K, Crowley J, et al: The IASLC Lung Cancer Staging Project: Proposals for Revision of the TNM Stage Groupings in the Forthcoming (Eighth) Edition of the TNM Classification for Lung Cancer, *J Thorac Oncol* 2016 Jan;11(1):39-51.

pleural involvement, wedge resection, poorly differentiated tumors, and unknown lymph node status[56,61] (see Table 24–11).

Cisplatin–vinorelbine is the most studied regimen for adjuvant chemotherapy; in practice, other cisplatin-based doublets are frequently used. Acceptable second agents include pemetrexed (for nonsquamous NSCLC), docetaxel, paclitaxel, etoposide, and gemcitabine. Cisplatin is preferred over carboplatin, but if cisplatin is not feasible, carboplatin–paclitaxel is an appropriate alternative.[56] Neoadjuvant chemotherapy offers several real and theoretical advantages over postoperative therapy, including better patient compliance, improved tumor resectability, earlier treatment of micrometastatic disease, and earlier assessment of clinical and pathologic response. There has been one randomized trial and one meta-analysis[62] that suggest the equivalence of the neoadjuvant and adjuvant approaches. Adjuvant treatment is the standard of care, but neoadjuvant chemotherapy could be

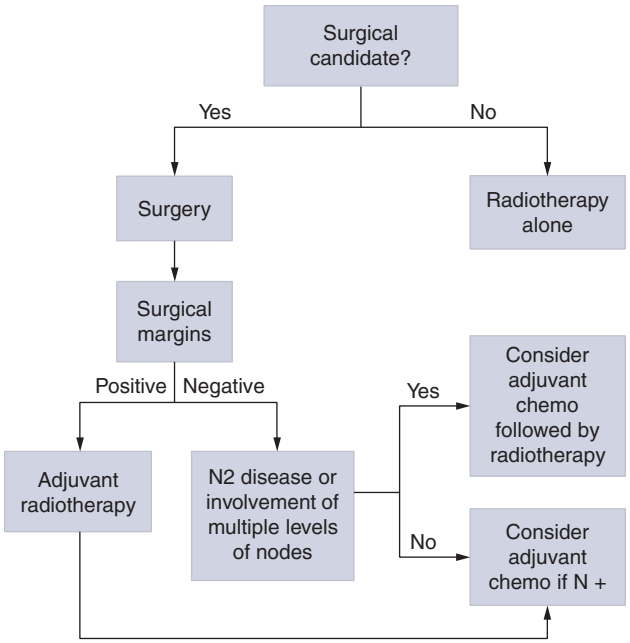

FIGURE 24–9 Treatment algorithm for stage I non–small cell lung cancer. See text for details.

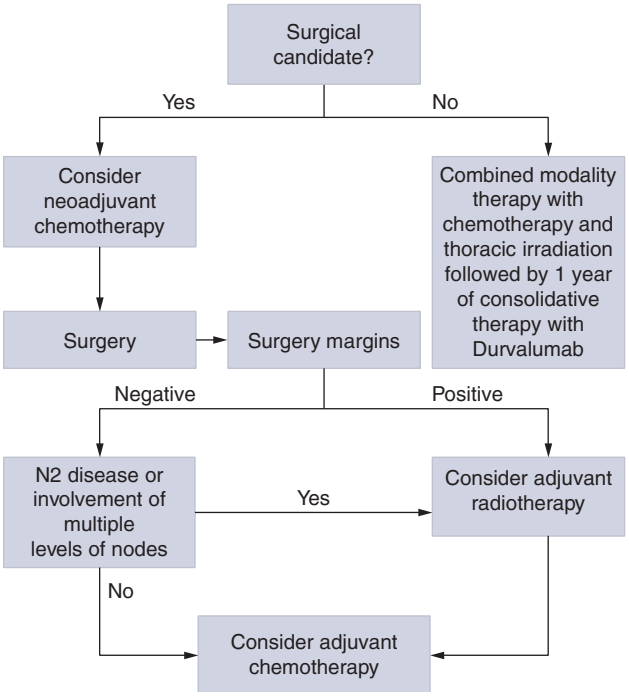

FIGURE 24–10 Treatment algorithm for stage II, incidental III non–small cell lung cancer. See text for details.

considered in special situations, such as for stage III disease when response to chemotherapy may help to determine whether a patient should undergo surgery or chemoradiation.

Adjuvant radiation or chemoradiation for resected stage I and II NSCLC has been shown to be detrimental and is not recommended.[63]

Stage III Disease

Patients with stage III disease have better outcomes with multimodality rather than single-modality therapy, and their care should be managed by an experienced multidisciplinary team. For patients with stage IIIB disease, chemoradiation represents the standard of care.

TABLE 24–11 Chemotherapy Regimens for Adjuvant Treatment of Patients with Non–Small Cell Lung Cancer

Trial	Regimen
IALT[57]	Cisplatin 80–120 mg/m^2 every 3 of 4 weeks for three or four cycles, with
	Vinorelbine 30 mg/m^2 weekly or
	Vinblastine 4 mg/m^2 every week for 5 weeks; then every 2 weeks or
	Etoposide 100 mg/m,^{2} days 1–3, with each cisplatin
ANITA[58]	Cisplatin 100 mg/m,^{2} day 1, every 4 weeks and vinorelbine 30 mg/m^2 weekly for four cycles
NCIC-CTG JBR.10[62]	Cisplatin 50 mg/m,^{2} days 1 and 8, every 4 weeks for four cycles; vinorelbine 25 mg/m^2 every week for 16 cycles
TREAT[60] (nonsquamous histology)	Cisplatin 75 mg/m^2 and pemetrexed 500 mg/m^2 every 3 weeks for four cycles
CALGB 9633[56]	Carboplatin AUC 6 and paclitaxel 200 mg/m^2 every 3 weeks for four cycles
Others	Cisplatin 75 mg/m^2 and docetaxel 75 mg/m,^{2} day 1, every 3 weeks for four cycles Cisplatin 75–80 mg/m,^{2} day 1; vinorelbine 25–30 mg/m,^{2} days 1 and 8, every 3 weeks for four cycles Cisplatin 75 mg/m,^{2} day 1, and gemcitabine 1250 mg/m,^{2} days 1 and 8, every 3 weeks for four cycles Carboplatin AUC 6 and pemetrexed 500 mg/m^2 every 3 weeks for four cycles (nonsquamous histology)

Chemoradiation is often used for patients with stage IIIA disease as well, but surgery with adjuvant treatment can be considered for carefully selected patients.

In a randomized trial of chemoradiation alone versus chemoradiation followed by resection, the patients who benefited from the surgical approach were those with stage IIIA disease who had limited involvement of mediastinal lymph nodes and who underwent lobectomy (as opposed to pneumectomy).[64] Neoadjuvant chemoradiation followed by surgery has been compared with neoadjuvant chemotherapy followed by surgery and adjuvant radiation[65] and was associated with more toxicity with no survival benefit. At MDACC, we consider surgical treatment in patients with stage IIIA disease with good performance status and without multistation or bulky (>2 cm) mediastinal adenopathy. These patients are typically treated with neoadjuvant chemotherapy followed by consideration of surgery. Adjuvant radiation therapy is typically given if there is evidence of mediastinal node involvement based on assessment of surgical pathology (Fig. 24–11).

Patients with stage IIIA disease and extensive mediastinal involvement or IIIB disease should be treated with concurrent chemoradiation and followed by consolidative ICI therapy. Concurrent chemoradiotherapy (CRT), when compared with sequential radiotherapy and chemotherapy, is associated with higher survival rates (23.8% vs 18.1% at 3 years; HR, 0.84; P =.004) with increased, but manageable, acute esophageal toxicity (grade 3–4 from 4% to 18% vs 4%; relative risk [RR], 4.9; P =.001) without a significant difference regarding acute pulmonary toxicity.[50]

Standard radiotherapy for stage III NSCLC consists of radiation given once daily for 6 weeks (30 fractions) to a total dose of 60 Gy. Attempts to increase efficacy through increased radiation dose have failed. In The Radiation Therapy Oncology Group 0617 trial, patients receiving high-dose radiation (74 Gy) had higher rates of locoregional failure (44% vs 35.3%; P =.04) and worse median survival times (19.5 vs 28.7 months; P =.0007) than those receiving standard-dose radiation (60 Gy).[66] Proton therapy is a newer technique that is able to deliver a higher dose to the tumor while delivering lower doses to normal surrounding tissue; it is currently being compared with standard radiation in a randomized phase III trial.

Multiple concurrent chemotherapy regimens have been tested against radiation alone with proven benefit[53]; however, these regimens have not been directly compared with each other, and multiple regimens are considered acceptable (Table 24–12). At MDACC, we favor carboplatin and paclitaxel based on our experience and retrospective data that suggest that this regimen is less toxic than cisplatin and etoposide.[67]

ICI therapy is standard as consolidation after CRT based on a landmark study, the A Phase III, Randomised, Double-blind, Placebo-controlled, Multicentre, International Study of MEDI4736 as Sequential Therapy in Patients With Locally Advanced, Unresectable Non-Small Cell Lung Cancer (Stage III) Who Have Not Progressed Following Definitive, Platinum-based, Concurrent Chemoradiation Therapy (PACIFIC) trial. For patients with unresectable, stage III NSCLC without progression after CRT, durvalumab demonstrated increased survival rates versus placebo leading to its approval by the Food and Drug Administration (FDA). Patients included in the PACIFIC study had stage III unresectable disease, received two or more cycles of platinum-based chemotherapy (containing etoposide, vinblastine, vinorelbine, paclitaxel, docetaxel, pemetrexed) concurrently with definitive radiation, without progression.[68] Patients previously treated with programmed cell death (ligand) 1 (PD-(L)1 inhibitors or grade 2 or greater pneumonitis from previous chemoradiation were excluded.[68] Patients were enrolled irrespective of PD-L1 status. Patients were randomized within

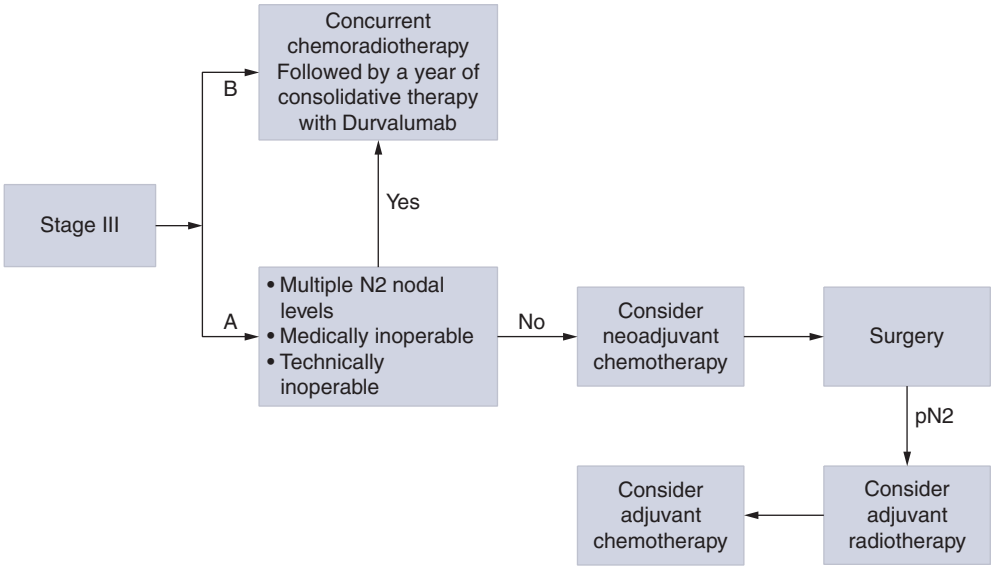

FIGURE 24–11 Treatment algorithm for stage III non–small cell lung cancer. See text for details.

TABLE 24–12 Chemoradiation Regimens for Stage III Non–Small Cell Lung Cancer

Regimen	Histology	Doses	Adjuvant Treatment After the Completion of Chemoradiation
Cisplatin + etoposide	All NSCLC	Cisplatin 50 mg/m^2 days 1, 8, 29,36 Etoposide 50 mg/m^2 days 1–5, 29–33	No
Cisplatin + vinblastine	All NSCLC	Cisplatin 100 mg/m^2 days 1 and 29 Vinblastine 5 mg/m^2 weekly × 5	No
Carboplatin + pemetrexed	Adenocarcinoma	Carboplatin AUC 5 day 1 every 21 days × 4 Pemetrexed 500 mg/m^2 day 1 every 21 days × 4	Yes; continue carboplatin + pemetrexed to a total of four cycles
Cisplatin + pemetrexed	Adenocarcinoma	Cisplatin 75 mg/m^2 day 1 every 21 days × 3 Pemetrexed 500 mg/m^2 day 1 every 21 days × 3	Yes; continue cisplatin + pemetrexed to a total of three cycles
Carboplatin + paclitaxel	All NSCLC	Carboplatin AUC 2 weekly during radiation Paclitaxel 45–50 mg/m^2 weekly during radiation	Yes; two cycles of carboplatin AUC 6 + paclitaxel 200 mg/m^2 every 21 days after the completion of chemoradiation

AUC, area under the curve; NSCLC, non–small cell lung cancer.

6 weeks of completing CRT to receive durvalumab 10 mg/kg intravenously every 2 weeks or placebo for up to 12 months.[68] They were stratified by age younger than 65 years vs 65 years and older), sex, and smoking status (current or former smoker vs never smoker). A total of 473 patients were randomized to durvalumab, and 236 patients were randomized to placebo.[68]

The addition of durvalumab improved progression-free survival (PFS) and OS; 12-, 24- and 36-month OS rates with durvalumab and placebo were 83.1% versus 74.6%, 66.3% versus 55.3%, and 57.0% versus 43.5%, respectively, and therapy was generally tolerated well with without compromising patient-reported outcomes.[69,70]

After radiation therapy to the involved lung, any grade of pneumonitis was observed in nearly one third of patients in the durvalumab arm, with 20% attributed to radiation pneumonitis and about 13% attributed to durvalumab.[71] Pneumonitis was the most common immune-related adverse event leading to treatment discontinuation, and four patients died from pneumonitis. This immune-related adverse event needs to be followed closely in patients undergoing this consolidative approach.

If patients have a contraindication to ICI therapy, such as organ transplant or active autoimmune disease, when the safety of immunotherapy has not been well established, consolidative chemotherapy can be considered. However, no level 1 randomized evidence supports a survival benefit with this treatment.[72,73]

Pancoast Tumors

Tumors in the lung apex invading apical structures, termed pancoast tumors (Figs. 24–12 and 24–13), are challenging. Patients with N0 to N1 tumors should undergo preoperative concurrent chemoradiation followed by resection. For these patients, 5-year disease-free survival rates are 40% to 50%.[74] Patients with N2 to N3 disease should be treated with concurrent chemoradiation followed by durvalumab therapy.

Stage IV Disease

The primary goals of systemic therapy in patients with metastatic NSCLC are to reduce symptom burden from cancer, delay progression of symptoms, and improve survival while maintaining quality of life. Before palliative systemic therapy, a consideration should be made for palliative radiotherapy in patients with symptomatic brain or spinal cord metastases, hemoptysis, postobstructiccmetastases. Early referral to specialized palliative care services has also been shown to improve OS.[75]

Advances in tumor analysis by next-generation sequencing (NGS) and other profiling technologies

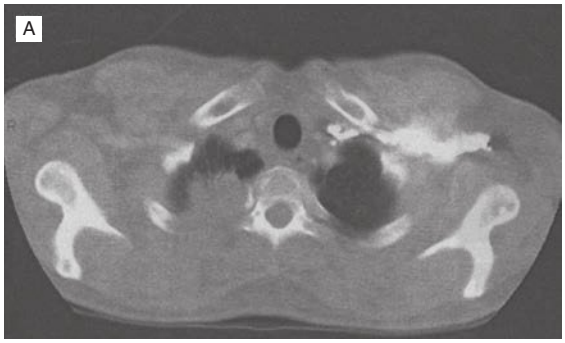

FIGURE 24–12 Pancoast tumor.

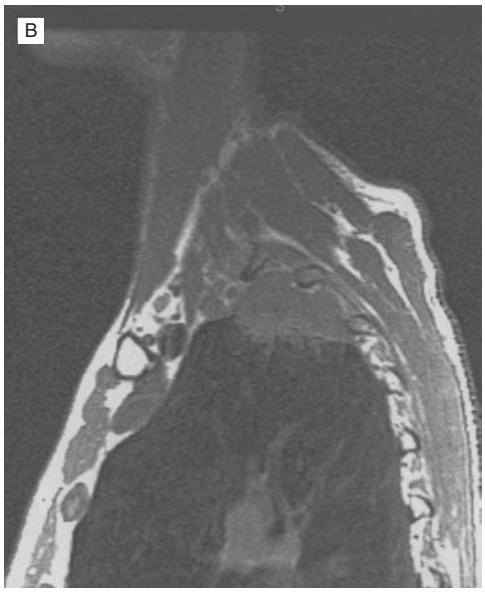

FIGURE 24–13 On magnetic resonance imaging, this non–small cell lung cancer tumor at the right lung apex invades the second right rib and extends apically into the right apical fat, with a loss of the fat plane between the tumor and the T1 nerve. The T2 nerve is also involved by the mass.

provide information on tumor diagnosis and prognosis and provide therapy options for patients. At MDACC, we recommend molecular profiling with NGS for locally advanced, metastatic NSCLC whenever feasible because multiplexed genetic sequencing panels, such as NGS, not only enables the simultaneous assessment of multiple genomic alterations such as *EGFR, ALK, BRAF, RET, ERBB2(HER2)*, and *MET* but also hundreds of other genes that may have potential roles in cancer development and targets for investigational therapies.

It is recommend that all adenocarcinomas, mixed adenosquamous carcinomas, NSCLCs not otherwise specified and all lung cancers occurring in nonsmokers should undergo comprehensive molecular profiling. Because of the importance of molecular testing, attempts should be made to obtain core biopsies rather than fine-needle aspirations to ensure sufficient tissue for profiling.[76] Systemic therapy for NSCLC with actionable molecular alterations is reviewed in Chapter 25, and this chapter focuses on systemic therapy for advanced NSCLC with no actionable mutations.

First-Line Systemic Therapy for Advanced Non–Small Cell Lung Cancer with no Actionable Tumor Mutation

Until 2016, chemotherapy combinations of cisplatin or carboplatin with paclitaxel,[77] docetaxel,[77] pemetrexed[78,79] (nonsquamous only), gemcitabine,[77] or nab-paclitaxel[80] were standard of care first-line therapy option because compared with best supportive care, chemotherapy had been associated with a modest improvement in median OS (1.5 months) and significant gains in symptom control.[81] Multiple platinum-based doublets are effective with response rates from 18% to 35%, PFS of 3 to 6 months, and OS of 8 to 12 months.[77–80,82] A deeper understanding of tumor–immune interactions and development of ICIs have dramatically changed the therapeutic landscape of NSCLC and other malignancies.[83]

Immunotherapy in Advanced Non–Small Cell Lung Cancer

Immune checkpoints are the T-cell regulatory mechanisms of co-stimulatory and inhibitory signals that control the amplitude and quality of immune response. The expression of inhibitory immune checkpoints can be upregulated by tumors and serve as an adaptive immune evasion mechanism.[84] Activation of the programmed cell death 1 (PD-1) receptor by its ligand (PD-L1) has been recognized as a major immune inhibitory mechanism in solid tumors.[85,86] Antibodies that inhibit the PD-1–PD-L1 and cytotoxic T-lymphocyte-associated protein (CTLA-4) pathway produce durable clinical responses in various solid tumors, including NSCLC.[87–90] PD-(L)1 inhibitors improve clinical outcomes compared with traditional chemotherapy and are now standard with or without chemotherapy for NSCLC without oncogenic driver alterations (Table 24–13).

Several factors are taken into consideration when selecting a first-line treatment option for a patient with metastatic NSCLC, including tumor histology, molecular profile, PD-L1 expression levels, preexisting autoimmune diseases, and other comorbid conditions. Next we discuss several of the available first-line options and studies that inform the choice of those options.

Immune Checkpoint Inhibitor Monotherapy

Previous trials focused on cancer vaccines in NSCLC, which were shown to induce tumor-specific immune responses but failed to improve survival.[91] Subsequently, identification and targeting immune checkpoints has renewed the interest in immunotherapy approaches for NSCLC. Clinical studies showed clinical benefit with therapies targeting CTLA-4, PD-1–PD-L1 axis in melanoma, which led to studies in other solid tumors, including metastatic NSCLC.[92] Initial studies in previously treated metastatic NSCLC reported a statistically significant improvement in OS with PD-(L)1 inhibitors compared with docetaxel in patients with platinum-refractory advanced NSCLC and revealed a relationship between higher tumor PD-L1 protein expression and greater efficacies.[93–96] These observations led to clinical trials with PD-(L)1 inhibitors in the

TABLE 24–13 Efficacy of Immune Checkpoint Inhibitor Monotherapy in the First-line Treatment of Patients with Non–Small Cell Lung Cancer

Trial	Patients (*n*)	Patient Population	Treatment Arm(s)	Control Arm	Overall RR	OS (months)	PFS (months)

[a]The recommended pembrolizumab dosage for this indication is 200 mg intravenously every 3 weeks.
[b]The recommended atezolizumab dosage for treatment of patients with non–small cell lung cancer (NSCLC) is 840 mg every 2 weeks, 1200 mg every 3 weeks, or 1680 mg every 4 weeks
[c]High programmed cell death ligand 1 (PD-L1) expression (PD-L1–stained ≥50% of tumor cells [≥50%] or PD-L1–stained tumor-infiltrating immune cells [ICs] covering ≥10% of the tumor area [IC ≥ 10%]) by the VENTANA PD-L1 (SP142) Assay (Ventana Medical Systems, Inc.).
CI, confidence interval; HR, hazard ratio; OS, overall survival; PFS, progression-free survival; RR, Response rate; TPS, tumor proportion score.

first-line setting with PD-L1 protein expression being a stratification and/or an inclusion criteria.

In the KEYNOTE 024 (NCT02142738) trial, patients with treatment-naïve NSCLC without *EGFR* or *ALK* gene aberrations and PD-L1 tumor proportion score (TPS) of 50% of higher (PD-L1 expression as determined by an IHC assay using the PD-L1 IHC 22C3 pharmDx Kit) were randomized to pembrolizumab 200 mg intravenously every 3 weeks for up to 35 cycles or platinum-based chemotherapy for four to six cycles.[97] The chemotherapy regimens included platinum–pemetrexed for patients with nonsquamous NSCLC and platinum–paclitaxel or gemcitabine for those with squamous NSCLC. Pemetrexed maintenance was allowed after initial platinum-based therapy. Crossover from chemotherapy to pembrolizumab was also allowed in the event of progression. A total of 154 patients were assigned to pembrolizumab, and 151 patients were assigned to chemotherapy, with the most common chemotherapy regimen being carboplatin plus pemetrexed.[97] The median PFS with pembrolizumab in patients with PD-L1 TPS of 50% or greater was 10.3 months versus 6.0 months in the chemotherapy group with an HR of 0.50 (95% CI, 0.37–0.68; P <.001).[97] In an updated analysis, median OSs were 30.0 months (95% CI, 18.3–months to not reached) with pembrolizumab and 14.2 months (95% CI, 9.8–19.0 months) with chemotherapy (HR, 0.63; 95% CI, 0.47–0.86). Eighty-two patients assigned to chemotherapy crossed over on study to receive pembrolizumab. When adjusted for crossover using the two-stage method, the HR for OS for pembrolizumab versus chemotherapy was 0.49 (95% CI, 0.34–0.69). Treatment-related grade 3 to 5 adverse events were less frequent with pembrolizumab compared with chemotherapy and were 31.2% vs 53.3%, respectively.[98] This trial demonstrated that in patients with NSCLC with PD-L1 TPS of 50% or greater, treatment with pembrolizumab monotherapy in the first-line therapy of metastatic NSCLC showed improved PFS,

OS, response rate, duration of response, and safety profile compared with platinum-based chemotherapy, leading to its approval in the first-line setting.

IMpower110 (NCT02409342), was a randomized, open-label trial in patients with therapy-naïve patients with stage IV NSCLC whose tumors expressed PD-L1 (tumor cells [TCs] ≥1% or tumor-infiltrating immune cells (ICs) ≥1% measured by VENTANA PD-L1 [SP142 assay]). Patients were randomized (1:1) to receive atezolizumab 1200 mg every 3 weeks versus platinum-based chemotherapy. Although there was no statistically significant difference in OS between the arms for the lower PD-L1 subgroups (TC ≥5% or IC ≥5% and TC ≥1% or IC ≥1%), in the high PD-L1 subgroup (TC ≥50% or IC ≥10%), the median PFS was 8.1 months in the atezolizumab arm and 5.0 months in the platinum-based chemotherapy arm (HR, 0.63; 95% CI, 0.45–0.88). Median OS was 20.2 months for patients in the atezolizumab arm compared with 13.1 months in the chemotherapy arm (HR, 0.59; 95% CI, 0.40–0.89; $P = .0106$). Confirmed overall response rate (ORR) was 38% versus 29%, and grades 3 to 4 treatment-related adverse events were reported in 12.9% in the atezolizumab arm compared with 44.1% in chemotherapy.[00]

Subsequently efforts focused on investigation of clinical efficacy of immunotherapy in tumors with low or absent PD-L1 expression. The KEYNOTE 042 (NCT02220894) study explored the use of pembrolizumab in the first-line setting by using a PD-L1 TPS 1% or greater as the cutoff. Patients were randomized to receive pembrolizumab 200 mg intravenously every 3 weeks or investigator's choice of a carboplatin-containing regimen with either pemetrexed or paclitaxel for their treatment-naïve locally advanced or metastatic NSCLC.[100] In addition to selection criteria, PD-L1 protein expression was also used for patient stratification (TPS ≥50% vs TPS 1-49%). OS in the TPS 50% or greater NSCLC subgroup, the TPS 20% or greater NSCLC subgroup, and the overall population (TPS ≥1%) were the major efficacy measures.[100] KEYNOTE 042 demonstrated statistically significant OS improvements for those randomized to pembrolizumab compared with chemotherapy in all three populations.[100] Although there was no significant difference in PFS or ORR between therapy arms in the TPS 1% or greater population (overall population), the median OS was improved to 16.7 months in the pembrolizumab arm compared with 12.1 months in chemotherapy arm (HR, 0.81; 95% CI, 0.71–0.93; $P = .0036$). It is important to point out that in this study, OS benefit had been largely driven by tumors that had high PD-l1 IHC TPS score. In the TPS 50% or greater subgroup, the estimated median OSs were 20 months in the pembrolizumab arm and 12.2 months for chemotherapy arm (HR, 0.69; 95% CI, 0.56–0.85; $P = .0006$). In contrast, for patients with PD-L1 TPS of 1% to 49%, there was no significant difference in OS compared with chemotherapy with a median OS of 13.4 versus 12.1 months (HR, 0.92; 95% CI, 0.77–1.11). The grade 3 to 5 drug-related adverse events were less frequent at 18% with pembrolizumab versus 41.0 % for chemotherapy.[100] These findings led to the FDA approval of pembrolizumab monotherapy for tumors with PD-L1 TPS of 1% or higher by a companion diagnostic test using PD-L1 IHC assay in the first-line therapy of patients with metastatic NSCLC.

In a similar trial design, the PD-1 inhibitor nivolumab failed to demonstrate improved OS benefit in the phase 3 CheckMate 026 (NCT02041533) study. This study compared nivolumab with histology-dependent platinum-based doublets in treatment-naïve metastatic NSCLC. PD-L1 expression level of 5% or greater on TCs was selected as a cutoff for eligibility. In this study, nivolumab did not show OS benefit compared with a platinum doublet.[101] When comparing results of KEYNOTE-042 and CheckMate 026, it should be noted that the chemotherapy arm in CheckMate 026 permitted crossover to nivolumab after disease progression, whereas KEYNOTE-042 did not. In CheckMate 026,60% of patients in the chemotherapy arm received subsequent ICI therapy at the time of their progression, but only 20% of patients in the chemotherapy arm received subsequent ICI therapy in the KEYNOTE 042 study, which might have contributed to a difference in OS benefit in these two studies.

Because of relative limited clinical activity in low PD-L1–expressing tumors and generally nonoverlapping toxicity profiles of PD-(L)1 inhibitors and chemotherapy, subsequent efforts shifted to combination therapy strategies, which included chemotherapy, biologic agents, and other ICIs. Multiple therapy combinations have resulted in improved clinical outcomes for first-line therapy of patients with NSCLC compared with platinum doublets and have received FDA approvals (Table 24–14).

Combination Therapies Containing Immune Checkpoint Inhibitors s

KEYNOTE 189 (NCT02578680) was a randomized open-label study of first-line treatment of metastatic nonsquamous NSCLC. Patients were randomized (2:1) to receive pembrolizumab 200 mg given intravenously every 3 weeks (or placebo) in combination with pemetrexed and investigator's choice of either cisplatin or carboplatin every 3 weeks for four cycles followed by pembrolizumab (or placebo) and pemetrexed maintenance. Treatment with pembrolizumab continued until disease progression, unacceptable toxicity, or a maximum of 24 months. The primary efficacy outcome measures were OS and PFS.[101] The trial demonstrated a statistically significant improvement in PFS and OS

[a]Comparative analysis for atezolizumab, carboplatin, paclitaxel, and bevacizumab arm versus platinum-based chemotherapy arm among patients with nonsquamous non–small cell lung cancer (NSCLC) without an *EGFR* or *ALK* mutation.
[b]The recommended dosages for metastatic NSCLC are nivolumab 3 mg/kg every 2 weeks and ipilimumab 1 mg/kg every 6 weeks.
[c]The recommended nivolumab dosage for this indication is 360 mg every 3 weeks with ipilimumab 1 mg/kg every 6 weeks and two cycles of platinum-doublet chemotherapy. The nivolumab and ipilimumab is continued until disease progression, unacceptable toxicity, or up to 2 years in patients without disease progression.
CI, confidence interval; HR, hazard ratio; OS, overall survival; PFS, progression-free survival; RR, Response rate.

for patients randomized to pembrolizumab plus chemotherapy. Median PFSs were 9.0 (95%CI, 8.1–9.9) months for pembrolizumab plus chemotherapy and 4.9 (95% CI, 4.7–5.5) months for placebo plus chemotherapy (HR, 0.48; 95% CI, 0.40–0.58), and the median OS was 22.0 (95% CI, 19.5–25.2) months versus 10.7 (95% CI, 8.7–13.6) months, respectively (HR, 0.56; 95% CI, 0.45–0.70). OS and PFS benefits with pembrolizumab were observed regardless of PD-L1 expression or presence of liver or brain metastases. The incidence of therapy-related grade 3 to 5 adverse events was similar in the pembrolizumab–chemotherapy (71.9%) and placebo–chemotherapy (66.8%) arms (HR, 0.49; 95% Confidence interval (CI) 0.38-0.64; P <.00001).[103]

KEYNOTE 407 (NCT02775435) had a trial design similar to KEYNOTE 189 but was conducted for metastatic squamous NSCLC, regardless of PD-L1 tumor expression status, as a first-line systemic therapy for metastatic disease. A total of 559 patients were randomized to pembrolizumab 200 mg or placebo in combination with carboplatin and investigator's choice of either paclitaxel every 3 weeks or nab-paclitaxel weekly on a 3-week cycle for four cycles followed by pembrolizumab or placebo. Patients continued pembrolizumab or placebo maintenance until disease progression, unacceptable toxicity, or a maximum of 24 months. The main efficacy outcome measures were OS, PFS, and ORR.[104] The trial demonstrated statistically significant improvements in OS, PFS, and ORR for patients receiving pembrolizumab plus chemotherapy compared with those randomized to placebo plus chemotherapy. The median PFSs were 6.4 and 4.8 months for the pembrolizumab plus chemotherapy and placebo plus chemotherapy arms, respectively (HR, 0.56; 95% CI, 0.45–0.70; P <.0001). The ORRs were 58% and 35%, favoring the pembrolizumab-containing arm (95% CI, 9.9–36.4; P = .0008). The median OSs were 15.9 and 11.3 months for the pembrolizumab plus chemotherapy and placebo plus chemotherapy arms, respectively (HR, 0.64; 95% CI, 0.49–0.85; P = .0017). Treatment-related adverse events of grade 3 or higher occurred in 69.8% of the patients in the pembrolizumab-combination group and in 68.2% of the patients in the placebo-combination group. But discontinuation of treatment because of adverse events was more frequent in the pembrolizumab-combination group than in the placebo-combination group (13.3% vs 6.4%).[104]

IMpower130 (NCT02367781) was a randomized, open-label trial for treatment-naïve stage IV nonsquamous NSCLC. Patients with activating mutations were allowed to receive prior *EGFR* or *ALK* kinase inhibitor if appropriate. The trial randomized 724 patients to receive atezolizumab 1200 mg as an intravenous (IV) infusion every 3 weeks plus protein-bound paclitaxel and carboplatin followed by single-agent atezolizumab maintenance or to receive protein-bound paclitaxel plus carboplatin followed by maintenance pemetrexed at the investigator's discretion (control). The primary efficacy outcome measures were PFS and OS.[105] In the primary analysis population (intention to treat, *EGFR* mutation, *ALK* translocation wild type n = 681), the median PFS was 7.2 months (95% CI, 6.7–8.3) for the atezolizumab arm compared with 6.5 months (95% CI, 5.6–7.4) for the control arm (HR, 0.75; 95% CI, 0.63–0.91; P = .0024). Median OSs were 18.6 months (95% CI, 15.7–21.1) and 13.9 months (95% CI, 12.0–18.7), respectively (HR, 0.80; 95% CI, 0.64–0.99; P = .0384). Treatment-related grade 3 to 4 adverse events were reported in 381 (81%) of 473 patients in the atezolizumab plus chemotherapy arm and 164 (71%) of 232 patients in the control arm.[106]

IMpower150 (NCT02366143), was an open-label, randomized, three-arm study for first-line treatment of patients with metastatic nonsquamous NSCLC and was designed to conduct comparisons between atezolizumab, carboplatin, paclitaxel, and bevacizumab (four-drug regimen); atezolizumab, carboplatin, and paclitaxel three3-drug regimen); or carboplatin, paclitaxel, and bevacizumab (control arm). After completion of four or six cycles of carboplatin and paclitaxel, patients continued to receive bevacizumab in the four-drug arm and the control arm and continued to receive atezolizumab in the two experimental arms until disease progression or unacceptable toxicity. In this study atezolizumab was given at 1200 mg as an IV infusion every 3 weeks. The major efficacy measures were OS and PFS.[107]

Among patients with nonsquamous NSCLC without an *EGFR* or *ALK* mutation, median PFSs were 8.5 months for patients receiving the four-drug regimen and 7 months for those in the control arm (HR, 0.71; 95% CI, 0.59–0.85; P = .0002). Median OSs were 19.2 months for patients receiving the four-drug regimen and 14.7 months for the control arm (HR, 0.78; 95% CI, 0.64–0.96; P = .016). The ORRs were 55% in the four-drug arm and 42% in the control arm. No significant differences in interim OS or final PFS were observed between the three-drug arm and the control arm. The incidence of treatment-related adverse events was reported in 219 (55.7%) of 393 patients in the four-drug arm and 188 (47.7%) of 394 patients in the control arm. The most common adverse reaction resulting in discontinuation of atezolizumab was pneumonitis (1.8%). With this study, the FDA approved the use of atezolizumab in combination with bevacizumab, paclitaxel, and carboplatin for the first-line treatment of patients with metastatic nonsquamous NSCLC with no *EGFR* or *ALK* genomic tumor aberrations. In a preplanned analysis, in patients with *EFGR* mutation (124 *EGFR* mutant, including 91 with sensitizing mutation), PFS was reported to be longer in

the four-drug arm than the control arm (median PFS, 8.3 months vs 6.8 months; stratified HR, 0.61; 95% CI, 0.52–0.72). Although the number is small this subgroup analysis provided evidence to use atezolizumab plus bevacizumab and chemotherapy in patients with *EGFR*-mutant NSCLC who have failed TKIs.[107] However, use of this regimen in patients with *EGFR*-mutant adenocarcinoma is not yet FDA-approved.

Efforts to spare toxicities of chemotherapy also led to exploration of non–chemotherapy-containing ICI combinations. CheckMate-227 (NCT02477826) was a randomized multiarm study in patients with stage IV or recurrent NSCLC.[108] As a part of this study, patients with PD-L1 of 1% or higher (by using PD-L1 IHC 28-8 pharmDx [Agilent Technologies, Inc.] platform) were stratified according to histologic subtype (squamous NSCLC vs nonsquamous NSCLC) and were randomized to nivolumab 3 mg/kg every 2 weeks plus ipilimumab 1 mg/kg every 6 weeks, platinum doublet (chemotherapy arm) every 3 weeks for up to four cycles, or nivolumab at a flat dose of 240 mg every 2 weeks. The median PFSs were 5.1 months (95% CI, 4.1 to 6.3) in the nivolumab plus ipilimumab arm and 5.6 months (95% CI, 4.6–5.8) in the chemotherapy arm (HR, 0.82; 95% CI, 0.69–0.97). Median OSs were 17.1 months (95% CI, 15–20.1) versus 14.9 (95% CI, 12.7–16.7) (HR, 0.79; 95% CI, 0.67–0.94; $P = .0066$) favoring nivolumab plus ipilimumab arm over the chemotherapy arm. Confirmed ORRs were 36% (95% CI, 31–41) and 30% (95% CI, 26–35), favoring the nivolumab plus ipilimumab arm. Median response durations were 23.2 months in the nivolumab plus ipilimumab arm and 6.2 months in the chemotherapy arm.[108] Based on this study, the FDA approved the use of ipilimumab and nivolumab combination as first-line treatment for patients with metastatic NSCLC whose tumors express PD-L1 (≥1%), as determined by an FDA-approved test.[109]

Addition of chemotherapy to ICI therapy has been considered particularly because of the early progression and transient higher death rates compared with the chemotherapy arms for patients, particularly with PD-L1 protein expression low or negative tumors (Fig. 24–14). This can be observed not only because

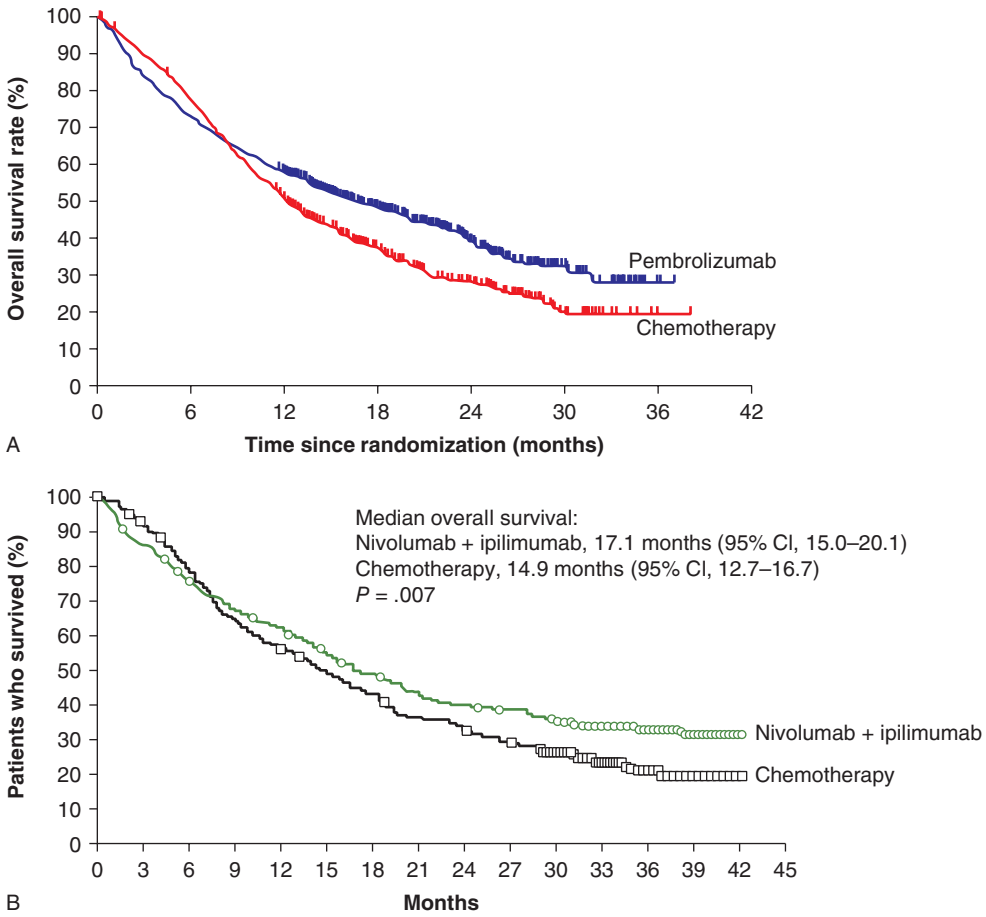

FIGURE 24–14 **Kaplan-Meier estimates of survival. A. KEYNOTE 042 in programmed cell death ligand 1 (PD-L1) tumor proportion score (TPS) 1% or greater population. B. CheckMate 227 in the PD-L1 %1 or greater population. In both studies, there is a crossover in overall survival because of early deaths with immune checkpoint inhibitors. CI, confidence interval.**

of the lack of response to ICI in primary resistance to immunotherapy but also because of delayed responses to ICI. Despite the OS benefit with combined ICI therapy in CheckMate 227, early progression and transient higher death rates compared with the chemotherapy arm led to studies exploring combination ICIs with an abbreviated course of chemotherapy. The aim was to rapidly achieve disease control and prevent early death while limiting the duration of cytotoxic therapy. Efficacy of this strategy was investigated in the CheckMate-9LA (NCT03215706) study, which randomized patients to receive standard platinum doublet vs nivolumab plus ipilimumab and two cycles of platinum-doublet chemotherapy as first-line treatment for patients with metastatic or recurrent NSCLC, unselected for PD-L1 expression and with no *EGFR* or *ALK* aberrations. Although these data are not yet published in final form, early progression and death were not observed on the ICI–chemotherapy arm, which was reflected in improved median PFS of 6.8 months (95% CI, 5.6–7.7) versus 5 months (95% CI, 4.3–5.6) (HR, 0.70; 95% CI, 0.57–0.86). Median OSs were 14.1 months (95% CI, 13.2–16.2) versus 10.7 months (95% CI, 9.5–12.5) (HR, 0.69; 96.71% CI, 0.55–0.87). Similar to other studies with combined ICI and chemotherapy, ORR was increased as well (38% (95% CI, 33–43) versus 25% (95% CI, 21–30), respectively).[110]

At MDACC, for patients with a good performance status and with tumor PD-L1 expression less than 50%, in patients with rapidly progressive disease or high disease burden regardless of the tumor PD-L1 status and in patients for whom tumor PD-L1 status is not readily available, we typically choose combined ICI and chemotherapy based on KEYNOTE 189, KEYNOTE 407, IMpower 130, IMpower 150, and CheckMate 9LA studies. For patients with tumor PD-L1 TPS score of 50% or greater and without high disease burden, we offer anti–PD-(L)1 monotherapy (KEYNOTE 024, IMpower 110). In patients with tumor PD-L1 1% or greater, the nivolumab and ipilimumab combination is an acceptable alternative, particularly for patients who wish to avoid chemotherapy (CheckMate 227). For frail patients with tumor PD-L1 1% or greater, pembrolizumab alone is appropriate (KEYNOTE 042).

Programmed Cell Death Ligand 1 As a Biomarker

In earlier studies with PD-(L)1 inhibitors, PD-L1 protein expression in the surface of the TCs correlated with responses to PD-(L)1 inhibitors. Subsequently, prospective trials validated the predictive utility of PD-L1 IHC. Thus, tumor expression of PD-L1 was approved by the FDA as a companion diagnostic before ICI therapy. There are numerous PD-L1 monoclonal antibodies, and efforts to incorporate stromal cell PD-L1 protein expression are ongoing. Currently, three platforms have been validated in prospective studies for patient selection of first-line NSCLC therapy. In PD-L1 monoclonal antibody clone 22C3 in Dako platform, PD-L1 protein expression is evaluated by means of IHC with PD-L1 scoring system based on tumor PD-L1 expression on TC membranes (TPS). This has been validated in the KEYNOTE 024, KEYNOTE 042, and KEYNOTE 189 studies.[97,100,102] The PD-L1 IHC 28-8 pharmDx platform has been prospectively tested in the CheckMate 227 study and received FDA approval.[111] With the IMPower110 study, the FDA also approved the VENTANA PD-L1 (SP-142) assay (Ventana Medical Systems, Inc.) as a companion diagnostic test for selecting patients with NSCLC for treatment with atezolizumab. It is important to note that the VENTANA platform is different compared with the PD-L1 IHC 22C3 pharmDx Kit and PD-L1 IHC 28-8 pharmDx because PD-L1 expression not only takes into account tumor cells but also tumor-infiltrating ICs.[99]

Different clones, protocol conditions, instruments, and scoring or readout methods may pose challenges in introducing different PD-L1 assays for immunotherapy.[112] Efforts to assess the feasibility of harmonizing the clinical use of independently developed commercial PD-L1 IHC assays led to the development of the Blueprint study, which assessed the comparability of PD-L1 scoring in commercially available PD-L1 IHC platforms. FDA-approved monoclonal anti–PD-L1 antibodies clone, 22C3, 28-8, SP263; their platforms PD-L1 IHC 22C3 pharmDx, PD-L1 IHC 28-8 pharmDx 28-8 and VENTANA PD-L1 (SP263), and their respective protocols showed close similarity and were comparable. In contrast, the VENTANA PD-L1 SP142 assay showed less sensitivity (lower TPS scores).[113] At MDACC, we use the 22C3 pharmDx qualitative IHC assay and TPS scoring because it was the first companion diagnostic test to receive FDA approval for ICI monotherapy in PD-L1–positive tumors. It is important to note that these assays were not compared in the setting of a prospective clinical trial; therefore, none can be deemed "interchangeable" with another.[112]

Therapies in the Setting of Contraindications to Immune Checkpoint Inhibitor Therapy

If ICI therapy is contraindicated owing to the presence of autoimmune or inflammatory diseases or in patients with organ transplants, cisplatin–carboplatin–based combinations with paclitaxel,[77] docetaxel,[77] pemetrexed[78,79] (nonsquamous only) gemcitabine,[77] nab-paclitaxel,[80] or vinorelbine[114] remain standard of care therapy (Table 24–15).

The addition of the vascular endothelial growth factor (VEGF)monoclonal antibody bevacizumab to carboplatin–paclitaxel can be considered in patients with nonsquamous NSCLC based on the phase III Eastern

TABLE 24–15 Summary of Platinum-Based Chemotherapy Trials in Patients with Non–Small Cell Lung Cancer

Pivotal Trial	Histology	Drug	Response Rate (%)	PFS (months)	OS (months)	Trial Interpretation
ECOG 1594 (2002)[77]	All NSCLC	Cisplatin 75 mg/m² day 1 + paclitaxel 135 mg/m² over 24 hours day 2 every 3 weeks	21	3.4	7.8	No significant difference between the four-drug regimens
		Cisplatin 100 mg/m² day 1 + gemcitabine 1000 mg/m² day 1, day 8 every 4 weeks	22	4.2	8.1	
		Cisplatin 75 mg/m² + docetaxel 75 mg/m² every 3 weeks	17	3.7	7.4	
		Carboplatin AUC 6 + paclitaxel 225 mg/m² every 3 weeks	19	3.1	8.1	
Socinski et al (2012)[80]	All NSCLC	Carboplatin AUC 6 day 1 + nab-paclitaxel 100 mg/m² days 1, 8, 15 every 3 weeks	33	6.3	12.1	Similar efficacy; nab-paclitaxel associated with more neutropenia and less neuropathy
		Carboplatin AUC 6 + paclitaxel 200 mg/m² every 3 weeks	25	5.8	11.2	
ECOG 4599 (2006)[82]	Nonsquamous	Carboplatin AUC 6 + paclitaxel 200 mg/m² +bevacizumab 15 mg/kg every 3 weeks × 6; then maintenance bevacizumab every 3 weeks	35	6.2	12.3	Benefit of adding bevacizumab to the induction and maintenance phases; high risk of bleeding in squamous histology
		Carboplatin AUC 6 + paclitaxel 200 mg/m² every 3 weeks × 6	15	4.5	10.3	
Scagliotti et al (2008)[78,79]	Nonsquamous	Cisplatin 75 mg/m² + pemetrexed 500 mg/m² every 3 weeks	29	5.5	12.6	Benefit of pemetrexed in nonsquamous histology
		Cisplatin 75 mg/m² + gemcitabine 1250 mg/m² day1, day 8 every 3 weeks	22	5.0	10.9	
	Squamous	Cisplatin 75 mg/m² + pemetrexed 500 mg/m² every 3 weeks	23	4.4	9.4	Benefit of gemcitabine in squamous NSCLC

AUC, area under the curve; ECOG, Eastern Cooperative Oncology Group; NSCLC, non–small cell lung cancer; OS, overall survival; PFS, progression-free survival.

Cooperative Oncology Group (ECOG) 4599 trial.[82] Patients were randomized to carboplatin and paclitaxel with or without bevacizumab. The bevacizumab-containing arm a had better response rate of 35% vs 15% (P <.001), better PFS at 6.2 months versus 4.5 months (P <.001), and improved OS at 12.3 months versus 10.3 months (P =.003). However, there were higher rates of adverse events in the bevacizumab-containing arm, including a higher risk of severe bleeding (4.4% vs 0.7%; P <.001). Patients with squamous histology,

hemoptysis, uncontrolled hypertension, and those older than 70 years of age are at a higher risk for bleeding from bevacizumab and are not candidates for bevacizumab.

Bevacizumab was also combined with pemetrexed and carboplatin in the phase III PointBreak study and compared with paclitaxel–carboplatin–bevacizumab (four cycles) followed by maintenance with pemetrexed plus bevacizumab or bevacizumab alone. Although there was a very modest PFS improvement for patients treated with pemetrexed (6 vs 5.6 months; HR, 0.83; 95% CI, 0.71–0.96), there was no improvement in OS.[115] No randomized data exist to substantiate the precise benefit of bevacizumab added to pemetrexed–carboplatin and pemetrexed maintenance.

At MDACC, for ICI-ineligible patients, we favor first-line therapy with pemetrexed–carboplatin followed by pemetrexed maintenance for patients with lung adenocarcinoma and either gemcitabine or taxane with carboplatin for SCC of the lung.

Maintenance Therapy

The triplet combination of carboplatin, pemetrexed, and pembrolizumab has become a standard of care for patients with nonsquamous NSCLC based on the KEYNOTE 189 trial, as detailed earlier. After four to six cycles of the triplet therapy, patients continue both pemetrexed and pembrolizumab as maintenance. Whether both pemetrexed and pembrolizumab need to be continued as maintenance therapy remains unknown, and clinical trials are planned to answer this question. For patients with SCC, pembrolizumab alone is continued as maintenance. Optimal duration of therapy with ICI has not been established. In the CheckMate 153 trial, patients who discontinued nivolumab within 1 year with those who continued treatment until disease progression or severe adverse events were compared as an exploratory endpoint. In preliminary results available from 163 patients, those continuing nivolumab treatment experienced an improvement in PFS (median PFS not reached [NR] vs 10.3 months; HR, 0.42; 95% CI, 0.25–0.71), and there was only a nonsignificant trend toward improvement in OS (NR vs 23.2 months; HR, 0.63; 95% CI, 0.33–1.22).[116] Although some clinical trials allowed therapy until progression or unacceptable toxicity occurs, some studies had 2 years of therapy with ICI; therefore, the optimal treatment duration remains an open question. It remains unclear if longer treatment duration leads to longer survivorship or increased risk of toxicity. At MDACC, we generally continue treatment with ICIs at least 2 years or until progression or unacceptable toxicity occurs. After 2 years of therapy, depending on the patient's tolerance and preferences, a recommendation is made to continue or discontinue therapy.

Before the immunotherapy era, multiple trials studied maintenance chemotherapy—either continuation maintenance (continuing the same nonplatinum drug or drugs) or switch maintenance (initiating a non–cross-resistant nonplatinum drug) (Table 24–16).[115,117–122] Pemetrexed maintenance has been shown to improve PFS and OS in two phase 3 studies in patients with nonsquamous NSCLC.[118,123] For example, in the PARAMOUNT study, 539 patients with an objective response or stable disease after four cycles of cisplatin and pemetrexed therapy were randomized to pemetrexed or placebo. Maintenance pemetrexed resulted in improved PFS (median, 4.1 vs 2.8 months; HR, 0.62; 95% CI, 0.49–0.79), OS (median, 13.9 vs 11.0 months), and 1-year survival rate (58% vs 45%).[123] Maintenance with bevacizumab versus pemetrexed versus the combination pemetrexed plus bevacizumab after therapy with pemetrexed, carboplatin, and bevacizumab was studied in the ECOG 5508 study. Although there was a statistically significant improvement in PFS (HR, 0.67; P <.001) with combined maintenance, there was no improvement in OS (HR, 0.90; P = .28)[124] compared with monotherapy with either pemetrexed or bevacizumab.

TABLE 24-16 Summary of Maintenance Chemotherapy Trials in Patients with Non–Small Cell Lung Cancer

Trial	Histology	Drug	Response Rate (%)	PFS (months)	OS (months)	Trial Interpretation
Fidias et al (2009)[117]	All NSCLC	Maintenance docetaxel 75 mg/m^2 every 3 weeks × 6 after 4 cycles of carboplatin + gemcitabine	41.4	5.7	12.3	Better PFS with switch maintenance; no OS benefit

TABLE 24-16 Summary of Maintenance Chemotherapy Trials in Patients with Non–Small Cell Lung Cancer (*Cont.*)

Trial	Histology	Drug	Response Rate (%)	PFS (months)	OS (months)	Trial Interpretation
PointBreak, (2013)[115]	Nonsquamous	Carboplatin AUC 6 + pemetrexed 500 mg/m^2 + bevacizumab 15 mg/kg every 3 weeks × 4; then maintenance pemetrexed 500 mg/m^2 + bevacizumab 15 mg/kg every 3 weeks	34	6	12.6	No difference between the two treatment strategies
		Carboplatin AUC 6 + paclitaxel 200 mg/m^2 + bevacizumab 15 mg/kg every 3 weeks × 4; then maintenance bevacizumab 15 mg/kg every 3 weeks	33	5.6	13.4	
ECOG 5508[124]	Nonsquamous	Carboplatin (AUC = 6), paclitaxel (200 mg/m^2) and bevacizumab (15 mg/kg) every 3 weeks for up to 4 cycles followed by maintenance therapy with bevacizumab (15 mg/kg)	NR	4.2	14.4	Even though there are statistically significant differences in progression free survival for the combination maintenance versus bevacizumab, there were no statistically significant differences in overall survival; thus, maintenance with either single-agent bevacizumab or single-agent pemetrexed is considered standard, and maintenance with the combination is not necessary
		Carboplatin (AUC = 6), paclitaxel (200 mg/m^2), and bevacizumab (15 mg/kg) every 3 weeks for up to 4 cycles followed by maintenance therapy with pemetrexed (500 mg/m^2)		5.1	15.9	
		Carboplatin (AUC = 6), paclitaxel (200 mg/m) and bevacizumab (15 mg/Kk) every 3 weeks for up to 4 cycles followed by maintenance therapy with bevacizumab (15 mg/kg) and pemetrexed (500 mg/m^2)		7.5	16.4	

AUC, area under the curve; ECOG, Eastern Cooperative Oncology Group; NA, not applicable; NSCLC, non–small cell lung cancer; OS, overall survival; PFS, progression-free survival; WT, wild type.

Thus maintenance therapy with either pemetrexed or bevacizumab is reasonable for nonsquamous NSCLC after bevacizumab-based first-line therapy.

At MDACC, if ICI therapy is contraindicated, we recommend pemetrexed maintenance as monotherapy for patients with nonsquamous NSCLC

Chemotherapy for Patients with Platinum-Refractory Disease

Patients with disease progression on or after first-line therapy who maintain good performance status are candidates for further palliative systemic therapy. The agents that have proven efficacy after progression on a platinum-based doublet include single-agent docetaxel, paclitaxel, nab-paclitaxel, gemcitabine, pemetrexed (in nonsquamous NSCLC only), and ramucirumab in combination with docetaxel[125] (see Table 24–16). If ICIs have not been given in the first line, then pembrolizumab, nivolumab, or atezolizumab can be given as a second-line therapy (Table 24–17).[78,93–95,97,125–133]

Reexposure to platinum in subsequent lines of therapy increases response rates but not PFS or OS, even in patients with long (>6 months) platinum-free intervals,[129] and is not frequently used. Currently, there are no data to support the use of a different PD-(L)1 inhibitor after failing immunotherapy when used either singly or in combination for first-line treatment (eg, the use of atezolizumab as second-line therapy after failing a pembrolizumab-containing combination as first-line therapy). The only combination therapy approved by the FDA in the second-line setting is docetaxel with the anti-VEGF receptor 2 (anti-VEGFR2) monoclonal antibody ramucirumab.[125] In the pivotal Ramucirumab plus docetaxel versus placebo plus docetaxel for second-line treatment of stage IV non-small-cell lung cancer after disease progression on platinum-based therapy (REVEL) trial comparing docetaxel alone with docetaxel plus ramucirumab in patients with NSCLC of any histology, the combination arm had better PFS (4.5 vs 3 months; $P < .0001$) and OS (10.5 vs 9.1 months; $P = .023$) with no increased risk of severe bleeding. It is important to highlight that only 14% of patients enrolled in the REVEL study had received prior bevacizumab, making it difficult to draw conclusions about this group. Also, unlike the phase III bevacizumab trials

TABLE 24–17 Summary of Second- and Third-Line Chemotherapy and Targeted Therapy Trials in Patients with Non–Small Cell Lung Cancer

Pivotal Trial	Histology	Drug	Response Rate (%)	PFS (months)	OS (months)	Trial Interpretation
***Second* Line**						
TAX 317 (2000)[126]	All NSCLC	Docetaxel 75 mg/m² every 3 weeks	7.1	2.65	7	Benefit of second-line docetaxel
		Best supportive care	0	1.67	4.6	
TAX 320 (2000)[127]	All NSCLC	Docetaxel 75 mg/m² every 3 weeks	6.7	2.1	5.7	Benefit of docetaxel over vinorelbine (less toxicity, same PFS and OS)
		Vinorelbine 30 mg/m² weekly or ifosfamide 2 mg/m²/day, days 1–3 every 3 weeks	0.8	1.9	5.6

AUC, area under the curve; AVAPERL, A Study of Avastin (Bevacizumab) With or Without Pemetrexed as Maintenance Therapy After Avastin in First Line in Patients With Non-Squamous Non-Small Cell Lung Cancer; DELTA, Docetaxel and Erlotinib Lung Cancer Trial; GOIRC, Italian Oncology Group for Clinical Research; IFCT-GFPC, Intergroupe Francophone de Cancérologie Thoracique-Groupe Francaus de Pneumo-Carcerologie; NSCLC, non–small cell lung cancer; NVALT, Dutch society of pulmonologists; OS, overall survival; PARAMOUNT, A Phase 3, Double-Blind, Placebo-Controlled Study of Maintenance Pemetrexed plus Best Supportive Care versus Best Supportive Care Immediately Following Induction Treatment with Pemetrexed + Cisplatin for Advanced Non-Squamous Non-Small Cell Lung Cancer; PFS, progression-free survival; REVEL, Ramucirumab plus docetaxel versus placebo plus docetaxel for second-line treatment of stage IV non-small-cell lung cancer after disease progression on platinum-based therapy; SATURN, Sequential Tarceva in Unresectable NSCLC, a phase 3 placebo controlled study; TAILOR, Erlotinib versus docetaxel as second-line treatment of patients with advanced non-small-cell lung cancer and wild-type EGFR tumours.

that excluded patients with SCC, 25% of patients on this trial had squamous cell histology, and there was no increased risk of bleeding seen in this group. As subsequent lines of therapy, pemetrexed (for nonsquamous NSCLC), docetaxel, and gemcitabine monotherapy can be considered if not used in prior lines of therapy, all of which significantly improve PFS after first-line chemotherapy. Notably, there have been no randomized clinical trials to compare these three agents nor is there evidence of OS benefit in this refractory setting.

TABLE 24–18 Summary of Immunotherapy Trials in the Second-line Treatment of Patients with Non–Small Cell Lung Cancer

Trial	Patients (n)	Patient population	Treatment Arm(s)	Control Arm	Overall RR	OS (months)	PFS (months)
CheckMate 017[94]	272	Previously treated squamous NSCLC	Nivolumab (N)[a]	Docetaxel (D)	20% (N) vs 9% (D)	9.2 (N) vs 6 (D) (HR, 0.59; 95% CI, 0.44–0.79; *P* <.001)	3.5 (N) vs 2.8 (D) (HR, 0.62; 95% CI, 0.47–0.81; *P* <.001)

OAK[151]	850	Previously treated NSCLC	Atezolizumab (A)	Docetaxel (D)	14% (A) vs 13% (D)	13.8 (A) vs 9.6 (D) (HR, 0.73; 95% CI, 0·62–0·87; *P* =·.0003).	2.8 (A) vs 4 (D) (HR, 0.95; 95% CI, 0·82–1.10; *P* = .49

[a]Nivolumab, at a dosage of 3 mg/kg every 2 weeks.
[b]Among patients with programmed cell death ligand 1 tumor proportion scores ≥50%, overall survival (OS) was 14.9 months (pembrolizumab 2 mg/kg) versus 8.2 months (docetaxel); hazard ratio (HR), 0.54; 95% confidence interval (CI), 0.38–0.77; *P* = .0002. OS was 17.3 months (pembrolizumab 10 mg/kg) versus 8·2 months (docetaxel); HR, 0.50; CI, 0.36–0·70; *P* <.0001).
NSCLC, non–small cell lung cancer; OAK, A Study of Atezolizumab Compared With Docetaxel in Participants With Locally Advanced or Metastatic Non-Small Cell Lung Cancer Who Have Failed Platinum-Containing Therapy (OAK); PFS, progression-free survival; RR: response rate.

Toxicity profile, prior therapies, and patient preferences generally guide this therapy decision.[126,127,134]

Treatment of Stage IV Non–Small Cell Lung Cancer in Older Adults

Treatment of advanced NSCLC in the older adults has been addressed in several prospective studies and retrospective analyses, and the International Society of Geriatric Oncology (SIOG) has issued clear guidelines.[135] The general consensus is that older adult patients (defined as patients 70 years of age or older) with good performance status should receive standard therapy. They derive the same level of clinical benefit as their younger counterparts. However, they may experience a higher level or toxicities secondary to an age-related decline in organ function, so close monitoring for toxicities is required.

Management of Oligometastatic Disease

The term "oligometastatic" was used initially by Hellman and Weichselbaum[136] to describe a restricted locoregional tumor load. It has now become synonymous with a limited number (typically one to five) metastatic lesions. Several retrospective and small prospective trials in the setting of oligometastatic NSCLC demonstrated a potential clinical benefit for patients receiving aggressive therapy.[137–142] In patients with solitary brain metastasis resection or stereotactic radiation of the brain lesion followed by definitive therapy to the primary tumor (resection or radiation), compared

with no treatment for the primary tumor, was associated with significant improvement in median OS (26 months vs 13 months) and 5-year survival rates (34% vs 0%).[143]

In patients with solitary adrenal metastasis, adrenalectomy and definitive therapy to the primary tumor result in good outcomes, with a median OS of 26 months and a 5-year survival rate of 30%, which has been consistent in multiple studies.[144] Patients who develop isolated adrenal metastasis more than 6 months after the resection of the primary tumor are the ones with the most benefit.

Patients with oligometastatic disease (one to five lesions) should undergo complete staging, including PET-CT scan and brain MRI. They can then be classified into three subgroups,[145] and aggressive consolidative therapies can be considered on a case-by-case basis after a multidisciplinary evaluation.

- **Low risk:** development of oligometastatic disease more than 2 months after resection of the primary tumor (5-year OS, 47.8%).
- **Intermediate risk:** synchronous metastases (at presentation or within 2 months of the resection of the primary) and no lymph node involvement (N0) disease (5-year OS, 36.2%)
- **High risk:** synchronous metastases and N1/N2 disease (5-year OS, 13.8%)

The term *local consolidative therapy (LCT)* is used when the primary tumor and isolated sites of metastasis are ablated by local treatment modalities, such as resection or radiation, after systemic therapy. A randomized phase II study comparing the efficacy of LCT versus standard systemic therapy only in oligometastatic NSCLC showed statistically significant improvement in efficacy outcomes in the LCT arm. Both the PFS and OS favored LCT, with PFS at 14.2 months (95% CI, 7.4–23.1 months) in LCT arm versus 4.4 months (95% CI, 2.2–8.3 months) with maintenance therapy or observation (MT/O) (P = .022) and the OS at 37.6 months in LCT arm versus 9.4 months in the MT/O arm.[146,147] Its important to note that early closure of this trial by the Data Safety and Monitoring Board resulted in random assignment of only 49 patients, which limited subgroup analysis in this study. Furthermore, because this trial preceded the integration of immunotherapy in NSCLC, it did not assess the impact of LCT in this context. Local consolidative therapies may work through multiple mechanisms. LCT may reduce the pool of systemic therapy-resistant cells.[146] Additionally, ablative therapies such as radiation afford the benefits of tumor antigen release, T-lymphocyte expansion, and T-lymphocyte receptor diversification that may manifest as enhanced immunosurveillance and antitumor immunity.[138–150]

At MDACC, we consider local consolidative therapy in patients with good systemic control, particularly those with oligometastatic presentation. However, further research is ongoing to help better define the patient population most likely to benefit from this therapeutic approach, especially with integration of ICI therapy.

FUTURE DIRECTIONS

The treatment for patients with NSCLC, especially in the metastatic setting, has witnessed remarkably rapid change over the past 10 years. This change has been driven by the recognition of significant molecular heterogeneity of disease, identification of targetable genetic changes defining the many subgroups, the development of well-tolerated and effective tyrosine kinase inhibitors, and the addition of immunotherapy to the NSCLC therapeutic armamentarium. Both targeted therapy and immunotherapy are being investigated in patients with early-stage NSCLC with the goal of increasing cure rates.

Certainly, the incorporation of immunotherapy has substantially altered the lives of patients with NSCLC, and its full impact is surely not yet fully realized. However, several challenges remain. An optimal biomarker that facilitates rational selection of initial immunotherapy still eludes us as does the identification of second-line immunotherapy effective in those who progress on PD-(L)1 inhibitors with without anti–CTLA-4. Both of these topics are top priorities in ongoing and future research.

MD ANDERSON PRACTICE TIPS

- We consider surgical treatment in patients with stage IIIA disease with good performance status and without multistation or bulky (>2 cm) mediastinal adenopathy. These patients are treated with neoadjuvant chemotherapy followed by consideration of surgery. Adjuvant radiation therapy is given if there is evidence of mediastinal node involvement based on assessment of surgical pathology.
- We recommend molecular profiling with NGS for all patients with metastatic or recurrent NSCLC
- We consider LCT in patients with good systemic disease control, particularly in those with oligometastatic presentation.

Targeted Therapies in Non–Small Cell Lung Cancer

Yasir Y. Elamin
Don L. Gibbons
Marcelo V. Negrao

KEY CONCEPTS

- Non–small cell lung cancer (NSCLC) can be classified based on recurrent genetic alterations in genes encoding proteins essential to cell proliferation and survival. These genetic alterations are transformative, meaning that they play a pivotal role in transforming a noncancerous cell into a cancerous one. NSCLCs that harbor these alterations are called oncogene-addicted. These genetic alterations are typically mutually exclusive and are characterized by impressive sensitivity to small-molecule receptor tyrosine kinase.
- Identifying patients with targetable alterations has important therapeutic and prognostic implications. Molecular profiling of advanced NSCLC using tumor tissue, cell-free DNA (cfDNA), or both is strongly recommended irrespective of tobacco exposure history.
- Oncogene-addicted advanced NSCLC should be treated with targeted agents specific to each genetic alteration. This is based on impressive clinical activity and the tolerability of targeted agents. There are Food and Drug Administration–approved targeted agents for NSCLC that harbor alterations in EGFR (epidermal growth factor receptor), *ALK* (anaplastic lymphoma kinase), ROS proto-oncogene 1 (ROS1), rearrangements, B-Raf proto-oncogene (BRAF), rearranged during transfection (RET), neurotrophic receptor tyrosinekinase gene (NTRK1-3), and MET (mesenchymal-epithelial transition) as well as promising agents for HER2 (human epidermal growth factor receptor 2) and NRG1 (neuregulin 1).
- Targeted treatment based on clinical demographic characteristics alone is not recommended.
- Emergence of resistance targeted therapy is inevitable. Resistance mechanisms can be broadly divided into target dependent or independent. The latter means activation of bypass pathways, leading to clinical resistance. Identifying resistance mechanisms to targeted therapy can determine treatment decisions and; therefore, obtaining a tissue biopsy, cfDNA, or both on progression is generally indicated.
- Treatment of patients with oncogene-addicted NSCLC upon progression on a targeted agent should be individualized. Treatment options include clinical trial enrollment, continuing the same targeted agent with local ablative therapy of progressing lesions, and cytotoxic chemotherapy with or without immunotherapy.

The wide use of molecular profiling techniques combined with a better understanding of signaling pathways in lung cancer and other tumors has led to the identification of mutually exclusive, activating genetic alterations in specific tyrosine kinases that can be targeted using tyrosine kinase inhibitors (TKIs). Matching a specific targeted TKI to the specific driver mutation identified has produced a paradigm shift in the treatment of non–small cell lung cancer (NSCLC), with targeted therapy considered the preferred initial treatment for patients with NSCLC who have such genetic alterations. We now have approved targeted therapies for NSCLC that harbor activating alterations in EGFR (epidermal growth factor receptor), *ALK* (anaplastic lymphoma kinase), ROS proto-oncogene 1 (ROS1), rearrangements, B-Raf proto-oncogene (BRAF), rearranged during transfection (RET), neurotrophic receptor tyrosinekinase gene (NTRK1-3), and MET (mesenchymal-epithelial transition), as well as promising agents for HER2 (human epidermal growth factor receptor 2) and NRG1 (neuregulin 1). Herein, we will discuss each of these genetic alterations.

The National Comprehensive Cancer Network (NCCN) guidelines recommend testing NSCLC for EGRF, *ALK*, ROS1, BRAF and NTRK (https://www.nccn.org/professionals/physician_gls/pdf/nscl.pdf).

This is largely consistent with recommendations from the College of American Pathologists, the International Association for the Study of Lung Cancer, and the Association of Molecular Pathologists.[1,2] There is not a single standard platform for testing that is typically done on tissue biopsies from the primary or metastatic sites. More recently, there has been increase in the use of cell-free DNA (cfDNA) for genotyping because it provides a less invasive source of tumor DNA. cfDNA is particularly useful in patients with insufficient tumor samples for molecular profiling or when obtaining a biopsy is not feasible. The currently available cfDNA profiling platforms have generally shorter turnaround time compared with tumor tissue sequencing; however, they are less broad in their coverage compared with tumor tissue profiling. The cfDNA specificity ranges between 60% and 95%.[3] A limitation of cfDNA is a false-negative rate of approximately 30%.[4,5] This may reflect limited tumor DNA shedding into blood as a result of limited tumor burden.[6,7] A negative result from cfDNA should not exclude the potential existence of a targetable alteration, especially when there is a strong clinical suspicion. Clinical therapeutic decisions can be made based on positive cfDNA results because clinical studies have shown comparable outcomes to those achieved based on tumor tissue sequencing.[8–12]

Table 25–1 summarizes the key genetic alterations and their testing techniques.

EGFR MUTATIONS

EGFR is a transmembrane protein and a member of the HER family of tyrosine kinase receptors that transduces important intracellular signaling.[13] Activating mutations in the *EGFR* gene lead to activation of downstream signaling, resulting in cell proliferation, survival, and migration independent of extracellular stimuli.[14–16] EGFR mutations are the most common targetable alterations in NSCLC, occurring in approximately 15% of lung adenocarcinoma in the United States.[17] These mutations occur more frequently in nonsmokers, females, and Asian populations. EGFR mutations can be divided into classical mutations, L858R, or exon 19 deletions, comprising most EGFR-mutant NSCLC cases, or atypical mutations spanning exons 18 to 21, including in-frame insertions or point mutations within exon 20.[18]

Classical EGFR Mutations

The most frequent EGFR mutations are in-frame deletions in exon 19 that represent approximately 45% of all EGFR mutations followed by point mutations in exon 21 (L858R), seen in 40%.

In advanced NSCLC, the presence of a classical EGFR mutation (exon 19 deletion or L858R) strongly predicts for sensitivity to EGFR TKIs such as erlotinib, gefitinib, afatinib, dacomitinib, and osimertinib; therefore, EGFR TKIs are standard-of-care first-line treatment for metastatic NSCLC harboring a classical EGFR mutation. Several phase 3 clinical trials showed the superiority of first-generation TKIs (erlotinib and gefitinib) and a second-generation TKI (afatinib) over platinum-based cytotoxic chemotherapy in terms of clinical efficacy and tolerability.[19–25] However, newer data suggest improved outcomes with the third-generation TKI osimertinib in the frontline setting.

In the phase III FLAURA trial, in which patients with treatment-naïve EGFR-mutant NSCLC were randomized to osimertinib or a standard of care EGFR TKI (gefitinib or erlotinib), osimertinib led to improved

TABLE 25-1 Key Genetic Alterations and Related Testing Techniques in Non–Small Cell Lung Cancer

Genetic Alteration	Frequency in Lung Adenocarcinoma (%)	Testing Techniques
EGFR mutations (exon 19 deletions, L858R, exon 20 insertions, others)	15	NGS, RT-PCR, Sanger sequencing
ALK fusions	3–5	FISH break-apart probe, IHC (*ALK* [D5F3] CDx Assay is FDA-approved), NGS, RT-PCR
ROS1 fusions	2	FISH break-apart probe, NGS, RT-PCR
BRAF mutations	4	NGS, RT-PCR, Sanger sequencing
MET exon 14 skipping mutations	2–4	NGS, RT-PCR
HER2 mutations	1.5	NGS, RT-PCR, Sanger sequencing
RET fusions	1–2	FISH break-apart probe, NGS, RT-PCR
NTRK fusions	1	NGS
NRG1 fusions	0.2–0.3	NGS, IHC

ALK, anaplastic lymphoma kinase; BRAF, rearrangements, B-Raf proto-oncogene; EGFR, epidermal growth factor receptor; FISH, fluorescence in situ; FDA, Food and Drug Administration; HER2, human epidermal growth factor receptor 2; IHC, immunohistochemistry; MET, mesenchymal-epithelial transition; NGS, next-generation sequencing; NRG1, neuregulin 1; NTRK1-3, neurotrophic receptor tyrosinekinase gene; RET, rearranged during transfection; ROS1, ROS proto-oncogene 1; RT-PCR: reverse-transcriptase polymerase chain reaction.

overall survival (OS) compared with standard of care TKI (38.6 months vs 31.8 months).[8] Progression-free survival (PFS) was also longer in patients treated with osimertinib compared with those treated with erlotinib or gefitinib (18.9 months vs 10.2 months). Objective response rates (ORRs) for osimertinib and standard-of-care TKIs were comparable (80% and 76%, respectively). Furthermore, osimertinib was better tolerated than standard-of-care EGFR TKI. Importantly, the PFS in the subset of patients with central nervous system (CNS) metastases receiving osimertinib was 15.2 months compared with 9.6 months in patients receiving a first-generation EGFR TKI. Among patients with brain metastases evaluable for response, the intracranial response rate was 91% with osimertinib compared with 68% with a first-generation EGFR TKI. Based on these data, osimertinib is now approved by the U.S. Food and Drug Administration (FDA) and the preferred EGFR TKI for the first-line treatment of patients with NSCLC that exhibits a classical EGFR mutation.

Dacomitinib is a second-generation TKI that was approved by the FDA in 2018 for the first-line treatment of patients with metastatic NSCLC with EGFR exon 19 deletion or L858R mutation. A phase III trial compared dacomitinib with gefitinib in patients with treatment-naïve EGFR-mutant NSCLC.[26] Dacomitinib demonstrated an improved OS (34 months vs 27 months) as well as improved PFS (14.7 months vs 9.2 months). Treatment-related toxicities were significantly higher in patients treated with dacomitinib, especially diarrhea and skin rash.

Treatment with an EGFR TKI is generally continued until there is disease progression. Upon progression, a biopsy of a progressive lesion is usually indicated to determine the mechanism(s) of EGFR TKI-acquired resistance. Resistance mechanisms that are observed in all TKIs may be broadly divided into EGFR dependent (eg, secondary EGFR mutations or EGFR amplification) and EGFR independent (eg, MET amplification and small cell transformation).[27–31] Mechanisms of acquired resistance to first- and second-generation TKIs include the acquisition of a secondary EGFR mutation. The most common secondary EGFR mutation is T790M, which increases the affinity of the mutant oncoprotein for ATP to near wild-type levels leading to TKI resistance.[29,32–34] In a phase III trial, osimertinib has shown superior outcomes compared with platinum-based chemotherapy in patients with acquired EGFR T790M-positive NSCLC who progressed on prior TKI. Osimertinib demonstrated a PFS of 10.1 months compared with 4.4 months observed with platinum-based chemotherapy.[35] Osimertinib is FDA-approved for EGFR T790M-positive NSCLC patients who progressed on first- or second-line EGFR TKIs.

EGFR TKIs are generally well tolerated. Their side effects are primarily related to inhibition of the wild-type EGFR tyrosine kinase activity. Accordingly, the commonest adverse events of EGFR TKIs include cutaneous reactions and diarrhea.[36] Cutaneous reactions include acneiform rash, xeroderma, pruritus and paronychia.[36,37] Given its selectivity for the mutant protein, osimertinib generally has a better safety profile.[38,39] Other notable rare adverse events, including interstitial lung disease (ILD), electrocardiogram QT prolongation, and cardiomyopathy, are seen in fewer than 1% to 3% of patients treated with EGFR TKIs.[36,40]

There are no approved targeted therapies for patients with disease progression on osimertinib. Therefore, such patients should preferably be treated in a clinical trial. Other treatment options include local ablative therapy with radiation or surgery with osimertinib continuation for patients with oligoprogressive disease and platinum-based chemotherapy. A subset of 111 patients with NSCLC with EGFR mutation or *ALK* fusion were included in the IMpower 150 trial, which investigated the addition of atezolizumab (anti–programmed cell death ligand 1 [PD-L1 antibody]) to the combination of carboplatin, paclitaxel, and bevacizumab, all of whom had progressed on a prior TKI. Patients with EGFR-/*ALK*-positive NSCLC who were randomized to receive atezolizumab had longer PFS (9.7 months vs 6.1 months) and OS (median not reached vs 17.5 months) compared with the control group.[41] As such, the combination of carboplatin, paclitaxel, bevacizumab, and atezolizumab may be considered for patients who progress on an EGFR TKI. A similar regimen is being investigated in KEYNOTE-789, a randomized phase 3 trial evaluating pemetrexed plus platinum chemotherapy (carboplatin or cisplatin) with or without pembrolizumab in patients with TKI-resistant EGFR-mutant metastatic NSCLC (NCT03515837). The trial outcomes are pending.

Atypical EGFR Mutations

Atypical EGFR mutations represent 10% to 15% of all EGFR mutations.[42–44] The most common of these are in-frame insertions within exon 20 of EGFR, which are generally resistant to currently approved EGFR TKIs.[45,46] Historical data for patients with EGFR exon 20 insertion mutations have shown that overall response rates are approximately 3% to 8% to first-line therapy with erlotinib, gefitinib, or afatinib. In silico modeling revealed that insertions in exon 20 of EGFR result in steric hindrance of the drug-binding pocket resulting in TKI resistance.[47] Currently, there are no targeted therapies approved for the treatment of patients with EGFR exon 20 insertion mutations. Clinical trials investigating novel EGFR TKIs, such as TAK-788 (mobocertinib) and poziotinib, are in progress.

Afatinib is approved for the first-line treatment of patients with NSCLC whose tumors contain EGFR

TABLE 25-2 Epidermal Growth Factor Receptor Mutations and Standard Therapies in Non–Small Cell Lung Cancer

EGFR Mutation Type	Frequency of All EGFR Mutations (%)	Approved TKIs
Exon 19 deletion and L858R	80–85	Osimertinib (preferred), erlotinib, gefitinib, afatinib, dacomitinib
Exon 20 insertions	5–10	None approved
Atypical point mutations (S768I, L861Q, and G719X	10–15	Afatinib

EGFR, epidermal growth factor receptor; TKI, tyrosine kinase inhibitor.

mutations S768I, L861Q, and G719X. The approval is a based on post-hoc analysis of a single group phase 2 trial (LUX-Lung 2) and randomized phase 3 trials (LUX-Lung 3 and LUX-Lung 6).[48] The analysis included 38 patients with EGFR S768I, L861Q, and G719X alone or in combination with each other. In this subset of patients, afatinib demonstrated an ORR of 71.1% with a duration of response of 11.1 months and PFS of 10.7 months. The KCSG-LU15-09 was a multicenter open-label phase II trial that tested osimertinib in the same population of rare EGFR mutations. ORR was 50% (18 of 36 patients; 95% confidence interval [CI], 33%–67%).[49] The median PFS was 8.2 months, and duration of response was 11.2 months (95% CI, 7.7–14.7 months).

Table 25–2 summarizes the types of EGFR mutations and their standard therapy.

ALK FUSIONS

The *ALK* gene was discovered in 1994 when a chromosomal rearrangement t(2;5), resulting in a nucleophosmin (NPM1)–*ALK* fusion, was described in anaplastic large-cell lymphoma.[50–53] Since then, *ALK* fusions have been discovered in several malignancies, including NSCLC. These fusion oncoproteins are transforming in vitro and in vivo, constitutively activating the *ALK* kinase. *ALK* fusions occur in 3% to 5% of patients with NSCLC and are associated with a history of never or light smoking and younger age.[50,51]

Echinoderm microtubule-associated protein-like 4 (EML4) is the most common *ALK* fusion partner in NSCLC resulting in the EML4-*ALK* fusion oncogene. Other rare *ALK* fusions have been described in NSCLC, including kinesin family member 5B (KIF5B)–*ALK*, kinesin light chain 1 (KLC1)–*ALK*, and protein tyrosine phosphatase nonreceptor type 3 (PTPN3)–*ALK* and striatin (STRN)–*ALK*.[54]

ALK fusions can be detected using fluorescence in situ hybridization (FISH), immunohistochemistry (IHC), or next-generation sequencing (NGS). All these tests are FDA-approved for detecting *ALK* fusion in patients with NSCLC.[55]

Metastatic NSCLC that harbors *ALK* fusions are highly sensitive to *ALK* TKIs, which are the standard-of-care first-line therapy for such patients. A summary of clinically relevant *ALK* TKIs is provided next.

Crizotinib

Crizotinib has demonstrated superiority over platinum-based chemotherapy in the frontline setting and was the first *ALK* TKI to be approved by the FDA.[56] However, crizotinib has now been replaced by next-generation *ALK* TKIs that have improved activity and efficacy.

Ceritinib

Ceritinib is a second-generation *ALK* TKI that, like crizotinib, has demonstrated superior efficacy over platinum-based chemotherapy in the first-line setting in terms of PFS and response rate.[57] It has also shown superior efficacy over single-agent chemotherapy in patients who have progressed on first-line crizotinib.

Alectinib

Alectinib is one of the currently preferred *ALK* TKI for the first-line treatment of patients with *ALK*-positive metastatic NSCLC.[58] In the global phase III study (ALEX), patients were randomly assigned to alectinib or crizotinib. The median PFS was 35 months in the alectinib group versus 11 months in the crizotinib group; OS results are not yet mature. The CNS response rates in the subset of patients with baseline measurable CNS lesions in the alectinib and crizotinib groups were 81% and 50%, respectively.

Brigatinib

Brigatinib was compared with crizotinib in the phase III trial ALTA-1L that enrolled treatment-naïve *ALK*-positive patients with advanced NSCLC.[59] Preliminary data demonstrate a PFS of 24 months with brigatinib versus 11 months with crizotinib. Among those with CNS metastases at baseline, the intracranial response rate was significantly higher with brigatinib (78% vs 26%). These data led to the recent FDA approval of brigatinib.

Emerging data indicate that *ALK* fusion variants may have biologic and clinical implications in *ALK*-positive lung cancer. Among EML4-*ALK* variants identified to date, the most common are variant 1 (v1; exon 13 of EML4 fused to exon 20 of *ALK* [E13;A20]) and v3a/b (exon 6a/b of EML4 fused to exon 20 of *ALK* [E6a/b;A20]).[60–62] Preclinical data suggest differential response to crizotinib based on EML4-*ALK* variant.[63] In an analysis of ALTA-1L phase III trial, patients with variant 3 had shorter PFS than patients with variant 1 in both study arms (brigatinib and crizotinib arms).[64] A similar trend was reported in the ALEX trial.[65]

Even though most patients derive clinical benefit from *ALK* TKIs, acquired resistance universally develops, leading to clinical progression. Parallel to what is seen in EGFR TKIs, resistance mechanisms to *ALK* TKIs include *ALK*-dependent and -independent mechanisms.[66–69] Acquired *ALK* resistance mutations are detected in 53% of patients with progressive disease after treatment with alectinib.[70] The most common *ALK* secondary mutations in patients treated with alectinib are G1202R followed by I1171 mutations (I1171T/N/S). G1202R maps to the solvent-exposed region of *ALK*, where the bulkier, charged side chain is thought to lead to steric hindrance of most *ALK* inhibitors.[70,71] Molecular simulation analysis indicated that the I1171T mutation is predicted to disrupt a hydrogen bond between E1167 and alectinib, thus impairing drug binding. *ALK*-independent resistance mechanisms include MET amplification, EGFR pathway activation via an NRG1–ERBB3 (erb-b2 receptor tyrosine kinase 3)–EGFR axis or a TGFα–EGFR autocrine loop, and epithelial–mesenchymal transition.[68,70–72]

Alectinib and brigatinib are generally better tolerated than crizotinib and ceritinib. Common side effects of crizotinib and ceritinib include nausea, vomiting, and diarrhea. The majority of these gastrointestinal toxicities are mild.[56–59] Visual disturbance is a frequent side effect of crizotinib, reported in 25% to 36% of patients treated with crizotinib in phase III trials.[58,59] All grades of pneumonitis and ILD are seen with crizotinib, ceritinib, alectinib, and brigatinib in 3%, 4%, 0.4%, and 4% to 9%, respectively, of patients treated with these TKIs (https://www.accessdata.fda.gov). Brigatinib-related pneumonitis is unique in its early onset (median time to onset, 2 days).[73] Therefore, current prescribing information recommends starting brigatinib at a leading dose of 90 mg for 1 week followed by escalation to 180 mg.

Lorlatinib is a third-generation reversible, ATP-competitive, macrocyclic TKI of *ALK* and ROS1 that has activity against the majority of the known *ALK* TKIs resistance mutations. In a phase II study that included previously treated patients with *ALK*-positive NSCLC,[74] lorlatinib yielded a response rate of 47% in patients who were previously treated by one or more *ALK* TKIs with a CNS response rate of 63%. In patients who were previously treated with two or more *ALK* TKIs, lorlatinib resulted in a response rate of 38.7%. In an analysis of the subset of patients who previously received a second-generation *ALK* TKI, lorlatinib demonstrated a response rate of 69% in patients with *ALK* secondary mutation, whereas the response rate was 27% in those without a secondary mutation.[74] Lorlatinib has been granted FDA approval for the treatment of patients with *ALK*-positive NSCLC who have progressed on crizotinib and at least one other *ALK* inhibitor, as well as for those who have progressed on either alectinib or ceritinib as frontline *ALK* inhibitor therapy for metastatic disease.

Patients with disease refractory to *ALK* TKIs should be considered for chemotherapy with or without immunotherapy. The aforementioned study, IMpower 150, showed that the combination of carboplatin, paclitaxel, bevacizumab, and atezolizumab results in longer median OS and PFS compared with the same regimen without atezolizumab in the subset of patients with TKI previously treated EGFR-/*ALK*-positive NSCLC.[41] Therefore, this combination may be considered for such patients. Alternatively, platinum-based chemotherapy without immunotherapy can be considered. NSCLCs harboring *ALK* fusions are associated with low ORRs to single-agent programmed cell death protein 1 (PD-1) and PD-L1 inhibitors.[75,76] Therefore, PD-1 and PD-L1 inhibitors should not be offered as single agent to patient with *ALK* fusion–positive lung cancer before exhausting other therapeutic options.

ROS1 FUSIONS

ROS1 is a tyrosine kinase receptor that is part of the insulin receptor family. This gene is located on the long arm of chromosome 6 (6q22) and encodes a transmembrane protein with intracellular C-terminal tyrosine kinase domain.[77,78] It shares marked sequence homology and structural similarities to the *ALK* oncogene.[78] ROS1 is susceptible to chromosomal rearrangements that can alter the protein function and lead to constitutive activation of downstream pathways such as mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K)–Ak strain transforming (AKT)–mammalian target of rapamycin (mTOR)to promote carcinogenesis.[78,79]

ROS1 fusions account for approximately 2% of NSCLC cases.[79] Clinical and histologic features that are commonly associated with ROS1-positive NSCLC include adenocarcinoma histology, never smokers, and younger patients.[79] CD74 and SLC34A2 are among the most common ROS1 fusion partners in NSCLC, but others such as SDC4 and EZR have also been described.[77,78,80,81] Although important for detection of ROS1 fusions, fusion partners have not been associated

with differences in clinical outcome.[80–82] ROS1 fusion detection can be performed by FISH or NGS.[82,83] For NGS, RNA-based methods are preferred because of higher sensitivity for detecting genomic rearrangements with multiple fusion partners.[84,85]

Crizotinib was the first approved ROS1 fusion TKI. Two phase II trials for advanced NSCLC harboring ROS1 fusions showed crizotinib 250 mg orally (PO) twice a day (bid) led to an ORR of 72%, median duration of response (DoR) of 20 to 24.7 months, and median progression free survival (mPFS) of 16 to 19.3 months.[80,81,86] Long-term follow-up of the PROFILE 1001 trial (median follow-up, 62.6 month) showed that Median overall survival (mOS) was 51.4 months, and 12-, 24-, 36-, and 48-month OS were 79%, 67%, 53%, and 51%, respectively.[81] The most common side effects reported were visual impairment (87%), nausea (51%), edema (47%), diarrhea (45%), vomiting (38%), elevated liver function test (LFT) results (36%), constipation (34%), fatigue (21%), dysgeusia (19%), and dizziness (19%). A total of 94% of events were G1 to G2. Most common G3 toxicities were hypophosphatemia (15%), neutropenia (9%), vomiting (4%), and elevated LFT results (4%).[81]

Ceritinib was also tested for treatment of advanced NSCLC harboring ROS1 fusion in a Korean phase II trial (n = 32). Patients with stage IV ROS1 fusion NSCLC (6% pretreated with crizotinib and 94% treatment-naïve) received ceritinib 750 mg/day until disease progression. With a median follow-up period of 14 months, ORR was 62%, disease control rate (DCR) was 81%, mPFS was 9.3 months (crizotinib-naïve patients, 19.3 months), median DoR was 21 months, and median OS was 24 months. Intracranial disease control and ORR were 63% and 25%, respectively. Despite its efficacy, ceritinib showed high rates of G1 to G2 adverse events, including diarrhea (78%), nausea (59%), anorexia (56%), vomiting (53%), cough (47%), and muscle pain (41%), and the rate of G3 fatigue was 16%.[87]

The incidence of brain metastases in patients with newly diagnosed ROS1 fusion stage IV NSCLC ranges from 19% to 36%.[88,89] A retrospective analysis showed that CNS progression can be the first and sole site of disease progression in almost half of patients treated with crizotinib (47%).[88] This demonstrates that the blood–brain barrier can hamper crizotinib's intracranial penetration and lead to intracranial disease progression. Other than low intracranial concentration, emergence of resistance solvent-front mutations (SFMs) have been shown to account for approximately 64% of cases of extracranial disease progression to crizotinib,[89] with G2032R, D2033N, and S1986F being the most commonly reported.[89,90] These mutations impede drug binding and promote crizotinib resistance.[89] Because of low intracranial penetration and poor activity of crizotinib for resistance SFM, novel ROS1 fusion inhibitors are under clinical development.

In 2019, entrectinib, a dual ROS1-NTRK inhibitor, was approved for treatment of patients with advanced NSCLC harboring ROS1 fusion based on a pooled analysis of three trials (STARTRK-1, STARTRK-2, and ALKA-372-001).[82] Patients with locally advanced or metastatic TKI-naïve ROS1 fusion NSCLC treated with entrectinib 600 mg/day were included in the efficacy analysis. The majority of patients had adenocarcinoma histology, 43% had brain metastasis, and only 32% were treatment-naïve. At median follow-up period of 15.5 months, ORR was 77%, intracranial ORR was 55%, mPFS was 19 months, and duration of response was 24.6 months. Median PFS for patients with IC disease was 13.6 months, and intracranial duration of response was 12.9 months. Median OS was not reached with 82% of patients alive at 18 months. Almost all patients had tumor shrinkage, and response occurred early, usually on the first scan. The most common on-target side effects were dizziness (32%), weight gain (26%), paresthesias (17%), and cognitive changes (6%), which are a result of the potent anti– Tropomyosin receptor kinases A-C (TRKA-C) activity of entrectinib.[82] Because of a better safety profile and higher intracranial activity, we recommend entrectinib for frontline standard-of-care treatment of patients with ROS1 fusion NSCLC.

Lorlatinib, a potent ROS1-*ALK* inhibitor, was specifically developed for higher intracranial penetration[83] and is currently under clinical testing for treatment of patients with ROS1 fusion NSCLC. In a phase I/II trial, the efficacy of lorlatinib 100 mg/day for treatment of patients with ROS1 fusion advanced NSCLC was dependent on prior TKI exposure. For TKI-naïve and crizotinib-pretreated patients, ORRs were 62% and 35%, intracranial response rates were 64% and 50%, and median DoRs were 25.3 and 13.8 months, respectively. Intracranial DoR was not reached. Of the six patients harboring G2032R resistance SFM, none achieved partial response (PR), one had progressive disease (PD), and five had stable disease (SD) (range of SD duration, 2.9–9.6 months).[83]

Repotrectinib is a TKI targeting ROS1-NTRK-*ALK* that exhibits potent activity for inhibiting ROS1 fusion proteins harboring SFM.[90] Repotrectinib also compares favorably with other ROS1 targeting TKIs, such as entrectinib, lorlatinib, ceritinib, and crizotinib, for targeting ROS1 harboring SFM in cell line models.[90] In a preliminary analysis of the dose-escalation part of the phase I/II TRIDENT-1 trial (NCT03093116), patients with TKI-naïve ROS1 fusion treated with repotrectinib (n = 10) had an ORR of 80% and an intracranial ORR of 100%. TKI pretreated patients (n = 17; majority pretreated with crizotinib) had an ORR of 18% and an intracranial ORR of 25%. Of the four patients harboring ROS1 G2032R SFM, three had SD, and one achieved PR.[91] This trial is ongoing to determine the recommended phase II dose, which will allow a better understanding of the efficacy of this agent.

Non–ROS1-mediated resistance remains poorly understood, and no directed therapies are available in this setting. ROS1 fusion NSCLC has low tumor mutational burden,[92] and although data are limited, small benefit from treatment with single-agent PD-1 and PD-L1 inhibitors has been seen (ORR, 17%; PD within 2 months of starting treatment, 43%).[76] Even in the presence of positive (≥1%) or high-positive (≥50%) PD-L1 expression, we do not recommend treatment with single-agent PD-1/PD-L1 inhibitors. Therefore, after exhaustion of targeted therapies, we recommend combination treatment with a platinum doublet plus a PD-1/PD-L1 inhibitor (triple therapy)[93] with or without bevacizumab (quadruple therapy).[41]

BRAF MUTATIONS

BRAF is a proto-oncogene located on the long arm of chromosome 7. The BRAF gene encodes a serine/threonine protein kinase named BRAF, which is a part of the MAPK pathway and a key driver of cell proliferation and growth.[94] Despite being enriched in melanoma,[95] BRAF mutations occur in approximately 4% of NSCLC cases and are usually found in ever smokers.[96–100] BRAF mutations have been previously classified as V600 and non-V600, but in recent years, a better understanding of the non-V600 mutations has allowed further classification of the BRAF mutations into three classes: 1, 2, and 3.[94] Class 1 mutations correspond to V600 mutations, of which V600E is the most common. Class 1 mutations promote RAS-independent constitutive activity of BRAF in the form of a monomer.[101–104] Class 2 BRAF mutations are also RAS-independent constitutively active kinases, but contrary to class 1 mutations, they promote downstream signaling in the form of BRAF homodimers.[94,101] BRAF class 2 mutations are further subcategorized into three groups: a, b, and c.[101] Class 2a refers to mutations located in the activation segment of BRAF and include the K601, L597, and E586 loci.[101] Class 2b refers to mutations located in the glycine-rich P-loop and generally includes the G464 and G469 loci.[101] Class 2c includes BRAF fusions, where coupling of the C-terminal kinase domain with the N-terminal dimerization domain leads to constitutive dimerization and activation of BRAF.[94] It also includes in-frame deletions that remove about five amino acids near the β3–αC region of the BRAF kinase and switch the α-C helix to an activated conformational state to promote dimerization and downstream signaling.[94] BRAF class 3 mutations are RAS-dependent kinase impaired mutations that promote downstream signaling in the form of heterodimers with wild-type RAF (eg, C-RAF). This commonly co-occurs because of additional RAS signaling either through activating RAS mutations or NF1 loss-of-function alterations.[102,103]

Currently, only BRAF class 1 V600E mutations have FDA-approved targeted therapies in NSCLC. Vemurafenib, an anti-BRAF targeting TKI, showed an ORR of 37% to 42%, mPFS of 6.5 to 7.3 months, and median OS of 15.4 months for treatment of patients with NSCLC harboring BRAF V600E mutations.[105,106] The combination of MAPK/ERK Kinase (MEK) inhibitor trametinib and BRAF inhibitor dabrafenib has shown an ORR of 63% to 64%, mPFS of 9.7 to 10.9 months, and median duration of response (mDoR) of 9.0 to 10.4 months in the frontline and salvage settings for BRAF V600E mutant NSCLC.[107,108] Noteworthy, G1and G2 side effects from this combination include pyrexia (44%–53%), nausea (40%–56%), diarrhea (32%–33%), peripheral edema (23%–36%), and skin rash (19%).[107,108] Other side effects of interest include skin squamous cell carcinoma (4%), decreased left ventricle ejection fraction (G3, 6%) and ocular toxicity, which includes conjunctivitis (2.8%–8.9%), uveitis (4%), retinal vein occlusion (0.2%), and serous retinopathy (3%–26%).[107–112]

Mechanisms of resistance to single-agent BRAF inhibitor are better understood than for BRAF-MEK inhibitor combinations. Resistance to BRAF inhibitors can develop through reactivation of downstream signaling of the MAPK pathway by acquired BRAF V600E splice site alterations,[113] C-RAF mutations,[114] and NRAS/MEK mutations.[115] Because of this, novel treatment strategies for overcoming resistance include additional downstream inhibition of the MAPK pathway, such as with ERK inhibitors (eg, ulixertinib, LTT462). Another approach is novel BRAF inhibitors that have dimer inhibition activity (eg, LXH254, fili-rafenib). These compounds are currently undergoing clinical investigation. Clinical trial enrollment is recommended and warranted for this population.

There are currently no approved targeted therapies for lung cancers harboring BRAF class 2 and 3 mutations. Similar to investigational approaches for targeting resistance in BRAF V600E mutant tumors, BRAF dimer inhibitors, MEK inhibitors, ERK inhibitors, and SHP2 inhibitors are undergoing clinical development either as single agents or as combination regimens. This is based on preclinical or early clinical data suggesting that non-V600 mutations may be sensitive to these agents.[116–120] Therefore, clinical trial enrollment is encouraged and recommended for this population.

Recent retrospective data from our group and others have shown that advanced NSCLC harboring BRAF mutations may be more susceptible to PD-1/PD-L1 checkpoint blockade compared with other oncogene-driven NSCLC, yielding better ORR and mPFS.[121,122] In addition, high ORR and prolonged PFS have been reported for phase I/II trials combining BRAF and MEK inhibitors with PD-1/PD-L1 blockade in metastatic melanomas harboring BRAF V600 mutations. These findings are based on preclinical data suggesting that

BRAF and MEK inhibition can enhance antitumor immunity and have synergistic effect with immune checkpoint inhibitors by promoting immunogenic cell death[123] and increased T-cell infiltration and activation in the tumor microenvironment.[124,125] Phase III trials testing TKI plus immune checkpoint blockade combinations in metastatic melanoma are expected to read out soon. If positive results emerge, it is likely that a similar approach will be studied in NSCLC as well.

For patients with advanced NSCLC whose tumors harbor a BRAF V600E mutation, we recommend frontline treatment with dabrafenib and trametinib as standard of care. Upon progression, our approach is to recommend treatment with a chemotherapy-immunotherapy backbone, such as carboplatin, pemetrexed, and pembrolizumab, or an immunotherapy combination with nivolumab and ipilimumab. For other BRAF mutations, we recommend frontline chemoimmunotherapy or nivolumab–ipilimumab combinations because of a lack of prospective clinical data showing efficacy of MEK+/-BRAF inhibitor in this population. Clinical trial enrollment is encouraged for all patients with NSCLC harboring class 1, 2, and 3 BRAF mutations and for patients with NSCLC harboring BRAF class 1 V600E mutations that have become resistant to BRAF+/-MEK inhibitors.

MET ALTERATIONS

MET is a proto-oncogene that codes for the tyrosine kinase hepatocyte growth factor receptor. It is located in the long arm of chromosome 7 at position 31.2. Two types of genetic alterations are described for MET oncogenesis: exon 14 skipping mutations and amplification.

MET exon 14 skipping mutations are oncogenic drivers in 3% to 4% of NSCLCs and 8% to 32% of sarcomatoid lung carcinomas.[126] These alterations are typically enriched in patients with older age.[127] Exon 14 encodes a juxtamembrane region of the MET protein receptor that harbors a CBL E3 ubiquitin ligase binding site, Y1003, and loss of this site impairs ubiquitin-mediated degradation of the MET receptor. This leads to decreased turnover of MET and increases MET signaling through the MAPK and PI3K pathways to drive oncogenesis.[10,128] Diverse mutational mechanisms such as point mutations, insertion and deletions, and large deletions are involved. They can disrupt distinct splicing sites flanking exon 14 and lead to exclusion of this exonic region at the RNA level[128,129] or promote deleterious alterations in the Y1003 locus within exon 14.[130] Tissue RNA-based NGS assays are preferred for detecting MET exon 14 skipping mutations because of previous reports showing a 36% false-negative rate for DNA-based assays.[131,132] However, caution is warranted because RNA-based assays rely on the quality of the RNA extracted from tumor tissue.[131] NGS blood-based assays for circulating tumor DNA (ctDNA) detection can also be used and represent an important tool for detecting MET exon 14 skipping mutations both for clinical trial enrollment and for standard clinical practice.[10]

The TKI crizotinib has shown activity for treatment of patients with advanced NSCLC harboring MET exon 14 skipping mutations in an expansion cohort of the PROFILE 1001 trial (n = 69 patients). Treatment with crizotinib led to an ORR of 32%, median DoR of 9.1 months, and mPFS of 7.3 months.[129] Although crizotinib is not approved by the FDA, it is supported by the NCCN guidelines, which recommend treatment with crizotinib for patients with advanced NSCLC harboring a MET exon 14 skipping mutation (NCCN.org). This is further supported by retrospective data suggesting that patients with NSCLC harboring MET exon 14 skipping mutation treated with a targeted agent have longer mOS (24.6 months) compared with patients who never received a MET TKI (8.1 months; hazard ratio, 0.1; 95% C,I 0.0–0.9; P = .04).[133]

Currently, three novel MET TKIs are in clinical development: capmatinib, tepotinib, and savolitinib. These three compounds have shown more potent activity in preclinical models compared with crizotinib (half maximal inhibitory concentration (IC50) 0.6–3.0nM vs 22.5 nM).[134] In addition, capmatinib, tepotinib, and savolitinib have shown activity in NSCLC harboring MET exon 14 skipping mutations in treatment-naïve and previously treated patients.[10,126,134–136] Table 25–3 summarizes the current findings for TKIs targeting MET exon 14 skipping mutations. Capmatinib 400 mg PO bid recently received FDA Accelerated Approval and is now standard of care for advanced NSCLC harboring MET exon 14 skipping mutations. Tepotinib 500 mg PO daily has also received U.S. FDA Breakthrough Therapy Designation for this same indication and is currently under evaluation.

The two most common side effects of MET TKIs are peripheral edema (36.6%–63.0%) and nausea (26%–48.8%), but grade 3 to 4 events of these toxicities were reported in 1% to 7.5% of patients. Other common side effects include increased LFT results (7%–31.7%), diarrhea (11.4%–22%), vomiting (6%–31.7%), increased creatinine (18%–19.5%), hypoalbuminemia (16%–19.5%), pyrexia (24.4%), anemia (17.1%), and decreased appetite (8%–17.1%). Upper abdominal pain and fatigue can also occur in approximately 5% and 7% to 13.8% of patients, respectively. Pneumonitis was an uncommon event (1.5%).[10,134,135]

Mechanisms of acquired resistance to MET TKIs remain poorly understood. Preliminary data suggest both on-target (eg, secondary MET mutations, MET

TABLE 25-3 Efficacy Results for Tyrosine Kinase Inhibitors Targeting MET Exon 14 Alterations in Patients with Non–Small Cell Lung Cancer

	Capmatinib		Tepotinib	Savolitinib	Crizotinib
	Treatment-Naïve (*n* = 28)	Previously Treated (*n* = 69)	(*n* = 99)	(*n* = 70)	(*n* = 69)
ORR (%)	67.9	40.6	46.5	42.9	32

mPFS (mo)	9.7	5.4	8.5	6.9	7.3
Intracranial disease (*n*)	13		11	NA	NA
Intracranial ORR (%)	54		55	NA	NA

DCR, disease control rate; mDoR, median duration of response; MET, mesenchymal-epithelial transition; mPFS, median progression free survival; NA, not available; ORR, objective response rate.

amplification) and off-target bypass-pathway mediated resistance (eg, RAS and PI3K pathway activation, EGFR amplification), but in up to 50% of the cases, the mechanism(s) of resistance are unknown.[10,130,137,138]

Upon progression with MET TKIs, treatment options include chemotherapy, immunotherapy, or both. Clinical benefit from single-agent or combination immune checkpoint inhibition is modest for treatment of patients with NSCLC harboring MET exon 14 skipping mutations. In a small retrospective cohort, ORR was 17%, and mPFS 1.9 was months.[139] Therefore, we recommend combination treatment with PD-1/PD-L1 inhibitor plus platinum doublet chemotherapy with or without bevacizumab (triple or quadruple therapy)[41,93] as standard of care for patients with NSCLC harboring MET exon 14 skipping mutations that progress on MET TKI as long as performance status and clinical condition allow for it. Clinical trial enrollment, if feasible, is warranted for further drug development in this space. One example is Sym015, which consists of an antibody mixture targeting two nonoverlapping sites in the MET extracellular domain.[140] Sym015 has shown early signs of activity in NSCLC previously treated with MET targeting agents (*n* = 9), including DCR of 56%, PFS of 5.4 months, and DoR of 6.5 months.[141]

MET amplification occurs in 1% to 4% of NSCLCs[142,143] and is a poor prognosis biomarker.[143] It is important to differentiate amplification (true gene focal copy number gain) from high polysomy. For MET amplification, this has been defined through FISH as an increase in the ratio of MET gene copy number gain relative to centromere 7 (CEP7).[144] Commercially available NGS assays use copy number callers to distinguish high polysomy from true copy number gain amplification. However, it remains unclear what is the optimal definition of NGS copy number gain to predict benefit from targeted therapies. Real-time quantitative polymerase chain reaction (RT-qPCR) is also currently used to select patients for clinical trial enrollment.[141]

Treatment strategies under investigation for patients with MET-amplified or -overexpressing tumors include TKIs, monoclonal antibodies, and antibody–drug conjugates. In part 2 of the A8081001 trial, 14 patients with MET amplification, defined as a MET-to-CEP7 ratio of 1.8 or greater, were treated with crizotinib (TKI). Confirmed ORR with crizotinib was dependent on the level of MET amplification: low (MET-to-CEP7 ratio, 1.8–2.2; ORR, 0%), intermediate (MET-to-CEP7 ratio, 2.3-4.9; ORR, 17%), and high (MET-to-CEP7 ratio, ≥5.0; ORR, 67%).[144] In addition, the GEOMETRY-1 study evaluated capmatinib (TKI) in previously treated (cohort 1a: *n* = 69) and treatment-naïve (cohort 5a: *n* = 15) MET-amplified (defined as gene copy number ≥10) advanced NSCLC. ORRs were 40% and 29%, and DCRs were 66.7% and 71% for treatment-naïve and previously treated cohorts, respectively. Median DoR was 7.5 to 8.3 months, and mPFS was 4.1 to 4.2 months.[145] Other MET TKIs are currently under investigation. In a phase I trial, the antibody drug–conjugate telisotuzumab vedotin (ABBV-399) showed an ORR of 18.8%, mDoR of 4.8 months, and mPFS of 5.7 months for treatment of patients with NSCLC with MET overexpression (*n* = 16) as defined by an IHC H-score of 150 or greater.[146] In a dose-escalation phase I trial, the monoclonal antibody Sym015 also showed activity in MET-amplified (defined as ISH MET-to-CEP7 ratio ≥2.2 or NGS/qPCR >5 copies) treatment-naïve NSCLC (*n* = 7) with an ORR of 40%, DCR of 100%, mPFS of 5.5 months, and mDOR of 18.4 months.[141] Because of these promising novel compounds, clinical trial enrollment, if feasible, is encouraged for patients with MET-amplified NSCLC.

HER2 MUTATIONS

Human epidermal growth factor receptor 2 (HER2/ERBB2) is an HER/ERBB family receptor tyrosine kinase. HER2 mutations occur in approximately 1.5% of lung adenocarcinomas.[147] The most frequent HER2 mutations in lung cancer occur in exon 20 with the Y772dupYVMA mutation involving 34% of all HER2 mutations.[147] Point mutations, such as L755X and V777L, have also been detected in NSCLC. Targeting HER2 mutations remain an unmet clinical need in which TKIs and HER2 monoclonal antibodies are currently being tested.

Trastuzumab deruxtecan (t-DxD) is a novel antibody–drug conjugate that was tested in a phase 2 trial that enrolled 42 patients with HER2-mutant NSCLC. The ORR was 61.9% with a PFS of 14 months.[148] In a smaller study of 18 patients, ado-trastuzumab emtansine (also known as T-DM1), another antibody–drug conjugate, resulted in an ORR of 44%.[149] The combination of trastuzumab and pertuzumab yielded an ORR of 21% when tested in a cohort of 36 patients.[150]

Numerous TKIs are under development in this setting. Pyrotinib resulted in an ORR of 32% with a duration of response of 7 months in patients with HER2 exon 20 mutant NSCLC.[151] Afatinib, dacomitinib, and neratinib have limited clinical activity in this setting.[152–154] Other TKIs in clinical testing include poziotinib[147] and mobocertinib (TAK-788).

RET FUSIONS

The RET receptor tyrosine kinase is oncogenically activated by chromosomal rearrangements producing RET gene fusions in 1% to 2% of patients with NSCLC.[155] Several multikinase inhibitors with some degree of anti-RET activity demonstrated modest activity in RET fusion–positive lung cancer in phase 2 studies.[156–158] In a retrospective registry study of 165 patients with RET-positive NSCLC, the response rates to cabozantinib, vandetanib, and sunitinib were 37%, 18%, and 22%, respectively.[159]

Selpercatinib is a highly potent and specific small-molecule inhibitor of the RET kinase, with minimal inhibition of other kinase and nonkinase targets. In a phase II study that enrolled 105 patients with RET-positive NSCLC with prior treatment with platinum-based chemotherapy, selpercatinib resulted in a response rate of 68%. Median DoR was 18 months, and median PFS was 17 months.[160,161] Selpercatinib has received approval from the U.S. FDA for patients with RET fusion–positive advanced NSCLC. Selpercatinib is generally well tolerated. The most common treatment-related adverse events (TRAEs) were dry mouth (33.3%), increased aspartate aminotransferase (AST; 24.5%, increased alanine aminotransferase (ALT; 23.8%), hypertension (23.2%), diarrhea (19.7%), and fatigue (16.8%). Only 2% (14 of 702) of patients discontinued selpercatinib because of TRAEs.[161]

Pralsetinib (BLU-667) is a highly potent and selective RET inhibitor targeting oncogenic RET alterations, including those that confer resistance to multikinase inhibitors.[11] The Arrow study is a phase 1/2 trial evaluating pralsetinib in RET fusion–positive advanced tumors. The ORRs in previously untreated and platinum-pretreated patients with NSCLC were 61% and 73%, respectively.[162]

Emerging data suggest that both selpercatinib and pralsetinib have potent intracranial activity. In patients with baseline measurable CNS disease (selpercatinib, 22 patients; pralsetinib, nine patients), the intracranial ORRs were 81.8% and 56%, respectively.[162,163]

NTRK FUSIONS

The tropomyosin receptor kinase (TRK) family includes three transmembrane receptor proteins: TRKA, encoded by NTRK1, which is located in the long arm of chromosome 1; TRKB, encoded by NTRK2, which is located in the long arm of chromosome 9; and TRKC, which is located in the long arm of chromosome 15.[164,165] TRK receptors have tyrosine kinase activity and are activated by binding with the neurotrophins nerve growth factor, brain-derived neurotrophic factor, and NT-3/4/5.[164] After activation, these receptors promote downstream signaling through the MAPK and PI3K-AKT pathways to promote increased proliferation, cellular growth, and survival.[164] These receptors are expressed in neuronal tissue and are particularly important for nervous system development during embryogenesis.[165] After birth, these receptors continue to be primarily expressed in neuronal tissue and modulate sensory perception (eg, pain, proprioception), body weight, and memory.[165]

TRK can become an oncogenic driver by intra- or interchromosomal rearrangements. This occurs when the TRK tyrosine kinase domain 3¢ terminal is joined by a 5¢ sequence partner to generate a fusion protein that is constitutively activated or overexpressed[164] and promotes continues downstream signaling. Currently, several fusion partners have been detected for NTRK, such as CD74, TPM3, and ETV6.[164,166] Although NTRK fusions can occur in all three NTRK genes, NTRK1 and NTRK3 are the most commonly affected.[167,168] In NSCLC, NTRK fusions are rare oncogenic drivers and occur in approximately 0.2% of adenocarcinomas.[169]

The test of choice for detecting NTRK fusion is NGS with an RNA-based method.[169] Because of the diversity of fusion partners and the need to cover all three NTRK genes, FISH requires large amounts of tissue to

test all necessary probes. IHC has shown lower sensitivity compared with RNA NGS for detecting NTRK fusions[169] likely because of limitations related to staining intensity and location and the tumors site of origin. Because NTRK are rare drivers, NGS allows for testing of several gene fusions, simultaneously decreasing the need for specific NTRK testing, contrary to IHC and FISH. NGS RNA-based methods are also preferred compared with DNA NGS-based methods because of higher sensitivity[169] due to diversity of fusion partners and inaccuracy for detecting truly activating fusions, which are those that include the entire TRK tyrosine kinase domain.

Currently, two TKIs are approved for treatment of patients with solid tumors, including NSCLC, harboring TRK fusions: larotrectinib and entrectinib. In a pooled analysis of three phase 1/2 trials including 159 patients with solid tumors harboring a NTRK fusion, larotrectinib showed an ORR of 79%, mDOR of 35.2 months, and mPFS of 28.3 months.[170] For patients with NSCLC (n = 12), ORR was 75%, and mDOR was not reached.[170] Three patients had measurable intracranial disease with two achieving intracranial response. Most common G1 to G2 toxicities were fatigue (30%), ALT or AST increase (24%–25%), cough (27%), constipation (27%), diarrhea (23%), nausea or vomiting (24%), and dizziness (25%).[170] Most common G3 to G4 toxicities were anemia (10%) and decreased neutrophil count (5%), and no treatment-related deaths were reported.[170] Similarly, the efficacy of entrectinib for treatment of patients with solid tumors harboring NTRK fusions was also evaluated in a pooled analysis of three phase 1 or 2 trials.[168] For the 54 patients evaluated, ORR was 57%, mDoR was 10 months, and mPFS was 11 months.[168] For the NSCLC population (n = 10), ORR was 70%.[168] Twelve patients had baseline intracranial disease, and of them, intracranial ORR was 50%, and intracranial DCR was 83%. Median time to CNS progression was 17 months.[168] Most common G1 to G2 adverse events included dysgeusia (47%), constipation (28%), fatigue (28%), diarrhea (27%), peripheral edema (24%), and dizziness (24%). Most common G3 and G4 adverse events included anemia (12%), weight increase (10%), and fatigue (7%).[168] Of note, additional reported on-target adverse events included peripheral sensory neuropathy (8%), disturbance in attention (4%), hyperesthesia (3%), ataxia (3%), and diplopia (4%). Congestive heart failure was reported in 2% of patients.[168] In light of these results, we recommend frontline treatment with larotrectinib or entrectinib for patients with NSCLC harboring NTRK fusions.

Resistance to NTRK inhibitors can be on target through NTRK mutations or off target by activation of bypass or downstream pathways. On-target NTRK mutations typically occur in the TRK kinase domain and hamper drug binding. Examples include NTRK1 G595R and G667C, NTRK2 G639R, and NTRK3 G623R and G623E mutations.[90,171,172] Currently, two novel TRK inhibitors are undergoing clinical testing to overcome resistance in the presence of these on-target mutations: LOXO-195 and repotrectinib. Both agents have shown high activity in preclinical models harboring NTRK resistance mutations, and both have shown early signs of clinical activity by inducing responses in patients with tumors harboring NTRK1 G595R, NTRK3 G623E, and NTRK3 G623R mutations.[90,173] Preliminary results of a phase I trial evaluating LOXO-195 (NCT03215511) for treatment of patients whose tumors had progressed or had become intolerant to TRK TKIs showed impressive activity of this compound with ORR ranging from 25% to 50% depending on the location of the acquired NTRK resistance mutation.[174]

Integrated preclinical and clinical work with patient-derived cell lines, mouse xenograft models, and paired blood molecular profiling suggests that activation of bypass pathways, such as MAPK through BRAF and KRAS mutations and MET amplification and overexpression, can drive off-target resistance to TRK TKIs.[175] In addition, targeting these pathways with BRAF/MEK inhibitors or MET inhibitors showed activity for overcoming resistance in these cases.[175]

In the setting of disease progression on entrectinib or larotrectinib, we recommend repeat molecular profiling through either blood or tissue-based assays and enrollment or referral for enrollment in clinical trials designed for NTRK fusion tumors that have developed resistance to TRK targeting TKIs.

NRG1 FUSIONS

Neuregulins (NRGs) are signaling proteins that mediate cell–cell interactions in the nervous system, heart, and breast.[176] NRG-producing cells bind to the extracellular domain of the receptor tyrosine kinases ERBB3 and ERBB4 of the NRG-responsive cells to promote ERBB homo- and heterodimerization.[176–178] This activates intracellular pathways, such as PI3K-AKT and MAPK, which regulate proliferation, apoptosis, migration, differentiation, and adhesion.[176,178]

The *NRG1* gene is located on the short arm of chromosome 8.[176] NRG1 proteins and isoforms have an extracellular EGF-like domain that induces activation of ERBB tyrosine kinase receptors.[178] Most NRG1 isoforms undergo proteolytic cleavage and release of the EGF-like domain, with the exception of type III, which has a membrane-tethered EGF-like domain that restricts signaling to cell–cell interactions.[177,178]

NRG1 fusions promote expression of NRG1 III-β3 on the cancer cell surface. This leads to ERBB3

binding and activation, which in turn dimerizes with other ERBB tyrosine kinase receptors. This promotes autocrine, paracrine, and juxtacrine activation of PI3K-AKT and MAPK pathways and ultimately leads to cell growth and oncogenesis.[85,177,178] NRG1 fusions are present in 0.2% of cancers and 0.3% of NSCLCs, making NSCLC the most common histology for these alterations (61%).[84,179] Currently, 17 fusion partners have been identified for NRG1, but CD74 (47%), SLC3A2 (16%), and SDC4 (7%) are the three most common in NSCLC.[84] NRG1 fusions are enriched in invasive mucinous adenocarcinomas (27%–31% of cases) and are often mutually exclusive from KRAS, another driver known to be enriched in this histologic subtype.[84,85,180] Because the DNA rearrangements that generate NRG1 fusions typically occur in two large intronic regions and because the fusion partners are diverse and incomplete characterized, RNA sequencing is favored compared with DNA sequencing for detecting these alterations.[84,85] FISH for NRG1 and IHC for p-ERBB3 are alternatives for NRG1 fusion detection.[84,177,180]

There are currently no approved therapies for patients with NSCLC harboring NRG1 fusions. Responses have been reported with the pan-HER family inhibitor afatinib (DoR, 6–12 months) and with the anti-ERBB3 monoclonal antibody GSK2849330 (DoR, 19 months).[84,85,181] Several agents capable of inhibiting ERBB3, both TKI and monoclonal antibodies, are under investigation for treatment of patients with NRG1 fusion–positive NSCLC (seribantumab [MM-121]; zenocutuzumab [MCLA-128] [NCT04100694; NCT02912949]; GSK2849330). Therefore, enrollment in clinical trials is recommended for these patients.

CONCLUSION

The past decade has seen remarkable progress in the lung cancer field with novel actionable mutations and development of increasingly more effective targeted therapies. However, the universal development of resistance focuses research efforts in this arena.

There is also excitement in the field for targeting driver oncogenes that were previously untargetable, and we look forward to novel compounds in this regard. One example of this is KRAS with several G12C inhibitors under clinical development. Efforts are also being made toward targeting tumor suppressor genes. Despite a current lack of approved therapies in this setting, novel treatment strategies are under investigation. Examples include STK11, KEAP1, and TP53. Although not as straightforward as targeting oncogene driver alterations, we believe the field is making important progress, and we look forward to results of upcoming clinical trials in this setting.

MD ANDERSON CANCER CENTER PRACTICE TIPS

- Use broad genomic profiling for all NSCLC using tumor tissue and cfDNA irrespective of tobacco exposure history. NSCLC should be tested at least for EGFR, *ALK*, ROS1, RET, MET, BRAF, and NTRK.
- If a patient requires start of systemic therapy before genomic profiling results become available, consider starting cytotoxic chemotherapy only for the first cycle. If the patient's tumor is found to harbor a targetable oncogene alteration, this will prevent overlapping toxicities from targeted therapy and immune checkpoint inhibition, such as pneumonitis and hepatitis, when changing treatment to targeted therapy in the subsequent 2 to 3 weeks.
- Always consider clinical trial enrollment if feasible and safe for the patient.
- In patients with oligometastatic disease, consider local consolidation therapy (LCT) with surgery or radiation at the time of best response. LCT should also be considered for patients with oligoprogressive disease along with continuing targeted therapy.
- Tumor biopsy and cfDNA testing should be obtained to identify acquired resistance mechanisms. Clinical trials of novel targeted agents and rationale combinations should be considered based on molecular profiling results.

26 Head and Neck Cancer

Ruth Sacks
David Boyce-Fappiano
Amy Moreno
Frank Mott

KEY CONCEPTS

- Head and neck cancers are diverse. In this chapter, we focus on the management of squamous cell carcinomas of the head and neck (HNSCC).
- Tobacco and alcohol use are major risk factors, and the human papillomavirus (HPV) is a risk factor for oropharyngeal cancer (OPC).
- All patients should undergo a multidisciplinary evaluation that includes surgical, medical, and radiation oncology specialists.
- For early-stage HNSCC, surgery or definitive radiation provides excellent local control.
- Most patients present with locally advanced disease requiring a multimodality approach focusing on organ preservation, managing metastatic risk, and minimizing acute and chronic toxicities.
- Immune checkpoint inhibitors are now standard in recurrent and/or metastatic HNSCC.

EPIDEMIOLOGY

In the United States, head and neck cancer is estimated to represent approximately 3.6% (65,630) of new cancer cases and 2% (14,500) of cancer deaths as of 2020.[1] However, the disease is more common in many developing countries, with a worldwide annual incidence of more than 800,000 cases.[2] In more than 90% of these tumors, the histology is squamous cell carcinoma (SCC). Squamous cell carcinoma of the head and neck (HNSCC) primarily affects men, and the median age at diagnosis is 60 years old. Established risk factors include tobacco and alcohol use. Although public health efforts have led to a decrease in tobacco use and thus a reduction in smoking-related malignancies, the incidence of oropharyngeal cancer (OPC) has been steadily rising as a result of the impact of human papillomavirus (HPV) infection.[3,4]

GENETIC PREDISPOSITION

The majority of head and neck cancers are multifactorial diseases influenced by the interaction between carcinogens and/or oncogenic viruses and genetic susceptibility. Certain genetic factors, such as metabolic polymorphisms, DNA repair gene polymorphisms, and variations in other pathways may contribute to carcinogenesis.[5–7] Impaired apoptosis (programmed cell death) may increase the risk of malignancy.[8,9] In HPV-related HNSCC, only a small proportion of HPV-infected individuals have cancer, likely because of genetic susceptibility.[8,10–12] Rare germline mutations have been associated with familial atypical multiple-mole melanoma and Fanconi anemia and confer a risk for the development of HNSCC.[13–15]

RISK ASSESSMENT

The risk of developing HNSCC increases with age; most patients are older than age 50 years. Moreover, there is a clear association with HNSCC development and the use of tobacco and alcohol. Smokeless tobacco and betel quid (combination of betel leaf, lime, and areca nut), commonly used in India and areas of Asia, are associated with the development of oral cavity

cancers. Molecular studies provide evidence that carcinogens found in these substances have a causal role. Mutations in the tumor suppressor gene p53 are prominent in cancers of patients with a history of tobacco and alcohol use.[16] Cancers of the oral cavity, larynx, and hypopharynx are uncommon in individuals with no smoking history. Patients with HNSCC with heavy tobacco and alcohol exposures are at high risk of multiple cancers developing, with "field cancerization" throughout the upper aerodigestive tract and bladder.[17]

In the United States, greater than 70% of cancers arising in the oropharynx, particularly in the palatine tonsils and tongue base, are HPV- related.[18–20] The incidence of OPC in the United States is increasing, primarily because of HPV-associated cases in men.[21] HPV-positive OPC represents a distinct clinical and pathologic subgroup of HNSCC, with poorly differentiated basaloid histopathology and marked tumor responsiveness to radiation and chemotherapy.[22] HPV 16 is the most common viral genotype, with other high-risk HPV genotypes such as HPV 18, 31, or 33 being less common.[20]

Oncogenic oral HPV prevalence is higher in men compared with women and increases with the number of lifetime oral sexual partners and tobacco use.[23] In a study investigating patients with HPV-positive OPC and their long-term sexual partners, the prevalence of oral HPV infection in the partners was comparable with that of the general population, suggesting that the majority of long-term partners had cleared any exposure to active oral HPV infection. However, several patients had a previous or current sexual partner with cervical dysplasia or cervical cancer.[24] A retrospective study from the Swedish Family Cancer Database from 1958 to 1996 found that husbands of women with cervical cancer have a twofold increased risk of tonsillar cancer, supporting HPV transmission via oral sex from a partner with an oncogenic genital HPV infection.[25]

MOLECULAR PATHOGENESIS

The progression of HNSCC is thought to involve multiple stepwise alterations of molecular pathways in the squamous epithelium.[26] Aberrations in the p53 and Rb tumor suppressor pathways are the most common molecular events. The epidermal growth factor receptor (*EGFR*) is also overexpressed in invasive HNSCC in a majority of sample tumors.[27] Binding to *EGFR* by its natural ligands, mainly epidermal growth factor or transforming growth factor–α (TGF-α), prompts dimerization of the receptor, resulting in autoactivation of tyrosine kinase from the intracellular domain of the receptor, intracellular signaling, inhibition of apoptosis, activation of cell proliferation and angiogenesis, and increased metastatic potential.[28]

The molecular pathogenesis of HPV-positive tumors differs from that of HPV-negative tumors. The HPV virus contains a double-stranded genome that encodes proteins E1–E7, associated with viral gene regulation and cell transformation, and L1–L2, associated with the formation of structural capsid proteins for the virus. The E6 and E7 proteins promote carcinogenesis through their respective interactions with tumor suppressor p53 and pRb.[29] The E6 oncoprotein leads to ubiquitination and degradation of p53, causing loss of cell-cycle arrest and apoptosis. In addition, E6 can activate cellular telomerase, allowing the infected cell to maintain telomere length, which plays an essential role in cellular immortalization and transformation. The E7 oncoprotein inactivates Rb proteins, resulting in overactivation of E2F transcription factor with upregulation of cell-cycle genes, which leads to increased DNA synthesis and cell proliferation. Inactivation of Rb proteins produces increased levels of p16, an inhibitor of cyclin dependent kinase–4/cyclin D, via a feedback control mechanism, which is the reason p16 expression serves as a surrogate biomarker for HPV infection.[30]

Smoking-related HNSCCs have a mutation rate approximately twice that of HPV-positive HNSCCs. Mutations include *TP53*, *CDKN2A*, *PTEN*, *PIK3CA*, and *HRAS*. Additional mutations in genes that regulate squamous differentiation, such as *NOTCH1*, *IRF6*, and *TP63* have been described as well as mutations in genes regulating apoptosis.[31]

DIAGNOSIS AND STAGING

Optimal treatment outcomes depend on the precise identification of the primary tumor (Fig. 26–1) as well as the local, regional, and distant extent of disease.

Patients with early-stage disease may present with vague symptoms and minimal physical findings. Patients with locally advanced disease may present with signs and symptoms according to the subsite in the head and neck. Sinusitis, unilateral nasal airway obstruction, and epistaxis may be early signs of cancers of the nasal cavity or paranasal sinuses. Recurrent otitis media may be associated with nasopharyngeal cancer (NPC). Chronic otalgia, dysphagia, odynophagia, and throat soreness lasting weeks may be symptoms of OPC or hypopharyngeal cancers. Many patients with HPV-associated OPC present with an otherwise asymptomatic neck mass and may have limited or no smoking history. Persistent hoarseness demands visualization of the larynx. In supraglottic laryngeal neoplasms a neck mass may be the presenting sign. Careful examination of facial, cervical, and supraclavicular lymph nodes is important because the anatomic patterns of

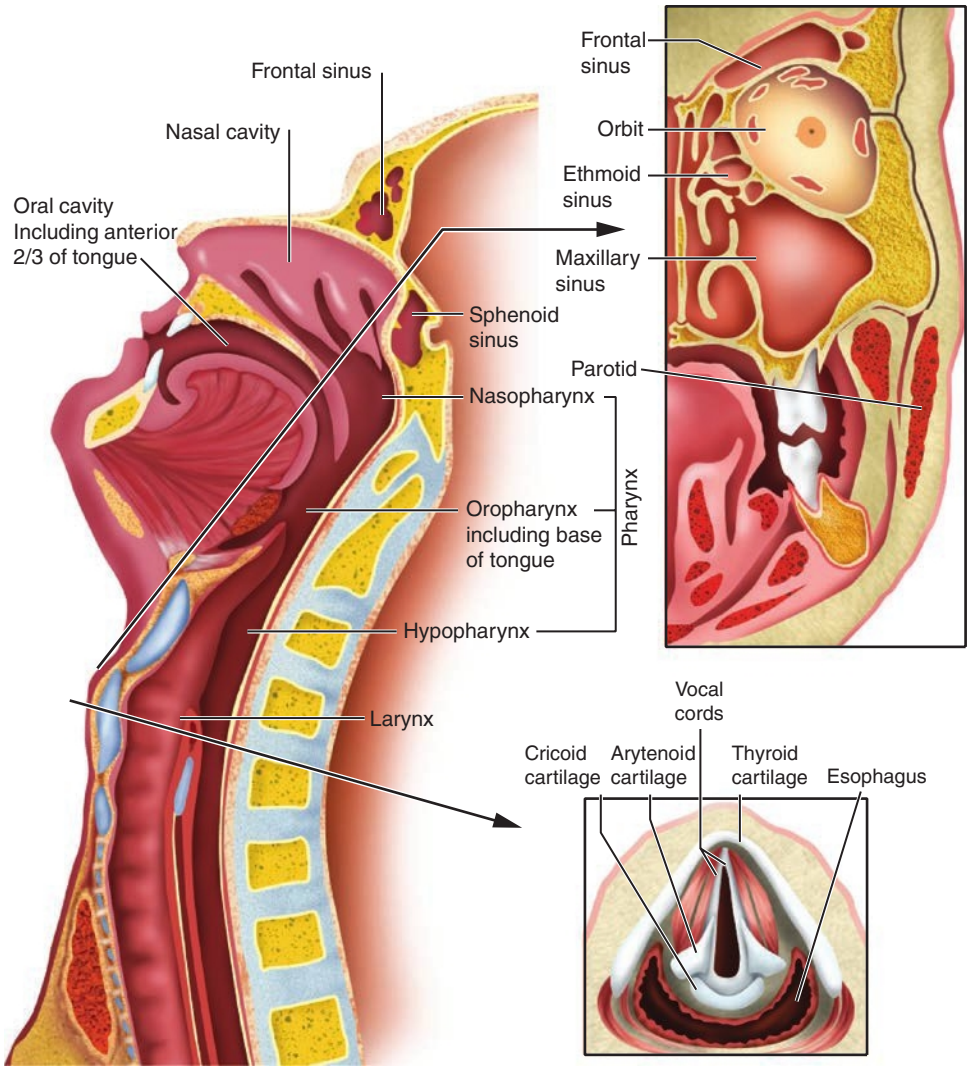

FIGURE 26–1 **Head and neck anatomy.**

lymphatic drainage may reflect the specific subsite of the primary tumor (Fig. 26–2).[32]

Physical examination should include careful inspection of the skin and oral/oropharyngeal mucosal surfaces; palpation of the tongue, floor of the mouth, and oropharynx; systematic palpation of the neck; and an indirect mirror examination of the oropharynx, hypopharynx, and larynx, complemented by fiberoptic endoscopy.[33,34] Leukoplakia (white mucosal patches that cannot be removed by scraping) and higher-risk erythroplakia (red or mixed red-white patches) are the most common premalignant lesions in the head and neck. Any suspicious surface in the oral mucosa should undergo biopsy.

Patients who present with a suspicious neck mass should undergo a systematic examination of the head and neck. If no obvious primary site is found, fine-needle aspiration (FNA) of the mass may establish a diagnosis of cancer. Detection of HPV or Epstein-Barr virus (EBV) DNA in a lymph node suggests a tumor of oropharyngeal or nasopharyngeal origin, respectively. Direct laryngoscopic examination under anesthesia may detect a primary tumor. Suspicious lesions are biopsied, and consideration may be given to tonsillectomy and/or biopsies of the nasopharynx, base of the tongue, and hypopharynx, depending on the pattern of lymphadenopathy. Open biopsy of the neck mass may be performed if FNA and panendoscopy have failed to yield a diagnosis, or in patients suspected of having an alternative process (ie, lymphoma). An experienced head and neck surgeon may be prepared to proceed with selective neck dissection if SCC of unknown head and neck primary origin is determined.

Three-dimensional imaging with computed tomography (CT) from the vertex to clavicles is the preferred local imaging modality for HNSCC.

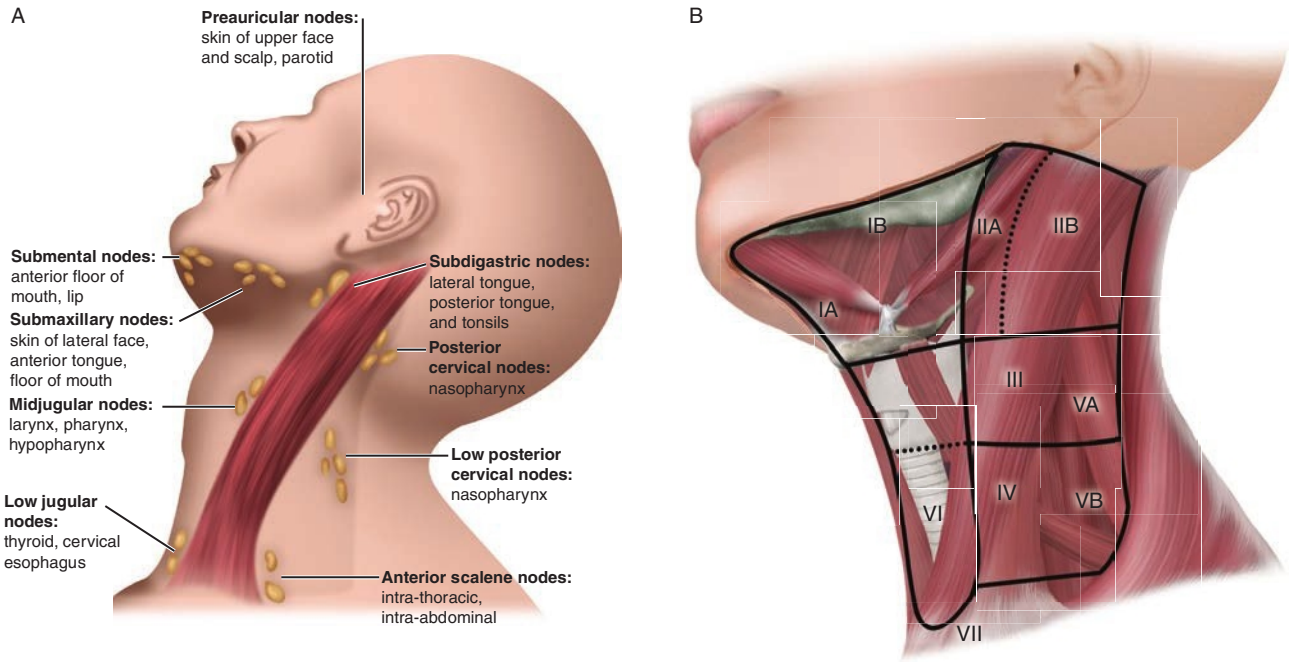

FIGURE 26–2 **A. Nodal drainage. B. Nodal levels in the head and neck. (Reproduced with permission from Hong WK, Bast RB Jr, Hait WN, et al: Cancer Medicine. 8th ed. Shelton, CT: BC Decker—People's Medical Publishing House-USA; 2010: 959-998.)**

Magnetic resonance imaging (MRI) is warranted in specific disease sites such as NPC and skull-base tumors. Because the lungs are the most common site of distant metastases, a chest radiograph or CT for symptomatic or high-risk patients (ie, patients with multiple nodal sites, low neck [level 4] nodes, or supraclavicular metastases) should also be performed. An 18-fluorodeoxyglucose positron emission tomography (FDG-PET) scan is indicated when the primary site is unknown or in the setting of indeterminate findings on cross-sectional imaging. FDG-PET does not replace dedicated imaging with CT and/or MRI of the primary site and neck.

All patients should undergo a thorough multidisciplinary evaluation that includes specialists from surgery, medical oncology, and radiation oncology. Dental, nutrition, and speech/swallow evaluations as well as smoking cessation are recommended. Modified barium swallow tests and baseline audiology examinations should be considered depending on the disease site and expected treatment paradigm.

The American Joint Committee on Cancer (AJCC) TNM staging system classifies tumors according to anatomic site and extent of disease.[35] Head and neck primary tumor (T) staging is complex and varies with the primary subsite. Classifications for lymph nodes (N) are uniform for all sites, with the exception of HPV-positive OPC and NPC.[36] The eighth edition of the AJCC has divided OPC staging based on HPV positivity because of significant differences in prognosis (Table 26–1A, B, C).

NATURAL HISTORY AND IMPLICATIONS FOR THERAPY

For patients with T1/2 disease (stage I/II), surgery or radiotherapy as a single modality is most often applicable and effective. Depending on the primary site and stage, a curative outcome will be achieved in 70% to 95% of cases. Two-thirds of patients with HNSCC will present with stage III or IV disease.[37] In these cases, combined treatment strategies are the standard of care, designed to balance competing goals of tumor eradication and organ preservation.[26,38,39] Despite optimal local therapy, 25% to 50% of patients may develop local or regional recurrence, and nearly 20% to 30% are at risk for development of distant metastases depending on the primary site and staging.[40–42]

Nasopharynx

More than 95% of endemic NPCs are associated with EBV. NPC tends to occur in younger persons and is not associated with tobacco use. NPC is aggressive, with cervical lymph node metastases present in 60% to 90% of patients at diagnosis. Radiotherapy alone to the nasopharynx and bilateral neck is standard of care for clinical T1N0M0 NPC and is associated with high locoregional tumor control rates of more than 90%.[43]

For locally advanced disease, including stage II (T2N0), chemoradiation is preferred.[44] For years, the

Table 26–1A Clinical TNM Staging for Oropharynx (p16–)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
Tis	Carcinoma in situ
T1	Tumor ≤2 cm in greatest dimension
T2	Tumor >2 cm but not >4 cm in greatest dimension
T3	Tumor >4 cm in greatest dimension or extension to lingual surface of epiglottis
T4	Moderately advanced or very advanced local disease
T4a	Moderately advanced local disease Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible[a]
T4b	Very advanced local disease Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional node metastases
N1	Metastasis to a single ipsilateral lymph node ≤3 cm in greatest dimension and ENE(–)
N2	Metastasis to a single ipsilateral lymph node >3 cm but not >6 cm in greatest dimension and ENE(–); or metastases in multiple ipsilateral lymph nodes none >6 cm in greatest dimension and ENE(–); or in bilateral or contralateral lymph nodes none >6 cm in greatest dimension and ENE(–)
N2a	Metastasis in a single ipsilateral lymph node >3 cm but not >6 cm in greatest dimension and ENE(–)
N2b	Metastasis in multiple ipsilateral lymph nodes but not >6 cm in greatest dimension and ENE(–)
N2c	Metastases in bilateral or contralateral lymph nodes none >6 cm in greatest dimension and ENE(–)
N3	Metastasis in a lymph node >6 cm in greatest dimension and ENE(–); or metastasis in any node(s) and clinically overt ENE(+)

standard of care was concurrent chemoradiotherapy followed by adjuvant chemotherapy based on the Head and Neck Intergroup 0099 trial.[45] As of this writing, induction chemotherapy followed by concurrent chemoradiotherapy is standard for node-positive patients.[46–49] For patients with T1 node-positive tumors, sequential induction followed by radiation can be considered to avoid the toxicity of concurrent chemoradiation. For node-negative patients (T2-4N0) chemoradiation alone is standard.[50,51] Because of the rarity of NPC, patients should be treated at tertiary referral centers when feasible.

The GORTEC 2006-02 trial compared induction docetaxel-cisplatin-5-fluorouracil (TPF) followed by concomitant cisplatin-radiation (RT) versus concomitant therapy alone and showed 3-year progression-free survival (PFS) and overall survival (OS) of 73.9% and 86.3% versus 57.2% and 68.9%, respectively, statistically favoring induction (P = .042 for PFS and P = .05 for OS).[47] In 2019, a phase 3 trial evaluating induction chemotherapy with gemcitabine and cisplatin followed by concurrent chemoradiotherapy versus concurrent chemoradiotherapy alone demonstrated improved 3-year recurrence-free survival (85.3% vs

76.5%; hazard ratio [HR] 0.51, 95% CI 0.34–0.77) and OS (94.6% vs 90.3%; HR 0.43, 95% CI 0.24–0.77) in the induction group.[48]

Intensity-modulated radiation therapy (IMRT) improves tumor coverage, quality of life, and reduces xerostomia compared with 3-D conformal techniques.[52–54] Because of protons' unique physical characteristics (Bragg peak, ie, region of maximal dose deposition within tissue followed by a sharp dose falloff and no exit dose) may be advantageous in treating NPC given its proximity to critical organs such as the temporal lobes, brainstem, and optic structures.[55] Two-year locoregional control (LRC) and OS rates of 100% and 89%, respectively, have been demonstrated for proton therapy in NPC.[56] Moreover, reductions in feeding tube placement with intensity-modulated proton therapy (IMPT) versus IMRT is thought to correspond with significant reductions in mean oral cavity doses.[57]

Oral Cavity

The majority of oral cavity neoplasms occur in the anterior two-thirds of the tongue (oral tongue) and the floor of the mouth (Fig. 26–3). Additional subsites include the buccal mucosa, lips, hard palate, gingiva, and retromolar trigone. Forty percent of patients present with clinically evident lymph nodes, and bilateral nodal involvement is not uncommon.

Surgical resection is a common and effective local treatment approach.[26,39] Local tumor control rates after surgery for patients with stage I and II tumors can approach 80% to 90% and 50% to 80%, respectively.[58] For deeply invasive T1/2 disease, we favor surgical resection of the primary tumor with simultaneous selective neck dissection.

After surgery, postoperative radiotherapy should be recommended for patients with high-risk factors including pT3 or pT4 disease, pN2 or pN3 disease, low neck (level IV–V) disease, perineural invasion, and lymphovascular invasion, whereas concurrent chemoradiation should be pursued in the presence of positive margins or extranodal extension.[59,60] Refer to "Combined-Modality Therapy" for further details.

Oropharynx

The most common cancers of the oropharynx are of the base of tongue and tonsils, and greater than 80% are HPV-positive and are associated with a better prognosis than HPV-negative disease.[42,61–64] This led to the recent development of separate staging systems for OPC based on HPV status (Table 26–1A, B, C); thus, all patients should undergo tumor HPV DNA testing by in situ hybridization and p16 testing by immunohistochemistry to determine the appropriate prognosis and staging.[61] Ideally, both tests should be performed, but if only one is feasible then p16 is preferred because it reflects HPV-driven carcinogenesis, whereas some tumors may have the HPV virus as a passenger. Despite differences in prognoses, management for HPV-positive and HPV-negative malignancies is similar.[65]

Radiation therapy is used as a single modality for T1 and many T2 tumors, with local control rates of greater than 90%.[66] In most cases, bilateral neck regional lymph nodes are targeted with radiation therapy; however, unilateral neck radiation can be considered for select well-lateralized tonsillar primaries. At MDACC, patients considered ideal candidates for unilateral neck radiotherapy include those with T1–2, N0–N1 tonsillar primary tumors restricted to the tonsillar fossa or anterior pillar, with less than 1 cm of soft palate involvement, and no base of tongue involvement. Five-year OS and disease-free survival rates of 95% and 96% have been reported, with a contralateral nodal recurrence rate of 2%.[67] Unilateral neck radiotherapy for such tonsillar cases is favored because it

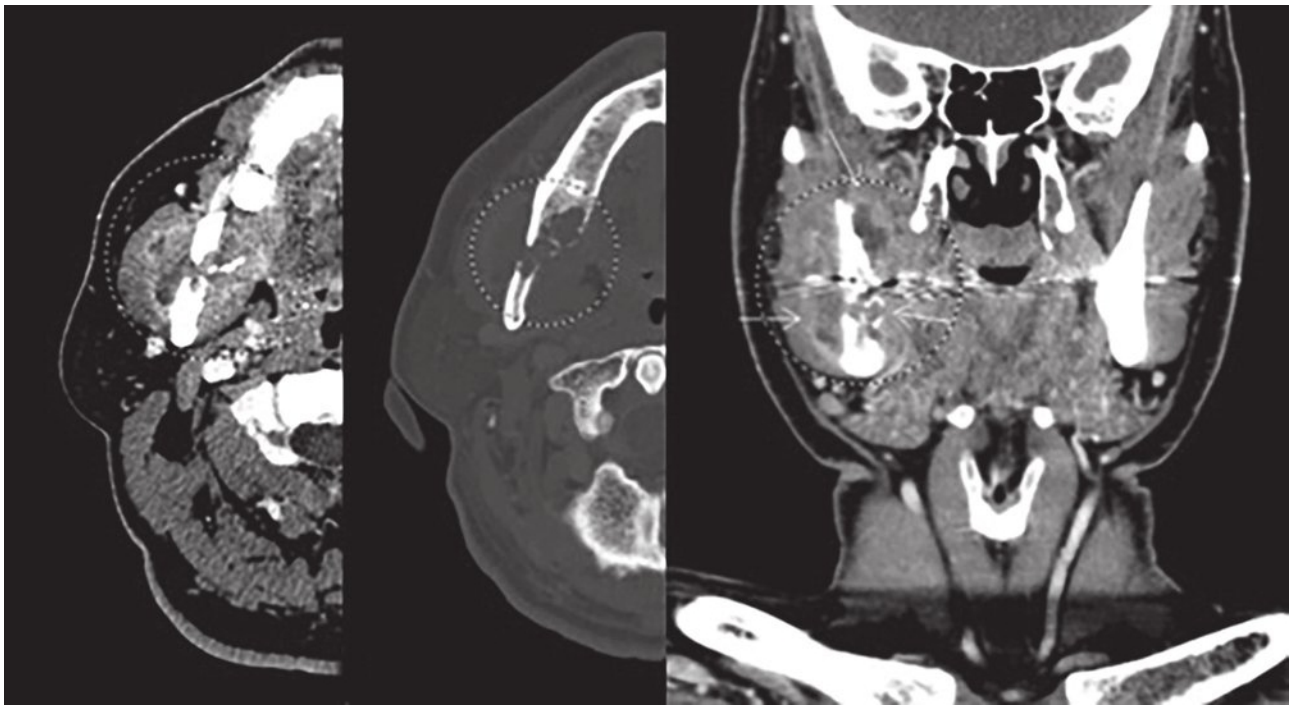

FIGURE 26–3 **Right alveolar ridge cancer with bony destruction and masticator space invasion and bilateral cervical adenopathy, cT4bN2bM0.**

also greatly reduces the radiation doses to the contralateral parotid gland and key swallowing structures.

Surgery with minimally invasive transoral robotic surgery (TORS) approaches is an option for some patients with OPC. The phase 2 ORATOR study compared TORS with definitive radiotherapy. In this study, 71% of patients in the TORS group received postoperative radiotherapy, and 68% of the radiotherapy arm received concurrent chemotherapy for node-positive disease. Survival outcomes were excellent in both groups with data regarding quality-of-life measures seeming to favor definitive radiotherapy.[68]

For locally advanced disease, concomitant chemoradiotherapy is the current standard of care. Because HPV-associated OPC has an improved prognosis, several treatment de-intensification efforts have been studied including systemic therapy de-intensification, radiation dose reduction, and potential toxicity reduction using proton therapy. Proton therapy may be a promising de-intensification option compared with IMRT (Fig. 26–4). MDACC is leading a national multi-institutional phase 2/3 study comparing IMPT versus IMRT for stage III/IV OPC (NCT01893307).

Larynx

Given the critical role of the larynx in communication, swallowing, respiration, and airway protection, organ preservation to maintain functional status and quality of life has been the focus of laryngeal cancer treatment since the 1970s. The most widely used treatment of T1 and T2 tumors is radiotherapy, with control rates greater than 90% for T1 disease and 70% to 80% for T2 tumors.[69] For patients with potentially resectable, locally advanced disease, organ-preserving approaches using chemotherapy and radiation have proven effective and have replaced upfront surgery for many patients.

The Veterans Affairs laryngeal study established induction chemotherapy followed by radiation and surgical salvage, if needed, as an organ-preserving alternative to primary surgery followed by postoperative radiation.[70] The RTOG 91-11 trial established concurrent chemoradiation as an acceptable standard of care.[40] These treatment strategies are discussed in further detail in the "Organ Preservation" section.

Hypopharynx

With 65% to 85% of lesions occurring in the pyriform sinus, carcinoma of the hypopharynx is relatively uncommon but virulent (Fig. 26–5). Treatment is similar to that for the larynx. Small-volume disease may be treated with surgery or radiation, but later-stage disease requires multimodal therapy. At presentation, more than 75% of patients have advanced disease

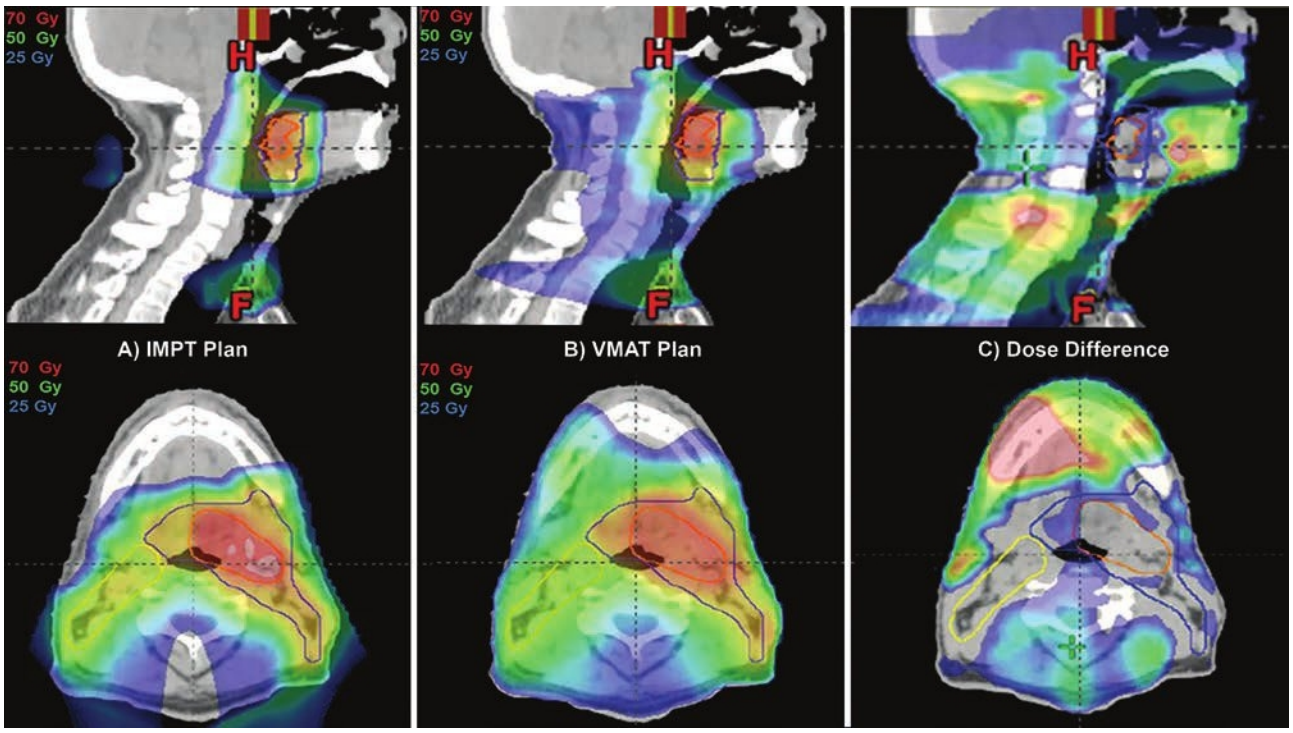

FIGURE 26–4 **Comparative radiation therapy plans for an oropharyngeal case. A. IMPT plan. B. VMAT. C. Dose difference plans. IMPT, intensity-modulated proton therapy; VMAT, volumetric-modulated arc therapy.**

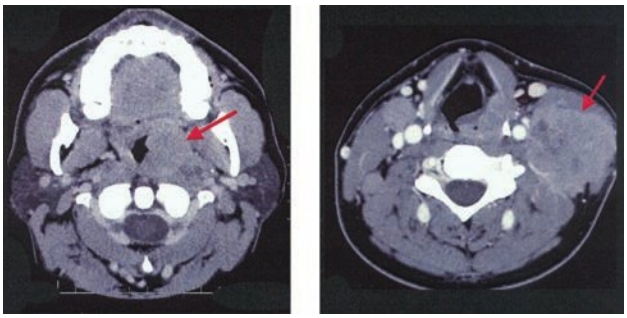

FIGURE 26–5 Axial computed tomography of advanced squamous carcinoma of the pyriform sinus, cT3N3M0.

(T3 or T4). The 5-year OS rate is lower than 30%. For many patients, surgical treatment also requires removal of the larynx. The European Organization for Research and Treatment of Cancer (EORTC), in a phase 3 trial, demonstrated that laryngeal preservation with sequential chemoradiotherapy is a feasible alternative to radical surgery.[71] Refer to the "Organ Preservation" section for further discussion.

COMBINED-MODALITY THERAPY

Induction Chemotherapy

Induction (neoadjuvant) chemotherapy is given before surgery or radiation. It has been investigated as an approach to improve outcomes in terms of OS and tumor control in patients with stage III/IV disease undergoing definitive local therapy. Theoretical advantages to this approach include reducing the risk of distant disease recurrence, enhancing organ preservation, improving response to definitive radiotherapy by reducing tumor bulk, and modification of subsequent local therapy to response. In a 2009 meta-analysis, although concomitant chemoradiation was superior to induction chemotherapy followed by radiation for local control and survival, induction chemotherapy was more effective at decreasing distant failure.[72] This conclusion lent credence to contemporaneous trials investigating induction chemotherapy followed by chemoradiation.

In 2007, two multicenter phase 3 trials, the European TAX 323 and the North American TAX 324, demonstrated the superiority of induction TPF over PF (cisplatin, 5-fluorouracil) (Table 26–2).[73,74] However, these trials did not directly compare induction chemotherapy with definitive chemoradiotherapy. Nevertheless, these trials led to FDA approval of induction TPF for patients with locally advanced HNSCC in 2007. Despite the results of TAX 324, the value of adding induction chemotherapy to chemoradiation remained an unanswered question given the lack of definitive randomized trials comparing this approach with upfront chemoradiation.

Three phase 3 studies compared induction chemotherapy followed by chemoradiation versus chemoradiation alone.[75–77] The Spanish Head and Neck Cancer Group cooperative trial randomly assigned patients with locally advanced SCC of the oral cavity, oropharynx, hypopharynx, and larynx to (1) induction TPF followed by concurrent chemoradiation, (2) induction PF followed by concurrent chemoradiation, or (3) concurrent chemoradiation alone. There were no statistically significant differences between PFS, time-to-treatment failure, and OS in the three groups; however, approximately half of the patients did not complete concurrent chemoradiation.[77]

The PARADIGM trial randomly assigned patients with locally advanced SCC of the oral cavity, oropharynx, hypopharynx, or larynx between induction TPF followed by chemoradiation that was adapted based on induction chemotherapy response versus chemoradiation alone using an accelerated fractionation. Because of slow accrual, the trial closed with 145 patients enrolled, less than half of the planned enrollment. Overall 3-year survival was 73% (95% CI 60%–82%) in the induction TPF followed by chemoradiation group versus 78% in the chemoradiation alone group.[75]

The DeCIDE trial randomized patients with N2/3 M0 disease (based on the AJCC 7th edition staging) between induction TPF followed by chemoradiation or chemoradiation alone.[76] This trial also failed to accrue well, enrolling 280 patients versus the planned 400 patients. There were no statistically significant differences in OS (HR 0.91; 95% CI 0.59–1.41) or relapse-free survival. In competing risk analysis, there was a statistically significant reduction in risk of distant relapse without locoregional recurrence in the induction arm ($P = .043$).

Thus, induction chemotherapy remains investigational, but it is appropriate (1) as a "bridge" to control disease before logistical delays in surgery or radiation, (2) to facilitate locoregional therapy of very advanced disease, and (3) in patients deemed high risk for distant recurrence, such as those with N3 and/or low neck disease. In laryngeal and hypopharyngeal cancer, the induction chemotherapy approach is an effective organ preservation strategy and is further discussed in the "Organ Preservation" section.

Induction chemotherapy is also being studied as a method to select chemosensitive patients to reduce the intensity of subsequent treatment. In a phase 2 ECOG-ACRIN Cancer Research Group trial, response to induction chemotherapy was used to select patients with stage III/IV HPV-associated OPC for reduced radiation dose. Patients who did not achieve a complete

Table 26–2 Induction Chemotherapy Trials

Trial	Phase	Patients	Inclusion Criteria	Treatment	Progression-Free Survival	Overall Survival
European TAX 323	III	358	Stage III/IV, nonmetastatic, untreated SCCHN	TPF followed by RT vs PF followed by RT	Median PFS: 11 vs 8.2 mo (P = .007) 3-y PFS: 17% vs 14%	Median OS: 18.8 vs 14.5 mo (P = .02) 3-y OS: 37% vs 26%

response after induction therapy were given a higher dose of radiation (69.3 Gy in 33 fractions) compared with those who achieved a complete response (54 Gy in 27 fractions). Seventy percent of the total patients achieved a complete clinical response. In patients who received lower-dose radiation with 54 Gy, the 2-year PFS was 80% and OS was 94%, with approximately 3-year median follow-up. There were fewer radiation complications in the lower-dose radiation group such as dysphagia (40% vs 89%; $P = .011$) and nutritional impairment (10% vs 44%; $P = .025$).[78]

Concomitant Radiotherapy and Chemotherapy

Meta-analysis of prospective clinical trials demonstrates enhanced local tumor control and improved survival with combined therapy over radiation alone, establishing chemoradiation as the standard of care in locally advanced nonsurgical disease. The effect of chemotherapy was higher with single-agent platinum than any other types of monotherapies (HR 0.74, 95% CI 0.67–0.82; $P = .006$).[72] Single-agent cisplatin is preferred in this setting.[79–82] For patients with contraindications to cisplatin, cetuximab, an EGFR-targeted monoclonal antibody, is an acceptable alternative. Based on retrospective data, carboplatin was less effective than cisplatin in one randomized trial,[83] although the use of carboplatin in responders, subsequent to induction chemotherapy, is acceptable based on the TAX 324 and PARADIGM trials, especially for cisplatin-ineligible patients.[63,75] Taxanes, potent radiosensitizers, are feasible and effective in weekly low-dose schedules after induction chemotherapy.[63,75,84]

Cetuximab is approved for use in combination with radiation in previously untreated patients. In a landmark study, patients with locoregionally advanced HNSCC were randomly assigned to receive high-dose radiotherapy alone or high-dose radiotherapy plus weekly cetuximab.[85] Locoregional control and OS favored the combination. However, the rates of distant metastases at 1 and 2 years were similar in both groups. Retrospective analysis demonstrated that the main benefit was in patients with OPC.

Cetuximab plus radiotherapy was directly compared with cisplatin plus radiotherapy in 849 patients with locally advanced HPV-associated OPC in a multicenter, noninferiority phase 2 randomized trial (RTOG 1016). In the cetuximab arm, there was inferior PFS (67 vs 78%, HR 1.72, 95% CI 1.29–2.29), decreased OS (78 vs 85%, HR 1.45), and greater locoregional failure (17 vs 10%, HR 2.05, 95% CI 1.35–3.10) at 5 years.[42] In the international trial De-ESCALaTE HPV, 334 patients with locally advanced, low-risk (nonsmoker or <10 pack-year smoking history) HPV-positive OPC were randomly assigned to cetuximab plus radiotherapy versus cisplatin plus radiotherapy. The trial demonstrated decreased OS for cetuximab with radiotherapy with a 2-year rate of 89% versus 98% and increased disease recurrence with a 2-year rate of 16% versus 6%.[86] Given the results of these trials, platinum-based chemoradiation remains standard of care for HPV-positive OPC, with cetuximab-radiotherapy being recommended for patients who are ineligible for cisplatin or patient preference because of concern for cisplatin-related side effects.

The MARCH meta-analysis reported an absolute OS benefit using hyperfractionation over standard fractionation, but survival significantly worsened when adding concomitant chemotherapy.[87] Equivalent outcomes were observed with accelerated radiotherapy and two doses of bolus cisplatin compared with standard fractionation and three doses of bolus cisplatin in the RTOG 0129 trial for patients with stage III/IV HNSCC.[88] Both approaches were feasible and there was less cisplatin-associated toxicity in the accelerated arm.

Adjuvant Chemoradiotherapy

Adjuvant chemoradiotherapy is indicated in patients at high risk of recurrence after surgical resection, generally defined as having positive margins or extracapsular spread.[59,60,89] Two large phase 3 studies, RTOG 9501 and EORTC 22931, tested cisplatin-based concomitant chemoradiotherapy in the adjuvant setting.[59,60]

In RTOG 9501 after a median follow-up of 9.4 years, concomitant chemoradiotherapy significantly improved LRC and disease-free survival with a trend toward improved OS in patients with extracapsular extension and/or positive margins.[90] The incidence of acute grade 3 or greater adverse effects was 34% in the radiotherapy group and 77% in the combined-therapy group ($P < .001$), with no differences in late toxicity. In the EORTC 22931 trial, both the PFS and OS rates were significantly higher in the combined-therapy group than in the radiotherapy group. Severe acute adverse effects were more frequent after combined therapy than in the radiotherapy group. A combined analysis of both adjuvant therapy trials showed significant risk reduction of 48% in locoregional relapse, 30% in disease-free survival, and 28% in OS when using chemoradiation for patients with extracapsular extension and/or positive margins.[91]

RTOG 0234 explored the incorporation of cetuximab into adjuvant chemoradiation.[92,93] This phase 2 trial demonstrated that two biochemoradiotherapy regimens, docetaxel/radiation/cetuximab and cisplatin/radiation/cetuximab, outperformed the historical control of high-dose cisplatin-based chemoradiotherapy from RTOG 9501. Although these results are

promising, comparison with historical controls is problematic, and adding cetuximab to adjuvant chemoradiation is not currently standard.

ORGAN PRESERVATION

Many HNSCCs are diagnosed at a late stage. Stages III and IV tumors often necessitate extensive or radical surgery, which may alter organ function. Problems with radical surgery include loss of speech, loss of swallowing function, or disfigurement without a concomitant improvement in survival time. Therefore, preservation of function is a major challenge.

The Veterans Affairs laryngeal study randomly assigned patients with stage III/IV SCC of the larynx to induction platinum-5FU (PF) followed by definitive radiotherapy or surgery with postoperative radiotherapy.[70] In the chemotherapy group, patients who had no tumor response after two cycles underwent salvage laryngectomy, whereas those with a complete clinical or partial response received a third cycle of chemotherapy followed by radiotherapy. Two-year OS was 68% for both arms, and larynx preservation was achieved for 64% of patients treated with chemotherapy. However, salvage laryngectomy was required for 56% of patients with T4 tumors. Patterns of failure differed with decreased local failures favoring surgery (2% vs 12%; $P < .01$) but decreased distant metastasis favoring sequential therapy (11% vs 17%; $P < .001$). Lefebvre et al later reported that sequential chemotherapy and radiation could also be effective in selected patients with cancers of the hypopharynx.[71]

The RTOG 99-11 study randomly assigned patients with larynx cancer to induction chemotherapy PF followed by radiotherapy versus concomitant cisplatin-radiotherapy versus radiotherapy alone.[94] Surgical salvage was reserved for patients with persistent or locally recurrent disease. Both chemotherapy groups demonstrated improved laryngectomy-free survival, the primary end point of the trial, compared with radiotherapy alone. Crude larynx preservation rates, at 10 years, regardless of survival, were higher with concurrent treatment: 82% compared with 68% and 64% in the sequential chemotherapy/radiation and radiation alone arms. Locoregional control was significantly improved with concomitant chemoradiotherapy (HR 0.58; 95% CI 0.37–0.89; $P = .005$), whereas the induction chemotherapy group showed a nonsignificant trend toward improved OS (HR 1.25; 95% CI, 0.98–1.61; $P = .08$).[95] There were late increased noncancer-related deaths observed with chemoradiation (Table 26–3).[40]

The GORTEC 2000-01 trial compared induction cisplatin/5FU with and without docetaxel followed by radiation therapy in partial responders with both larynx and hypopharynx cancers. The 5-year larynx preservation rate was 60% in the docetaxel arm (vs 39%), at least in part because of the higher response rate with that combination. Survival was the same in both arms. Thus, the TPF regimen, if feasible, is preferred in this setting.[96]

These trials indicate that, for patients with intermediate-stage SCC of the larynx, a combined treatment program with the objectives of tumor eradication and laryngeal preservation is appropriate. It is also important to recognize that patients with locally advanced, destructive primary laryngeal cancers (ie, T4 tumors) were not included in the RTOG 91-11. These patients require total laryngectomy for optimal tumor control.

It should be noted that nonsurgical treatment also carries a risk of morbidity and functional impact. Radiation produces tissue changes that can result in immediate and long-term alterations in speech and swallowing. The adverse impact of radiation may equal or exceed that associated with surgery, depending on the treatment dose and volume, and the sequelae of treatment may manifest or increase in severity years after the completion of treatment. Fibrosis may reduce the range of motion of the tongue and jaw and diminish pharyngeal wall motion.

Historically, 20% to 40% of patients receiving chemoradiotherapy for SCC of the oropharynx and hypopharynx may require long-term gastrostomy tube feedings. However, the long-term gastrostomy rate for patients with OPC treated with modern radiation therapy is less than 10%.[97] Radiation to the larynx often results in swallowing problems related to pharyngeal transport. To counteract the deleterious effects of radiation and chemoradiotherapy, there are rehabilitative options that are best administered by a qualified speech pathologist.

RECURRENT OR METASTATIC DISEASE

Prognosis for recurrent or metastatic HNSCC is generally poor, with median survival ranging from 6 to 15 months. Locoregional recurrence remains the most common pattern of failure, occurring in approximately 20% to 30% of patients.[98] As a result, local therapy is often clinically indicated and most commonly involves radiation therapy with or without surgical resection whenever feasible. Considering that a majority of these patients have received prior radiation therapy for their initial disease, there are concerns regarding the increased risks of toxicities with reirradiation.

Earlier reirradiation studies report 2-year LRC rates of 30% to 50% using 3-D conformal radiotherapy or IMRT but with significant costs in grade 4 and 5

toxicity (Table 26–4).[99–111] Proper patient selection and the use of newer radiation techniques such as stereotactic body radiation therapy (SBRT) are showing promising results. SBRT is a highly conformal therapy that uses advanced image guidance and noncoplanar beam arrangement to deliver highly ablative doses of radiation with millimeter precision in three to five treatments. Preliminary findings of a prospective registry study conducted at MDACC comparing SBRT, proton therapy, and IMRT reported equivalent OS and LRC between modalities, with a significantly lower rate of acute grade 3 and 4 toxicities using SBRT.[99]

Systemic therapy options are determined based on prior therapies, patient comorbidities, performance status, distribution of disease, and programmed death ligand 1 (PD-L1) expression status. It is essential for providers to obtain adequate core biopsies rather than FNAs to perform a PD-L1 combined positive score (CPS), a test mandated by the FDA, on tumor specimens in the setting of first-line metastatic disease. CPS is the number of PD-L1 staining cells (tumor cells and immune cells) divided by the total number of viable tumor cells multiplied by 100.

The randomized phase 3 study KEYNOTE-048 established pembrolizumab (PD-1 monoclonal antibody) with chemotherapy as a first-line regimen in patients with cisplatin-sensitive (no prior cisplatin or >6 months after the completion of chemotherapy as part of curative-intent treatment) metastatic or recurrent HNSCC.[112] Eight-hundred fifty-four patients were stratified based on PD-L1 CPS, p16 status, and ECOG PS and randomly assigned to receive pembrolizumab alone, pembrolizumab plus platinum/5-FU, or cetuximab plus platinum/5-FU.

Pembrolizumab plus chemotherapy compared with cetuximab plus chemotherapy improved OS in the total population (HR 0.65, 95% CI 0.63–0.93; $P < .0001$) along with CPS greater than or equal to 1 and greater than or equal to 20 populations.[112] Single-agent pembrolizumab improved OS compared with cetuximab plus chemotherapy in patients with CPS greater than or equal to 1 (HR 0.78, 95% CI 0.64–0.96; $P = .0086$) and CPS greater than or equal to 20 (HR 0.61, 95% CI 0.45–0.83; $P = .0007$). Notably, in the total population, pembrolizumab alone was not inferior to platinum/5-FU and cetuximab (Table 26–5).

Based on the findings from this trial, patients with PD-L1–positive disease qualify for treatment with pembrolizumab alone; however, we recommend using the CPS as a guide to determine the optimal treatment approach. For patients with CPS 20 or higher, consider pembrolizumab alone. For patients with CPS 1 or higher and lower than 20, consider pembrolizumab with or without chemotherapy depending on ECOG

Table 26–4 Reirradiation Trials and Studies

Study	Patients	Cohort Details	RT Technique	Outcomes	Toxicity
Lee et al 2007 MSK[101]	105	86% SCC (34% surgery, 71% CRT)	IMRT (70%) and 3DRT	2-y LRC: 42% 2-y OS: 37%	G3–4: 15% Brain necrosis: 4%

3DRT, 3D conformal radiation therapy; CRT, chemoradiation; CTV1, clinical target volume 1; ECE, extracapsular extension; G, grade; IMRT, intensity-modulated radiation therapy; LC, local control: LRC, locoregional control; LRF, locoregional failure; ORN, osteoradionecrosis; RC, regional control; RT, radiation; SABR, stereotactic ablative radiotherapy; SBRT, stereotactic body radiation therapy; SCC, squamous cell carcinoma.

Table 26–5 Immunotherapy Trials for Metastatic and Recurrent Head and Neck Cancer

Trial	Phase	Patients	Inclusion Criteria	Treatment	Outcome
KEYNOTE-048	3	882	Treatment naïve, metastatic or recurrent SCC of the oropharynx, oral cavity, hypopharynx, or larynx	Pembrolizumab + platinum + 5-FU vs cetuximab + platinum + 5-FU Pembrolizumab vs cetuximab + platinum + 5- FU	**Median OS:** Total study population: 13 vs 10.7 mo PD-L1 CPS ≥20: 14.7 vs 11 mo PD-L1 CPS ≥1: 13.6 vs 10.4 mo **2 yr OS:** PD-L1 CPS ≥20: 35 vs 19% PD-L1 CPS ≥1: 31 vs 17% **Median OS:** Total study population: 29 vs 19% PD-L1 CPS ≥20: 14.9 vs 10.7 mo PD-L1 CPS ≥1: 12.3 vs 10.3 mo **2 yr OS:** PD-L1 CPS ≥20: 38 vs 22% PD-L1 CPS ≥1: 30 vs 18%
KEYNOTE-040	3	495	Recurrent or metastatic SCCHN of oral cavity, oropharynx, hypopharynx, larynx; failed platinum therapy	Pembrolizumab vs investigator choice therapy	**Median OS:** Total population: 8.4 vs 6.9 mo PD-L1 CPS ≥ 50%: 11.6 vs 6.6 mo PD-L1 CPS <50%: 6.5 vs. 7.1 mo PD-L1 CPS ≥ 1%: 8.7 vs 7.1 mo PD-L1 CPS < 1%: 6.3 vs 7 mo **12 mo OS:** Total population: 37 vs 26.5% PD-L1 CPS ≥ 50%: 47 vs 25% PD-L1 CPS ≥ 1%: 40% vs 26%
KEYNOTE-012	1b	192	Recurrent or metastatic SCCHN	Initial cohort: Pembrolizumab 10 mg/kg q2wk Expansion cohort: Pembrolizumab 200 mg q3wk	**Median OS:** Total population: 8 mo PD-L1 CPS ≥ 1%: 10 mo PD-L1 CPS < 1%: 5 mo **OS 12 mo:** Total population: 38%
KEYNOTE-055	2	171	Recurrent or metastatic SCCHN of oral cavity, oropharynx, hypopharynx, or larynx resistant to both platinum and cetuximab	Pembrolizumab 200 mg q3wk	**Median OS:** 8 mo **OS 6 mo:** Total population: 59% HPV(+): 72%, HPV(–): 55% PD-L1 CPS >1%: 59% PDL-1 CPS <1%: 56%
Checkmate-141	3	361	Recurrent or metastatic SCCHN of oral cavity, pharynx, or larynx; platinum refractory	Nivolumab 3 mg/kg q2wk vs single-agent investigator's choice therapy	**Median OS:** Total population: 7.5 vs 5.1 mo PD-L1 CPS ≥1%: 8.7 vs 4.6 mo PD-L1 CPS <1%: 5.7 vs 5.8 mo **OS 1 y:** Total population: 36 vs 16.6%
NCT02369874	3	736	Recurrent or metastatic SCCHN; platinum refractory	Durvalumab alone vs Durvalumab + tremelimumab	Completed accrual, results pending

5-FU, 5-fluorouracil; CPS, combined positive score; HPV, human papillomavirus; ORR, overall response rate; PD-L1, programmed death-ligand 1; SCC, squamous cell carcinoma; SCCHN, squamous cell carcinoma of the head and neck.

PS. For patients with CPS of 0 or score unavailable, consider chemotherapy with or without pembrolizumab. In the setting of aggressive disease, to avoid early progression, the combination of pembrolizumab with chemotherapy should be considered independent of CPS.

The KEYNOTE 048 trial led to the FDA approval in June 2019 of PF as the designated chemotherapy regimen in combination with pembrolizumab. Although the trial utilized PF as the chemotherapy regimen, our preference at MDACC is a taxane (docetaxel or paclitaxel) in place of infusional 5-FU. This is supported by trials comparing platinum-taxane doublets with PF showing no difference in survival.[113,114] Infusional 5-FU requires a central line and administration via an ambulatory pump over 96 hours with a required second return to the treatment center for pump removal and line flush. It is frequently complicated by diarrhea, mucositis, hand-foot syndrome, and a rare but life-threatening potential for coronary vasospasm and arrhythmias. Hospital admissions to manage these toxicities are not uncommon, and thus the cost of this regimen both in physical toxicity and in monetary resources is high. Docetaxel, on the other hand, is easily administered through a peripheral vein over an hour. It is generally well tolerated, with cosmetic alopecia and neutropenia as its most common side effects. Prophylactic granulocyte–colony-stimulating factor is frequently given to prevent febrile neutropenia. Cumulative neuropathy may occur after several cycles, but therapy is typically limited to 4 to 6 cycles.

For immunotherapy-ineligible patients, frontline platinum doublets and cetuximab are recommended. The phase 3 EXTREME trial demonstrated that the addition of cetuximab to cisplatin/5-FU significantly increased OS, PFS, and response rates compared with cisplatin/5-FU alone.[92] The phase 2 GORTEC 2008-03 trial of the TPEx regimen (docetaxel, platinum, cetuximab) showed a favorable median survival of 14 months.[115] This regimen was subsequently compared against the EXTREME trial regimen (5-FU, platinum, cetuximab), thus substituting docetaxel for 5-FU. Patients with metastatic HNSCC were randomly assigned between EXTREME and TPEx as first-line treatment. After a median follow-up of 30 months, the median OS was 14.5 months for TPEx and 13.4 months for EXTREME (HR 0.87; P = .15). More significantly, the grade 4/5 adverse events were only 34% in the TPEx regimen versus 50% in the EXTREME regimen. Thus, substituting a taxane (specifically docetaxel) for 5-FU results in similar efficacy and reduced toxicity.[116] For patients not considered to be candidates for immunotherapy and/or combination chemotherapy, single agents can be given depending on predicted tolerance and previous exposure. Active single agents include platinums, 5-FU, taxanes, methotrexate, and cetuximab.[117–119]

Second-line therapy is primarily dictated by treatment eligibility and prior exposure to platinum and immunotherapy agents. Subsequent therapy for platinum-refractory disease (<6 months from prior platinum therapy) in immunotherapy-eligible patients includes pembrolizumab or nivolumab, monoclonal antibodies directed against programmed death-1 protein (PD-1). Two large nonrandomized studies, KEYNOTE-012 and KEYNOTE-055, and one phase 3 trial KEYNOTE-040 demonstrated the clinical benefit of pembrolizumab in this setting.[120–122] KEYNOTE-040 randomly assigned 495 patients that failed platinum therapy to pembrolizumab versus the investigator's choice of therapy (methotrexate, docetaxel, or cetuximab).[123] Although the differences in response rates were not statistically significant (15% vs 10%), the duration of response was longer in the pembrolizumab arm (18 months vs 5 months). Overall survival in the total population was 37% versus 27% at 12 months, and median OS was 8.4 versus 6.9 months (HR 0.8 95% CI 0.65–0.98). Exploratory analysis demonstrated that patients with PD-L1 expression of 50% or higher demonstrated a statistically significant survival benefit compared with those with PD-L1 expression lower than 50%.

Nivolumab has shown clinical activity and benefit in the phase 3 trial CHECKMATE-141.[124,125] Three-hundred sixty-one patients were randomly assigned to receive nivolumab versus single-agent physician's choice (methotrexate, docetaxel, or cetuximab). The study demonstrated superior OS (median 7.5 months vs 5.1 months; 97.73% CI 0.51–0.96, HR 0.70; P = .01) and response rates (13.3% vs 5.8%) in the nivolumab arm regardless of PD-L1 expression and p16 status (Table 26–5). A more significant survival benefit was seen in patients with HPV-positive disease (HR 0.56; 95% CI 0.3–0.99) and patients with PD-L1 expression 1% or greater (HR 0.55; 95% CI 0.36–0.83).

For patients with progression of disease after platinum-based therapy and who are immunotherapy ineligible or refractory, subsequent lines of treatment include cetuximab or single-agent chemotherapy. Phase 2 trials have demonstrated the benefit of cetuximab in the platinum-refractory setting and objective response rates are approximately 10%.[126,127]

RISK REDUCTION AND PREVENTION

Tobacco and alcohol use are major risk factors for the development of head and neck cancer; thus, tobacco and alcohol counseling are essential components of prevention and risk reduction. It is important for clinicians to stress the importance of tobacco cessation because of the risk of development of secondary malignancies and the impact on clinical outcomes in patients who continue to smoke during active treatment.

As the incidence of HPV-related head and neck cancer continues to rise, preventive strategies targeting this infectious agent are being explored. HPV vaccination is being used to prevent cervical and HNSCC cancer. Although the HPV vaccine has been shown to reduce the prevalence of oral HPV infections, its impact on the incidence of HNSCC is yet to be determined.[128] As of this writing, there are no chemoprevention strategies that have been shown to decrease the incidence of HNSCC, despite multiple trials with a variety of agents including vitamin A, vitamin E, beta carotene, and retinoid.[129–135]

MD ANDERSON PRACTICE TIPS

- Multidisciplinary discussion and management are necessary to determine the optimal treatment course and to address cancer as well as therapy-related symptoms.
- Early-stage disease is typically treated with curative intent and single-modality treatment, either surgery or radiation.
- Higher-volume stage III (T3N0–1) and stage IV disease without distant metastases should be approached with curative intent, multimodality therapy such as surgery and radiation, or concurrent chemoradiation.
- There are no definitive data that the incorporation of induction therapy before chemoradiation leads to improved survival except in the setting of node-positive nasopharyngeal cancer. Its use with sequential radiation as a larynx preservation strategy is a standard treatment option.
- Chemoradiation with cisplatin is the standard of care for locally advanced disease. However, cetuximab and other agents along with alternative approaches such as induction therapy, followed by carboplatin with radiation, are used in patients with contraindications to cisplatin.
- PD-L1 CPS, performance status, and prior therapies should play an integral role in determining the appropriate treatment in the recurrent or metastatic setting to balance potential therapy benefit with toxicity, especially in the palliative setting. Anti–PD-1 antibodies should be given to all patients with recurrent disease, unless contraindications exist.
- It is likely that immunotherapy will become a standard of care in curative-intent treatment in the near future.

KEY CONCEPTS

- Gastric cancer remains the third most common cause of cancer-related death worldwide.
- Two different pathogeneses of gastric cancer have been proposed, correlating to two histologic types: intestinal and diffuse.
- Gastrectomy is the recommended treatment in relatively early localized gastric cancer (T1b); however, in more advanced gastric cancers (T2N0, T1aN+, or T1b-T3N+), adjunctive therapy in addition to gastrectomy is recommended.
- The results of INT-0116 study (adjuvant chemoradiation) and Medical Research Council ST02/MAGIC and the FLOT study (perioperative chemotherapy) have shaped the current practice of resectable gastric cancer treatment in Western countries.
- In Asia, postoperative chemotherapy has been considered standard after gastrectomy with D2 dissection. In addition to the ACTS-GC trial and CLASSIC trial (S-1 for 1 year and CAPOX for 6 months, respectively), two new regimens (DS and SOX for 6 months) are established standards of care for stage II and/r LN-positive gastric cancer.
- Only 30% to 40% of patients with esophageal cancer have potentially resectable disease at presentation, and in many series, only 5% to 20% of those undergoing surgery alone for clinically localized disease are alive at 3 to 5 years.
- Endoscopic therapy is most effective when used to treat small (<2 cm diameter), solitary, flat lesions that are confined to mucosa (T1a).
- Surgery remains the best chance for durable survival for patients with locally advanced esophageal and gastroesophageal junction (GEJ) cancers.
- Results of the CROSS trial also emphasized the beneficial role of chemoradiotherapy before surgery, which led to a significant increase in overall survival (OS) irrespective of tumor histology.
- More than 60% of patients who present with newly diagnosed gastric, GEJ, and esophageal cancers will have advanced unresectable or metastatic disease. Although a cure is not possible, systemic therapy can prolong survival compared with best supportive care.
- As of this writing, patients in the United States are likely to undergo frontline therapy with platinum-, fluoropyrimidine-, or taxane-based chemotherapy regimens, with the addition of trastuzumab in patients with HER2-positive disease.
- Based on positive results from the RAINBOW trial, paclitaxel and ramucirumab (vascular endothelial growth factor receptor–2 targeted drug) is considered to be a standard for second-line treatment. Ramucirumab monotherapy is also considered a second-line option in advanced gastric cancer.
- Pembrolizumab is currently approved for the treatment of metastatic squamous cell carcinoma (SCC) of the esophagus as second-line treatment for tumors with combined positive score (CPS) more than 10 and programmed cell death protein 1 (PD-L1)–positive advanced gastric cancer as third-line treatment in the US. Nivolumab is also approved in the US for metastatic SCC of the esophagus regardless of PD-L1 expression, and in Japan, South Korea, and Taiwan for the treatment of gastric cancer.
- The Cancer Genome Atlas analysis has uncovered four genotypes of gastric cancer; however, it is not sufficient to change our treatment strategies, and additional work is needed.
- A multimodality approach to therapy will be the cornerstone to screening, diagnosing, staging, treating, and supporting patients with upper gastrointestinal cancers.

GASTRIC CANCER

Epidemiologic Characteristics

The incidence of gastric cancer varies widely worldwide. The highest incidence (>20 per 100,000 in men) is seen in Japan, China, Eastern Europe, and South America, whereas the lowest incidence (<10 per 100,000 in men) is seen in Northern America, parts of Africa, and Northern Europe.[1] In the United States, 27,600 new cases of gastric cancer were estimated in 2020, with 11,010 deaths.[2] Gastric cancers occur at a median age of 69 years for men and 73 years for women.[3] African Americans, Hispanic Americans, and Native Americans are 1.5 to 2.5 times more likely to develop gastric cancer than are Whites.[3] In the United States, there are changing epidemiologic patterns regarding the anatomic location of esophagogastric cancers, with a trend of decreased occurrence of distal or noncardia gastric cancers.[4] The reason for the decline is not known but may be related to change in dietary habits and food preservation. However, an increase in the incidence of gastric cardia cancers has been observed, from 2.4 cases per 100,000 individuals (1977–1981) to 2.9 cases per 100,000 individuals (2001–2006) in the White population.[4] Similarly, the Surveillance, Epidemiology, and End Results (SEER) cancer registry program in the United States shows an approximate 2.5-fold increase in the incidence of gastroesophageal junction (GEJ) adenocarcinomas from 1973 to 1992, from 1.22 cases per 100,000 individuals (1973–1978) to 2.00 cases per 100,000 individuals (1985–1990), with rates stabilizing in the last two decades, with an incidence of 1.94 cases per 100,000 individuals (2003–2008).[3,5]

Population studies suggest that proximal cancers have a different pathogenesis than distal cancers.[6] Potential causes of distal gastric cancers include *Helicobacter pylori* infection or E-cadherin expression loss, whereas proximal gastric cancers may behave similarly to distal esophageal and GEJ cancers, which progress from Barrett metaplasia to dysplasia to invasive adenocarcinoma. Only 26% of newly diagnosed gastric cancers are localized. The 5-year overall survival (OS) rate is 28.3%, which has not changed significantly over the past 30 to 40 years.[1] Surgery is still the only chance for cure, and survival can be improved with multimodality therapy. The 5-year OS rate of patients with advanced disease remains dismal, at less than 5%. Thus, despite decreasing incidence, gastric cancer remains a public health concern in the United States because of its high fatality rate.

Histologic Classification and Risk Factors

The most frequent type of gastric cancer is gastric adenocarcinoma (GAC). The WHO classifies GAC into tubular, papillary, mixed, and poorly cohesive carcinomas, whereas the Lauren classification divides GACs into intestinal, diffuse, and mixed types.[7] Intestinal-type GAC likely begins with an *H pylori* infection that leads to multistep progression (chronic active nonatrophic gastritis, multifocal atrophic gastritis, intestinal metaplasia, dysplasia, and invasive adenocarcinoma).[8] More than 40% to 50% of distal GACs are associated with *H pylori* infection.[6] Other environmental risk factors and inflammatory cytokines may influence and contribute to this multistep progression.

Population studies have identified certain environmental risk factors associated with gastric cancer. Low consumption of fruits and vegetables, high intake of N-nitroso compounds in salted and preserved foods, and occupational exposure in coal mining and nickel, rubber, and timber processing are commonly described risk factors. Additional notable risk factors include meat consumption,[9] smoking,[10] gastric surgery,[11] and reproductive hormones.[12]

Overall, the pathogenesis of intestinal-type GACs involves a series of events. This sequence of events—increased cell proliferation caused by the promotional effects of hypergastrinemia or bile reflux, increased luminal levels of mutagens (eg, N-nitroso compounds and free radicals), and decreased luminal levels of protective factors (eg, vitamin C)—provides an ideal milieu for carcinogenesis in susceptible hosts.[8]

In contrast to intestinal-type gastric cancer, diffuse-type GAC results from defective intracellular adhesion molecules, which is the consequence of loss of E-cadherin protein expression, which is encoded by the cadherin 1 (*CDH1*) gene. This can occur through germline or somatic mutation, loss of heterozygosity, or epigenetic silencing of gene transcription through aberrant methylation of the *CDH1* promoter. A study by Zheng et al showed a positive rate of E-cadherin promoter methylation in dysplasia, early cancer, and advanced cancer.[13] Furthermore, 30% of families with hereditary diffuse gastric cancer show *CDH1* germline mutations, whereas the rest remain genetically unexplained.[14] Currently, many families with hereditary diffuse gastric cancer have *CDH1* germline mutations. Inheritance is dominant. The lifetime cumulative risk for advanced gastric cancer has been estimated to be 40% to 67% in men and 60% to 83% in women.[15] Women in affected families are also at high risk for developing lobular breast cancer, with a cumulative risk of 52%.[15] A germline mutation in *TP53* is associated with familial gastric cancer,[14] which includes Li-Fraumeni syndrome. Another familial cancer syndrome associated with gastric cancer is hereditary nonpolyposis colorectal cancer, resulting from defects of DNA mismatch repair genes (*hMLH1* and *hMSH2*, more frequently) (Table 27–1).[16]

Epstein-Barr virus–associated gastric cancers have distinct clinicopathologic characteristics, including

Table 27–1 Summary of Selected Recurrent Cytogenetic Abnormalities and Frequent Molecular Changes Associated with Gastric Cancer

Conventional Cytogenetics	Simple Karyotypes	Complex Karyotypes
	+X, +8, +9, +19, del(7q), i(8q)	1, 3, 6, 7, 8, 11, 13, 17, 19
Molecular Cytogenetics	**Gains**	**Loss**
	3q, 7p, 7q, 8q, 13q, 17q, 20p, 20q	4q, 9p, 17p, 18q
Genes	**Abnormalities**	**Clinical Association**
c-met	Amplification	Tumor invasion, lymph node metastasis, poor prognosis
K-sam	Amplification	Advanced tumor stage/poor prognosis
c-erbB2	Amplification	Advanced tumor stage, lymph node and liver metastases, poor prognosis
c-myc	Amplification	Poor clinical course/predictor of aggressiveness
TP53	Loss of heterozygosity	Proliferative rate/lymph node metastasis/shortened survival
	Mutation	
	Hypermethylation	
BCL-2	Loss of heterozygosity	Depth of invasion, lymph node metastasis and survival
RUNX3	Deletion	Metastasis
	Hypermethylation	
	Loss of expression	
PTEN	Loss of heterozygosity	Advanced tumor stage/metastasis
	Mutation	
E-cadherin (*CDH1*)	Loss of heterozygosity	Tumor metastatic ability and poor prognosis
	Mutation	
	Hypermethylation	
	Reduced expression	
Cyclin E	Amplification	Disease aggressiveness/lymph node metastasis
p27	Reduced expression	Advanced tumor stage/depth of invasion/lymph node metastasis
p16	Reduced expression	Tumor invasion/metastasis
DNA repair genes/ microsatellite instability	Mutation	Age/low prevalence of lymph node metastasis/ prolonged survival
	Hypermethylation	
	Reduced expression	
Syndecan-1	Reduce expression	Tumor differentiation
β-catenin	Amplification	Lymph node metastasis
CD44s and *CD44v6*	Amplification	Lymph node metastasis
Sp1	Amplification	Cancer angiogenic potential, poor prognosis

male predominance, preferential location in the gastric cardia or postsurgical gastric stump, lymphocytic infiltration, and a more favorable prognosis.[17,18]

Despite recent progress, the precise etiologic characteristics of gastric cancer and the relationship between the environment and host are unknown. Ongoing research promises to better elucidate the tumorigenesis of gastric cancer.

Prevention

Results from a number of population studies have demonstrated an increased likelihood of *H pylori* infection in patients with gastric cancer, particularly cancer of the distal stomach.[19,20] However, gastric cancer does not occur in most patients infected with *H pylori*. Although the role of *H pylori* in gastric cancer

pathogenesis is well defined, currently there is no definitive evidence showing that mass eradication could reduce the incidence of gastric cancer.[21] A large Chinese study of 1630 patients showed no benefit in the prevention of gastric cancer with the eradication of *H pylori*.[22] However, in a subgroup of patients with no precancerous lesions on presentation, gastric cancer did not develop in any patient during a follow-up of 7.5 years after *H pylori* eradication treatment compared with six patients who received placebo ($P = .02$).[22] In another large study, short-term treatment with amoxicillin and omeprazole statistically significantly reduced gastric cancer incidence by 39% during the period extending 14.7 years after *H pylori* treatment.[23] A meta-analysis suggested that eradication could reduce the risk of gastric cancer; however, this meta-analysis was criticized for methodologic issues.[24] As of this writing, the treatment of this infection is strongly recommended for patients with peptic ulcer disease, patients with mucosa-associated lymphoid tissue lymphoma, and after endoscopic resection for esophagogastric cancer; a role for a broad prevention strategy has yet to be defined.

Clinical Presentation

At presentation, the majority of patients with symptoms will have advanced disease. Symptoms can be constitutional, such as night sweats and unintentional weight loss, or they can be vague, such as early satiety, abdominal pain, and nausea. Dysphagia is more common in patients with cancer originating in the gastric cardia or GEJ. Occult gastrointestinal (GI) bleeding is also common, whereas overt bleeding is observed in only 20% of cases.

Pathologic and Molecular Characteristics

More than 95% of gastric cancers are adenocarcinoma. The remaining 5% include neuroendocrine tumor, lymphoma, SCC, and sarcoma.

The Cancer Genome Atlas Research Network has classified gastric cancer into four subtypes based on the molecular characterization of 295 primary adenocarcinomas in a way that can ultimately guide patient therapy.[25] They clearly converged on four major genomic subtypes of gastric cancer with distinct features and classes of molecular alterations:

1. Tumors containing Epstein-Barr virus, along with recurrent mutations in the *PIK3CA* gene pathway, extreme DNA hypermethylation, amplification of Janus kinase 2 (*JAK2*), and extra copies of programmed death ligand 1 (*PD-L1*) and *PD-L2* genes, which are suppressors of immune response. This group made up about 10% of the cancers, with nearly 80% harboring a protein-changing alteration in *PIK3CA*.
2. Tumors showing microsatellite instability, in which malfunctioning DNA repair mechanisms cause a high rate of mutations, including mutations of genes encoding targetable oncogenic signaling proteins. About 20% of tumors fell into this subtype.
3. The largest category of tumors, making up about half of the cancer specimens, was termed *chromosomally unstable*. These contained a jumble of extra or missing pieces of genes and chromosomes (aneuploidy) and have a striking number of genomic amplifications of key receptor tyrosine kinases. This subtype of tumor is frequently found in the junction between the stomach and the esophagus, a type of gastric cancer that has been increasing dramatically in the United States.
4. The fourth group was termed *genomically stable* because they lacked the molecular features of the other three types. These tumors, making up 20% of the specimens, were largely those of a specific class of gastric cancer enriched for the diffuse-type histologic variant, with approximately 30% of these tumors having genomic alterations in the Ras homolog gene family, member A (*RHOA*) signaling pathway. These tumors were characterized by the lack of high levels of aneuploidy and high metastatic potential.

This classification may serve as a valuable adjunct to histopathology and provides patient stratification as a guide to targeted agents.

Staging and Prognosis

Upper GI series with barium swallow and upper esophagogastroduodenoscopy (EGD) are mainstays for diagnosing gastric cancer and provide complementary diagnostic information. EGD is more sensitive and specific to obtain tissue diagnosis. A single biopsy has 70% sensitivity for diagnosing gastric cancer; performing seven biopsies from the ulcer margin and base increases the sensitivity to more than 98%.[26] In contrast, barium swallow with upper GI series can identify both malignant gastric ulcers and infiltrating lesions, including some early gastric cancers. However, the false-negative rate with barium swallow can be as high as 50%[27] and may be even higher for early gastric cancer, and sensitivity can be as low as 14%.[27]

Cancer staging is critical prior treatment, the staging system by the American Joint Committee on Cancer (AJCC) 8th edition (2017) is the most current used (Table 27–2)[28] and includes gastric carcinoma, gastric neuroendocrine carcinoma, GEJ carcinoma with an

epicenter more than 2 cm into the stomach, and cardia carcinoma.

In this newest version, three staging guidelines by the TNM (tumor, node, metastasis) classification of malignant tumors are available: clinical stage (c stage) based on databases from United States and Japan; pathologic stage (p stage) determined after primary surgery of localized GAC; and post-neoadjuvant therapy pathology classification (yp stage), after the use of neoadjuvant therapy before surgery. According to the AJCC 8th edition, Siewert-Stein type II tumors are staged according to the esophageal cancer system, and type III tumors are staged according to the gastric system.

Because of its noninvasive nature, computed tomography (CT) has become the cornerstone of gastric cancer staging, although it is not sensitive at detecting the tumor invasion depth and local and regional lymph node involvement. Contrast-enhanced CT scans of the chest, abdomen, and pelvis can assess the locale(s) of distant extension of GAC. Currently, CT is used in conjunction with endoscopic ultrasonography (EUS) of the primary site, which provides the most accurate data for depth of tumor invasion and locoregional lymph node involvement. Endoscopic ultrasonography has an accuracy of 77% (vs 40%–50% with CT) for staging depth and 69% for staging nodes.[29] The availability of EUS-guided biopsy of suspicious local and regional lymph nodes has circumvented its limitations (Figs. 27–1 and 27–2). Laparoscopy with peritoneal washings is more invasive than CT or EUS, but it has the advantage of directly visualizing the liver surface, peritoneum, and local lymph nodes. It is

Table 27–2 A. American Joint Cancer Committee TNM Staging System for Gastric Cancer

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial tumor with invasion of the lamina propria, high-grade dysplasia
T1	Tumor invades the lamina propria, muscularis propria, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria[a]
T3	Tumor penetrates the subserosal connective tissue without invasion of visceral peritoneum or adjacent structures[b,c]
T4	Tumor invades serosa (visceral peritoneum) or adjacent structures[b,c]
T4a	Tumor invades serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures/organs
Regional Lymph Nodes (N)	
Nx	Regional lymph node(s) cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1–2 regional lymph nodes
N2	Metastasis in 3–6 regional lymph nodes
N3	Metastasis in ≥7 regional lymph nodes
N3a	Metastasis in 7–15 regional lymph nodes
N3b	Metastasis in ≥16 regional lymph nodes
Distant Metastases (M)	
Mx	Distant metastasis cannot be assessed
M0	No distant metastases
M1	Distant metastases, microscopically confirmed

[a]A tumor may penetrate the muscularis propria with extension into the gastrocolic or gastrohepatic ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified as T3. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified as T4.
[b]The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.
[c]Intramural extension to the duodenum or esophagus is not considered invasion of an adjacent structure but is classified using the depth of the greatest invasion in any of these sites.

sensitive at diagnosing liver metastases and peritoneal carcinomatosis in up to 23% of patients in whom no such involvement was seen on CT[30] and up to 13% of patients with positive cytology only.[31] Diagnostic laparoscopy is usually performed when all noninvasive studies (CT and EUS) demonstrate localized or potentially resectable disease in patients with higher than T1b disease on EUS. Positive peritoneal cytology represents stage IV disease according to the AJCC system.

The effectiveness of fluorodeoxyglucose (FDG) positron emission tomography (PET) at diagnosing gastric cancer is uncertain because as many as 50% of primary tumors are FDG negative, particularly early gastric cancers.[32] Insufficient FDG uptake is mostly associated with diffuse-type gastric cancer with signet ring cells and mucinous content.[33] Currently, FDG-PET has no role in the primary detection of gastric cancer because of its low sensitivity. On the other hand, FDG-PET shows better results in the evaluation of lymph node metastases in gastric cancer compared with CT and could thus have a role in preoperative staging. For patients with FDG-positive disease, FDG-PET can be used to predict histologic response and survival outcomes,[34–36] similar to results seen among patients with distal esophageal and GEJ adenocarcinoma.[37] The addition of FDG-PET to CT increases diagnostic accuracy for recurrent gastric cancer because PET/CT is as sensitive and specific as contrast CT at detecting recurrent disease, except peritoneal seeding.[38]

Among patients with gastric cancer who had surgery, factors affecting gastric cancer prognosis include nodal involvement, tumor location, histologic grade, and lymphovascular invasion.[39] Patients with proximal gastric cancer have a poorer prognosis than those with distal gastric cancer, at 28.5 versus 58.6 months ($P < .02$).[40] Although associations have been found between molecular genetic changes and pathologic features and biologic behavior and prognosis, the clinical significance of these genetic changes has not yet been established. In other words, these genetic parameters have been unable to translate into meaningful clinical diagnostic, predictive, or prognostic biomarkers. Therefore, the putative biomarker screening method for gastric cancer also remains elusive. However, with better appreciation of the complex interplay between environment and host factors leading to gastric tumorigenesis, researchers hope to produce more effective screening methods for high-risk patients, better prognostic and predictive biomarkers, and superior therapeutic indices of cancer drugs.

Treatment

Gastric cancer is treated according to the cancer stage at presentation. Reflecting the newest changes in the AJCC staging system, treatment for GEJ and proximal gastric adenocarcinoma smaller than 5 cm from the GEJ is discussed in the esophageal cancer section. Treatment for patients with locally advanced gastric cancer is dichotomized into resectable and unresectable disease. Surgery remains the best chance for long-term survival, but 5-year survival rates after surgery alone are 20% to 50%, and adjunctive therapy, such as chemotherapy or chemoradiotherapy, must be offered. Localized gastric cancer can be classified as clinical T1 disease or higher with or without involved regional lymph nodes. A minimum of 15 examined lymph nodes is recommended for adequate surgical staging.[41] The adjunctive therapy used for the treatment of localized gastric cancer in addition to surgery depends on geographic location in the world. In North America and Europe, results from the Intergroup INT-0116[42] (the adjuvant chemoradiotherapy approach) and Medical Research Council Adjuvant Infusional Chemotherapy (MAGIC)[43] (the perioperative chemotherapy approach) trials established the standard of care in the early 2000s. Most recent trials like FLOT (continuous infusion 5-FU, leucovorin, oxaliplatin, and docetaxel) given perioperatively have also become standard of care. In Asia, however, adjuvant chemotherapy after a D2 nodal dissection is considered the gold standard.[44,45]

Unfortunately, the main therapeutic goal in patients with unresectable locally advanced disease remains symptom palliation. The treatment of unresectable locally advanced and metastatic gastric cancers is discussed in two separate subsections: Unresectable Locally Advanced Gastric, Gastroesophageal Junction, and Esophageal Cancers; and Advanced and Metastatic Gastric, Gastroesophageal Junction, and Esophageal Cancers.

Resectable Disease

Surgery

Surgical resection offers the best chance for long-term survival in patients with localized disease, particularly in combination with postoperative (adjuvant) chemoradiotherapy[42] or perioperative chemotherapy.[43] Even with newer staging modalities, the major barrier to accurately identify patients with potentially resectable disease is the ability to accurately stage disease. In the United States, 67% of patients present with stage III or IV disease, and only 10% present with stage I disease.[46]

By definition, curative resection (also referred to as R0 resection) involves removal of the primary cancer and regional lymph nodes with free margins. The goals of surgery are twofold: local control and (it is hoped) eradication of gastric cancer and (2) attainment of accurate pathologic staging. Considerations for surgical management of gastric cancer are the (1) extent of luminal resection (total vs partial gastrectomy) and (2) extent of lymph node dissection. Total gastrectomy is mainly reserved for proximal gastric cancer and large midgastric tumors or linitis plastica (wherein a large region of the stomach is extensively infiltrated by cancer, resulting in a rigid, thickened fold), whereas partial gastrectomy may be used in distal gastric tumors. Two randomized controlled trials have demonstrated similar survival outcomes for total and partial gastrectomy for distal gastric cancer.[47,48] OS rates improved from 5% for R2 (surgical resection with gross residual disease) to 50% for R0.[47]

Japanese surgeons routinely perform extended lymphadenectomy, whereas in the United States, 54% of patients who underwent primary gastrectomy undergo less than a D1 lymphadenectomy.[42] A D1 lymphadenectomy refers to a limited dissection of the perigastric lymph nodes, whereas D2 refers to the removal of nodes along the hepatic, left gastric, celiac, and splenic arteries, as well as those in the splenic hilum. A D3 lymph node dissection includes lymph nodes located within the porta hepatis and periaortic regions.

Proponents of extended lymphadenectomy argue that only with extended dissection can accurate staging be guaranteed, which also implies accurate prediction of stage-specific survival. Furthermore, with extensive nodal dissection, locoregional relapse rates are lower. Using SEER Project data from 1973 to 2000, Schwarz and Smith[49] evaluated 1377 patients with locally advanced gastric cancer (stages IIIA, IIIB, and IV, M0). The total lymph node (LN) count (or number of negative LNs examined; $P < .0001$) and number of positive LNs ($P < .0001$) were independent prognostic survival predictors. Furthermore, the stage-based survival prediction depended on the total LN number and number of negative LNs. In their earlier analysis of SEER data from 1973 to 1999, these same investigators demonstrated that for every 10 extra LNs dissected, survival improved by 7.6% (T1/2N0), 5.7% (T1/2N1), 11% (T3N0), or 7% (T3N1).[50] The results of this analysis demonstrated that for all T stages, extensive nodal dissection affects survival outcomes. Similarly, a 5-year survival benefit was reported for patients with D2 and D3 dissections compared with D1 lymphadenectomy (60% vs 54%, $P = .041$) in a Taiwanese study involving 221 patients with resectable gastric cancer.[51]

Despite this evidence, prospective studies performed in non-Asian countries were unable to confirm these findings.[41,52–54] The Medical Research Council (MRC) randomly assigned 400 patients with resectable gastric cancer to D1 or D2 nodal dissection. Postoperative morbidity and mortality rates were higher for D2

(46% and 13%) than for D1 (28% and 6%) dissection.[54] Both the initial and long-term follow-up results in the Dutch Gastric Cancer Group study demonstrated a significant increase in morbidity and mortality, with no survival difference between D1 and D2 dissections.[41,53] Although these large prospective studies performed in non-Asian countries could not confirm the initial findings, they went on to suggest that extended lymphadenectomy carries increased rates of morbidity and mortality, with a negligible change in survival.

Despite some disagreement about the benefits of D2 dissection, most experts agree that localized gastric cancer with clinical stage higher than T1b is best treated with multidisciplinary approaches and at high-volume centers, particularly by high-volume surgeons.[55,56] We acknowledge that the literature lacks convincing results in favor of D2 dissection in randomized studies to date that have compared D1 versus D2 dissections; however, the pendulum is swinging in favor of a more thorough nodal dissection by experienced surgeons. A nodal dissection approaching D2 can have the following advantages: accurate nodal staging and removal of more uninvolved nodes, which is associated with prolonged survival.[53,57] A 15-year update of the Dutch trial showed benefit in the D2 group in terms of the hazard ratio (HR) for gastric cancer–related death (0.74; 95% CI, 0.59–0.93; $P = .01$); however, only a few patients were at risk.[58]

Perioperative Chemotherapy

This approach is based on the assumption that neoadjuvant systemic therapy can lead to tumor downstaging, leading to an improved R0 resection rate. This is particularly significant in Western patients in whom the tumors are usually bulky at diagnosis.[59] The MAGIC trial established level 1 evidence for this approach.[43] The study enrolled 503 patients with gastric, GEJ, and esophageal adenocarcinoma.[43] These patients were randomly assigned to receive three cycles of perioperative chemotherapy consisting of epirubicin, cisplatin, and infusional 5-fluorouracil (5-FU) (ECF) followed by surgery, followed by three more cycles of ECF, or surgery followed by observation. In this trial, postoperative chemotherapy proved hard to deliver, with only 34% of patients receiving this treatment, and only 68% of patients underwent a curative resection. Despite this, both progression-free survival (PFS) and OS were improved in the group receiving ECF (HR for progression, 0.66; 95% CI 0.53–0.81; $P < .001$; HR for death, 0.75; 95% CI 0.60–0.93; $P = .009$). Five-year survival rates were 36.3% (95% CI 29.5%–43.0%) among patients in the perioperative chemotherapy group and 23.0% (95% CI 16.6%–29.4%) among those in the surgery group.[43] Taken together, these data suggest that the majority of the benefit may in fact come from the preoperative portion of the chemotherapy.

A second, French study supports the findings of the MAGIC trial. The Fédération Nationale des Centres de Lutte Contre le Cancer (FNCLCC) and the Fédération Francophone de Cancérologie Digestive (FFCD) multicenter phase 3 trial was terminated prematurely for poor accrual and is therefore not adequately powered.[60] Overall, 224 patients with resectable adenocarcinoma of the lower esophagus, GEJ, or stomach (only 25%) were randomly assigned to either perioperative chemotherapy (with cisplatin and 5-FU) and surgery followed by three to four cycles of cisplatin and 5-FU or surgery alone. Only approximately 50% of patients received any postoperative chemotherapy. Despite these issues, the chemotherapy and surgery group had a significantly higher OS (HR for death, 0.69; 95% CI 0.50–0.95; $P = .02$) and disease-free survival (DFS; HR for recurrence or death, 0.65; 95% CI 0.48–0.89; $P = .003$). Five-year survival rates were 38% (95% CI 29%–47%) in the chemotherapy and surgery group compared with 24% (95% CI 17%–33%) in the surgery group. These results are quite similar to those of the MAGIC trial and bring into question the usefulness of the addition of epirubicin to cisplatin and 5-FU.

In contrast, a study by the European Organization for Research and Treatment of Cancer (EORTC 40954) did not demonstrate a benefit from the addition of perioperative chemotherapy.[61] This trial showed a significantly increased R0 resection rate but failed to demonstrate a survival benefit with the addition of chemotherapy; however, it was not sufficiently powered to demonstrate a difference, given its premature termination because of poor accrual.

The Arbeitsgemeinschaft Internistische Onkologie (AIO) German group conducted a multicenter, open-label, randomized phase 2/3 trial (FLOT4) comparing four pre- and four postoperative cycles of conventional ECF versus FLOT in 716 patients with resectable gastric or GEJ adenocarcinoma. Most patients had T3–4 disease (79%–83%) and were node-positive (78%–81%), and a minority had diffuse histology primaries (27%). The OS was significantly improved with FLOT versus ECF (50 vs 35 months; HR 0.77; $P = .012$), with a projected improvement in 5-year OS (45% vs 36%). PFS was also improved with FLOT (30 vs 18 months; HR 0.75; $P = .0036$), as were rates of R0 resection (85% vs 78%), tumor stage T1 or higher (25% vs 15%), and nodal status N0 (49% vs 41%). Rates of adverse events were comparable for the two regimens. The FLOT4 study has established FLOT as the new standard of care for perioperative chemotherapy in patients with resectable gastric cancer who can tolerate a triplet chemotherapy regimen.[62]

The Japanese Clinical Oncology Group (JCOG 0501) published results from their randomized phase 3 trial of gastrectomy with or without neoadjuvant

S-1 plus cisplatin for type 4 (linitis plastica) or large type 3 (>8 cm ulcerative) gastric cancer. Patients were randomly assigned to surgery followed by adjuvant chemotherapy (S-1, days 1–28, q42d for 1 year) (Arm A) or neoadjuvant chemotherapy (NAC) (S-1, 80–120 mg/body, days 1–21 and cisplatin, 60 mg/m2, day 8, q28d, 2 courses) followed by gastrectomy plus the same adjuvant chemotherapy (Arm B). The primary end point was OS. S-1 adjuvant chemotherapy for one year showed remarkable survival results for type 4 or large type 3 gastric cancer, and additional NAC with S-1 plus CDDP was not recommended.[63]

Postoperative Chemoradiotherapy

The indication of adjuvant chemoradiotherapy comes from level 1 evidence of its benefit from the Intergroup INT-0116 trial that showed a significant improvement in OS in the group of patients treated with adjuvant chemoradiotherapy.[42,64] In this trial, 559 patients with stage IB to IV disease were randomly assigned to chemoradiotherapy after surgery or surgery alone. The chemoradiotherapy group received chemotherapy consisting of one 5-day cycle of 5-FU and leucovorin (LV) starting on day 1, followed by chemoradiotherapy beginning 28 days after the start of the initial cycle of chemotherapy. Chemoradiotherapy consisted of 45 Gy of radiation at 1.8 Gy/day 5 days per week for 5 weeks, with 5-FU (400 mg/m2/d) and LV (20 mg/m2/d) on the first four and the last three days of radiotherapy. One month after the completion of radiotherapy, two 5-day cycles of 5-FU (425 mg/m2/d) plus LV (20 mg/m2/d) were given one month apart. The 3-year survival rates were 50% in the chemoradiotherapy group and 41% in the surgery-only group. The HR for death in the surgery-only group, compared with the chemoradiotherapy group, was 1.35 (95% CI 1.09–1.66; $P = .005$). The HR for relapse in the surgery-only group, compared with the chemoradiotherapy group, was 1.52 (95% CI 1.23–1.86; $P < .001$).[42] Recently updated results of this study continue to demonstrate a benefit in terms of both OS and recurrence-free survival (RFS).[65] The major issue of this study was that the majority of patients did not receive an adequate LN dissection. Although a D1 resection was mandated per protocol, more than 50% of patients underwent a D0 resection, and only 10% of patients underwent a D2 nodal dissection. Therefore, it is questioned whether the survival difference occurred because of inadequate surgery rather than from a true benefit of chemoradiotherapy.[42]

Cancer and Leukemia Group B (CALGB) 80101, a US intergroup study, was designed to evaluate postoperative bolus 5-FU and LV with 5-FU plus concurrent radiation (an INT0116 trial treatment regimen) versus postoperative ECF (the MAGIC trial regimen) before and after 5-FU plus concurrent radiation in 546 patients with gastric or GEJ tumors after curative resection.[64] In a preliminary report presented at the 2011 American Society of Clinical Oncology annual meeting, patients receiving ECF had lower rates of diarrhea, mucositis, and grade 4 or worse neutropenia. Overall survival, the primary end point, was not significantly better with ECF (3-year OS, 52% vs 50% for ECF and 5-FU/LV, respectively), regardless of the location of the primary tumor.

The Adjuvant Chemoradiation Therapy in Stomach Cancer (ARTIST) trial compared adjuvant chemoradiotherapy with adjuvant chemotherapy after an R0 resection with D2 dissection in 458 patients.[66] The ARTIST trial was a negative study because its primary end point, 3-year DFS rate, was not statistically different between the two groups. In subgroup analyses, patients with node-positive disease in the adjuvant chemoradiotherapy group had a significantly improved 3-year DFS rate than those in the adjuvant chemotherapy group. The improved DFS among patients with node-positive disease was later confirmed in the recently published update; however, there was no improved OS despite the prolonged follow-up interval.[67] This improved DFS finding may suggest that compared with adjuvant chemotherapy, adjuvant chemoradiotherapy may be beneficial among patients with node-positive resectable gastric cancer, a theory that was tested in the ARTIST-2 trial (see below). Different from INT0116, all patients in the ARTIST-2 trial were required to have a D2 nodal dissection, and the chemotherapy administered to all patients consisted of S-1 versus S-1 and oxaliplatin with or without radiotherapy. Hence, ARTIST-2 was designed to evaluate the benefit of chemoradiotherapy after a D2 nodal dissection.[68,69]

The Dutch phase 3 (CRITICS) trial evaluated the strategy to integrate postoperative chemoradiotherapy with conventional perioperative strategy.[70] Postoperative chemoradiotherapy in addition to preoperative chemotherapy did not improve OS compared with perioperative chemotherapy in patients with resectable gastric cancer treated with adequate preoperative chemotherapy and surgery. In this study, only 60% of all randomly assigned patients could receive the planned postoperative treatment, which was consistent with the MAGIC approach. Optimizing preoperative strategies is the focus of the CRITICS II (NCT02931890) study.[71]

The TOPGEAR trial, which is underway in Australia, Europe, and Canada, directly compares perioperative chemotherapy alone (ECF/ECX/EOX or FLOT) versus preoperative chemoradiotherapy in patients with resectable adenocarcinoma of the stomach and GEJ (NCT01924819).[72] Ajani et al[73] reported the results of several phase 2 studies that demonstrated the

feasibility and effectiveness of a three-step strategy. Thirty-seven patients with locally advanced resectable gastric cancer were treated with trimodality therapy in a phase 2 clinical trial. Chemotherapy consisted of infusional 5-FU, cisplatin, and paclitaxel (FPT); 45 Gy of radiotherapy was administered concurrently with FPT. R0 and pathologic complete response (pathCR) rates were 95% and 30%, respectively. Fourteen percent of patients had only microscopic residual disease. Patients who achieved pathCR or pathologic partial response after preoperative chemoradiotherapy had significantly longer median survival durations than those who did not (63.9 vs 12.6 months; $P = .03$).

As a result of the MDACC's single-institution success with preoperative trimodality therapy, the Radiation Therapy Oncology Group (RTOG) sponsored a multi-institution cooperative study, RTOG 9904. The primary end point was pathCR rate. Forty-nine patients with localized resectable gastric cancer from 20 institutions received 5-FU, LV, and cisplatin (FLP) as induction chemotherapy, followed by concurrent chemoradiotherapy with 5-FU and weekly paclitaxel. The pathCR and R0 resection rates were 26% and 77%, respectively. At one year, more patients who had achieved pathCR (82%) were alive than those who did not (69%).[74] A D2 dissection was performed in 50% of patients. The heterogeneity of different treating institutions minimized the selection bias typical of single-institution results. Outcomes in RTOG 9904 were no better or worse than those of more recent studies, particularly the pathCR and D2 lymphadenectomy rates.

Postoperative Chemotherapy

The benefits of adjuvant chemotherapy after a D2 nodal dissection were initially demonstrated in Japan, and the chemotherapy used was S-1.[44] The Adjuvant Chemotherapy Trial of S-1 for Gastric Cancer (ACTS-GC) trial randomly assigned 1059 patients to one year of S-1 or observation. The updated analysis after 5 years of follow-up has demonstrated consistent results.[75] The OS rate at 5 years was 71.7% in the S-1 group and 61.1% in the surgery-only group (HR 0.669; 95% CI 0.540–0.828). The RFS rate at 5 years was 65.4% in the S-1 group and 53.1% in the surgery-alone group (HR 0.653; 95% CI 0.537–0.793).

Another Asian study, the Capecitabine and Oxaliplatin Adjuvant Study in Stomach Cancer (CLASSIC) trial, randomly assigned 1035 patients who had undergone D2 gastrectomy to capecitabine plus oxaliplatin for 6 months or observation.[45] The study demonstrated a benefit in patients treated with capecitabine and oxaliplatin for the primary end point of DFS (at 3 years; HR 0.56; 95% CI 0.44–0.72; $P < .0001$) at the prespecified interim analysis. After this analysis, the trial was stopped after a recommendation by the data monitoring committee. The mature OS data were published in *The Lancet Oncology*.[67] By the clinical cutoff date, 103 patients (20%) had died in the adjuvant capecitabine and oxaliplatin group versus 141 patients (27%) in the observation group (stratified HR 0.66; 95% CI 0.51–0.85, $P = .0015$). Estimated 5-year OS was 78% (95% CI 74%–82%) in the adjuvant capecitabine and oxaliplatin group versus 69% (95% CI 64%–73%) in the observation group. Based on these results, CAPOX has been established as another standard postoperative treatment for patients with stage II/III gastric cancer in Asia.

Recently, Japan Clinical Cancer Research Organization (JACCRO) demonstrated the superiority of RFS (HR 0.632) of docetaxel plus S1 (DS) versus S1 alone for stage III GC patients. In the DS group, one 3-week cycle of S1 was given on days 1 to 14, followed by six cycles of S1 (days 1–14) and 40 mg/m2 of docetaxel on day 1 every 3 weeks. This was followed by S1 on days 1 to 28 every 6 weeks for up to one year. Postoperative DS has become the new standard for the curatively resected stage III GC in Japan.[76,77]

The Korean phase 3 trial (ARTIST-II) randomly assigned, in a 1:1:1 ratio, patients with pathologically staged II or III, node-positive, D2-resected gastric cancer, to receive adjuvant S-1 (40–60 mg twice daily 4 weeks on/2 weeks off) for one year, S-1 (2 weeks on and 1 week off) plus oxaliplatin 130 mg/m2 (SOX) for 6 months, or SOX plus chemoradiotherapy 45 Gy (SOXRT). A total of 538 patients were included for this interim efficacy analysis.[78] The DFS at 3 years was found to be 65%, 78%, and 73% in the S-1, SOX, and SOXRT arms, respectively. No difference in DFS between SOX and SOXRT was found (HR 0.910; $P = .667$). The independent monitoring committee ended the trial early, concluding that in patients with curatively D2-resected, stage II/III, node-positive GC, adjuvant SOX was effective in prolonging DFS, when compared with S-1 monotherapy.

Positive results were also reported in another Korean trial, the PRODIGY study.[79] In this trial, 530 patients with newly diagnosed locally advanced gastric or GEJ adenocarcinoma (cT2,3/N[+]M0 or cT4/N[any]M0, per AJCC 7th ed), ECOG PS 0-1, were randomized 1:1 to NAC docetaxel, oxaliplatin, and S-1 (DOS) then surgery and adjuvant S-1 ($n = 266$), or surgery and adjuvant S-1 ($n = 264$). NAC was docetaxel 50 mg/m2 intravenous and oxaliplatin 100 mg/m2 intravenous on day 1, S-1 40 mg/m2 twice by mouth on days 1 to 14 every 3 weeks for 3 cycles. Standard surgery was D2 gastrectomy. DOS and postoperative S-1 showed longer PFS (primary end point) over postoperative S1 in cT2/3-LN positive or cT4 resectable GC.

All major phase 3 trials in localized gastric cancer and the most important ongoing studies in this setting are summarized in Tables 27–3 and 27–4. Given the variability in outcomes in many phase 3 trials, several

Table 27–3 Major Phase 3 Trials for Gastric Cancer in the Localized Setting

Trial	No. of Patients	Treatment Arms	HR for OS (*P* value)	Primary End Point Comparison in Months (Survival Rates in %)
Perioperative Chemotherapy				
Cunningham et al (MAGIC)[43]	503	ECF → surgery → ECF vs surgery	0.75 (.009)	5-y OS: 36.3% vs 23%
Ychou et al (FNLCC/FFCP)[60]	224	CF → surgery → CF vs surgery	0.69 (.02)	5-y OS: 38% vs 24%
Schuhmacher et al (EORTC 40954)[61]	144	CFL → surgery vs surgery (only preoperative CT)	0.16	Underpowered to demonstrate a survival end point because of limited accrual (144/360 patients)
Al-Batran et al (FLOT4)[62]	716	ECF → surgery → ECF vs FLOT → surgery → FLOT	0.77 (.012)	OS: 25 months vs 50 months 5-y OS: 36% vs 45%
Terashima et al (JCOG0501)[63]	300	Surgery → S1 vs S-1+cisplatin → surgery → S1	0.74	3-y OS: 17.5% vs 27.5%
Cunningham et al (MAGIC B/ST03)[80]	1063	ECX+bevacizumab → surgery → ECX+bevacizumab → maintenance bevacizumab vs ECX → Surgery → ECX	1.08 (.36)	3-y OS: 48.1% vs 50.3%
Park et al (ARTIST-2)[78]	538	Surgery → S-1 vs Surgery → S-1+oxaliplatin (SOX) vs Surgery → SOX+CTRT (SOXRT)	0.617 (.016) S-1 vs SOX 0.686 (.057) S-1 vs SOXRT	3-y DFS: 65% vs 78% vs 73%
Postoperative Chemoradiotherapy				
Macdonald et al (INT-0116)[42]	556	Surgery → FL/CTRT (45 Gy+FL)/FL vs surgery	1.32 (.004)	OS: 36 vs 27
Fuchs et al (CALGB 80101)[64]	546	Surgery → ECF/CTRT+FL/ECF vs surgery → FL/CTRT+FL/FL	1.03 (.80)	OS: 38 vs 37
Lee et al (ARTIST)[66]	458	Surgery → XP/XRT/XP vs surgery → XP	1.130 (.5272); N+ patients: HR for DFS, 0.70 (.04)	5-y OS: 75% vs 73%; N+ patients: 3-y DFS: 76% vs 72%
Cats et al (CRITICS)[70]	788	CT → surgery → CT vs CT→ surgery → CTRT	1.01 (.09)	OS: 43 vs 37
Postoperative chemotherapy				
Sasabo et al (ACTS- GC)[75]	1059	Surgery → S-1 vs surgery	0.68 (.003); HR at 5 years: 0.669	3-y OS: 80.1% vs 70.1%; 3-y RFS: 72.2% vs 59.6%
Bang et al (CLASSIC)[45]	1035	Surgery → CapeOx vs surgery	0.56 (< .0001)	3-y DFS: 74% vs 59%
Tsuburaya et al (SAMIT), 2× 2 factorial design[81]	1495	Surgery → UFT vs surgery → S-1 vs surgery → paclitaxel+UFT vs surgery → paclitaxel+S-1	HR for DFS 0.81 (.0048) for monotherapy (0.151 for noninferiority of UFT), 0.92 (.273) for monotherapy vs sequential	3-y DFS: 53% vs 58.2% (UFT vs S-1), 54% vs 57.2% (monotherapy vs sequential)
Yoshida et al (JACCRO GC-07)[77]	915	Surgery →S-1+docetaxel vs surgery →S-1	0.632 (<.001)	3-y RFS: 66% vs 58%

CapeOx, capecitabine and oxaliplatin; CF, cisplatin and 5-fluorouracil; CFL, cisplatin, 5-fluorouracil, and leucovorin; CT, chemotherapy; CTRT, chemoradiotherapy; DFS, disease-free survival; ECF, epirubicin, cisplatin, and 5-fluorouracil; FL, 5-fluorouracil and leucovorin; HR, hazard ratio; OS, overall survival; RFS, recurrence-free survival; SOX, S-1 + oxaliplatin UFT, tegafur and uracil; XP, capecitabine and cisplatin; XRT, capecitabine and radiotherapy.

Table 27–4 List of Ongoing Phase 3 Trials in Localized Gastric Cancer

Trials	No. of Patients	Treatment Arms	Control Arm	Status
Perioperative Chemotherapy				
Ychou et al (FNLCC 94012-FFCD 9703)[60]	250	CF → surgery (only neoadjuvant CT)	Surgery	Active, not recruiting
Postoperative + Preoperative Chemoradiotherapy

Kang et al (PRODIGY)[79]	530	CT→ Surgery→ S-1	Surgery → S-1	Active, not recruiting

CF, cisplatin and 5-fluorouracil; CT, chemotherapy; CTRT, chemoradiotherapy; CX, cisplatin and capecitabine; ECF, epirubicin, cisplatin, and 5-fluorouracil; ECX, epirubicin, cisplatin, and capecitabine; 5-FU, 5-fluorouracil; S-1 Ox, S-1 and oxaliplatin.

CHAPTER 27

Table 27–5 Perioperative or Postoperative Therapy for Localized Gastric Cancer: Results of Meta-Analyses

Reference	No. of Studies	No. of Patients	HR for OS	Treatment
Diaz-Nieto et al[82]	34	7,824	0.85	Postoperative chemotherapy
Ronellenfitsch et al[83]	14	2,422	0.81	Perioperative chemo(radio)therapy
Oba et al[84]	14	3,288	DFS: 0.92	Postoperative chemotherapy
Earle et al[84]	13	NR (non-Asian patients)	0.80	Postoperative chemotherapy

DFS, disease-free survival; HR, hazard ratio; NR, not reported yet; OS, overall survival.

meta-analyses have been undertaken (Table 27–5), all of which support a significant survival benefit for perioperative or adjuvant chemotherapy with somewhat better prognosis shown in Asian compared with Western populations,[82–84], including one that was limited to trials from Western (non-Asian) countries.[85] One of the most recent of these analyses evaluated data from 34 randomized trials comparing adjuvant systemic chemotherapy versus surgery alone, conducted in both Asian and Western populations.[82] The risk of death in patients receiving adjuvant chemotherapy was reduced by 15% (HR for death, 0.85; 95% CI 0.80–0.90).

Based on the previously mentioned trials and meta-analyses, postoperative chemoradiotherapy (United States), perioperative chemotherapy (Europe), and adjuvant chemotherapy after a D2 nodal dissection (Asia) can all be regarded as standards of care in the management of localized gastric cancer.

Figure 27-3A summarizes MDACC's approach to localized gastroesophageal cancer.

MD ANDERSON PRACTICE TIPS

RESECTABLE GASTRIC CANCER

- All patients with newly diagnosed gastric cancer undergo a CT imaging and upper endoscopy.
- Patients with resectable gastric cancer also undergo EUS and diagnostic laparoscopy with peritoneal washings.
- MDACC has been developing the practice of multimodality management in a multidisciplinary setting for all patients, but it is especially useful for those with resectable disease. Preoperative trimodality therapy consisting of induction chemotherapy followed by chemoradiotherapy and then surgical resection has been tested and evolved at MDACC over many years.

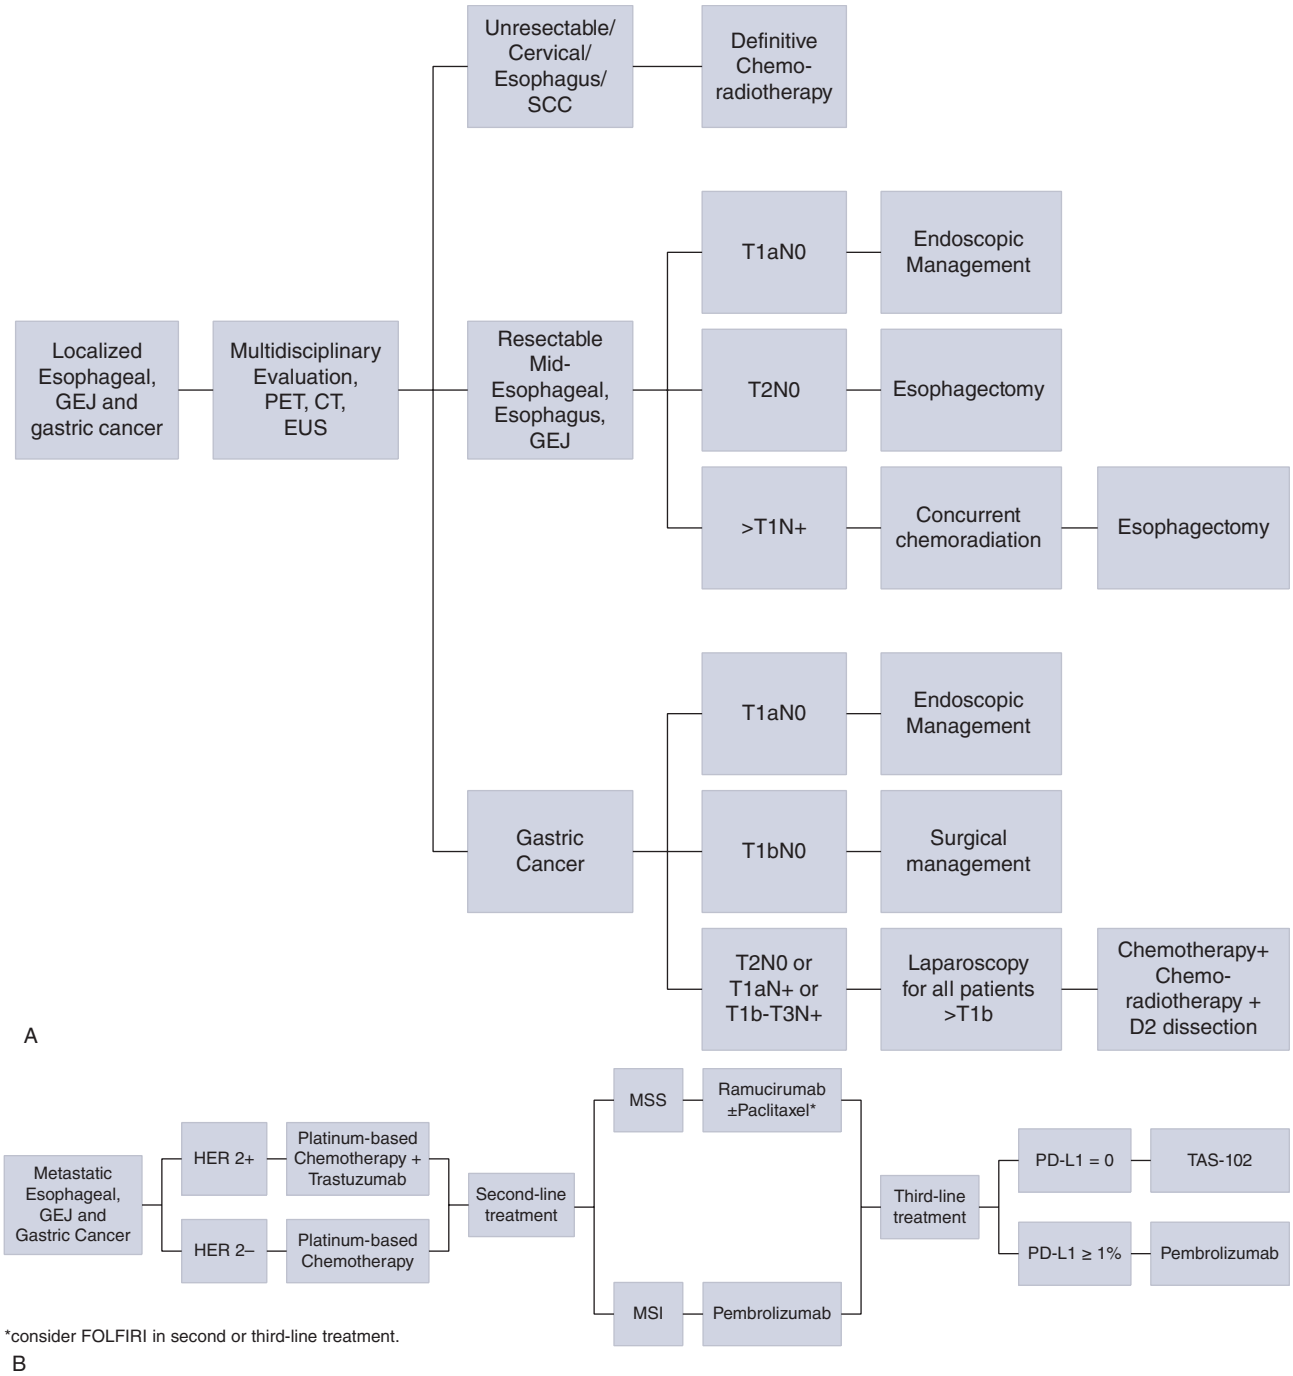

FIGURE 27–3 **The University of Texas MD Anderson Cancer Center Treatment algorithms for (A) localized gastroesophageal cancer and (B) metastatic gastroesophageal cancer. CT, computed tomography; EUS, endoscopic ultrasound; GEJ, gastroesophageal junction; HER2, human epidermal growth factor receptor 2; PET, positron emission tomography; PS, performance status; SCC, squamous cell carcinoma.**

ESOPHAGEAL AND GASTROESOPHAGEAL JUNCTION CANCERS

Esophageal cancer is estimated to be the eighth most common cause of cancer death among men in the United States and the fifth most common cause of cancer death worldwide.[86] In 2020, the estimated numbers of new cases and deaths from esophageal cancer in the United States are 18,440 and 16,170, respectively.2 Esophageal cancer is three to four times more common in men than in women,[87] with a mean age of 67 years.[88] The lifetime risk of developing esophageal cancer is 1 in 125 for men and 1 in 435 for women.[87] For

classification purposes (AJCC staging, 8th ed), primary tumors of the GEJ and proximal gastric cancer with epicenters extending no more than 2 cm into the stomach are included with esophageal cancers. The incidence of GEJ cancer has continued to increase over the last several decades. In recent years, this trend reached a new plateau, coinciding with the increased incidence of distal esophageal adenocarcinoma since the mid-1990s, a phenomenon confined to North America and other non-Asian countries. Overall, the prognosis of patients with esophageal/GEJ cancer remains poor. Histologic type makes a difference, because SCC has a poorer prognosis than adenocarcinoma. Surgery is still the only chance for cure, and survival can be improved with multimodality therapy.

Epidemiologic Characteristics

Although SCC is the most common histologic type in many parts of the world, it is relatively uncommon outside of Asian and Middle Eastern countries. Squamous cell cancer is 20 times more common in China than in the United States.*89* Esophageal cancer has a poor survival rate; only 19.9% of patients in the United States3 and 10% of patients in Europe[90] survive at 5 years.

Etiologic Characteristics and Risk Factors

The most significant risk factors associated with almost 90% of esophageal SCCs (ESCCs) are tobacco use, alcohol use, and a diet low in fruits and vegetables.[10,91] Smoking and alcohol can synergistically increase the risk of ESCC. Dietary associations with ESCC, such as foods containing N-nitroso compounds, have long been implicated.[92] Betel nut chewing, widespread in certain regions of Asia,[93] and the ingestion of hot foods and beverages (such as tea)[94] in other endemic regions, such as Iran, Russia, and South Africa, have been associated with ESCC. Long-standing achalasia increases the risk of SCC by 16 times.[95] On average, SCC develops 41 years after ingestion of lye. Tylosis, a rare disease associated with hyperkeratosis of the palms of the hands and soles of the feet, is associated with a high rate of ESCC.[96]

Unlike SCC, the risk factors for esophageal adenocarcinoma remain elusive. The strongest and most consistent risk factors include gastroesophageal reflux disease, smoking, obesity,[97] and dietary exposure to nitrosamines; these are found in almost 80% of cases in the United States.[98] According to a Denmark study, more than 50% of esophageal adenocarcinoma cases were found to have no history of symptomatic reflux disease.[99] However, a large study conducted in Sweden demonstrated an association between reflux symptoms and esophageal adenocarcinoma (odds ratio, 7.7) and adenocarcinoma of gastric cardia (odds ratio, 2.0).[100] A high-fat, low-protein, high-calorie diet can also increase the risk. Some data have suggested that interactions between risk factors may be more important than individual risk factors. A study was performed on 305 patients with esophageal adenocarcinoma and 339 age- and sex-matched controls; the strongest individual risk factor identified was reflux.[101]

Barrett esophagus (BE) is generally believed to be a consequence of severe and chronic gastroesophageal reflux disease. The presence of BE is associated with an increased risk of esophageal adenocarcinoma. The median age of BE diagnosis is 40 to 55 years, and it is most common in men.[102]

Clinical Presentation

The presenting symptoms of esophageal cancer usually include dysphagia, weight loss, bleeding, throat pain, and hoarseness. Early symptoms are usually nonspecific, and the patient may present with subtle symptoms, for example, food "sticking" transiently and reflux/regurgitation of food or saliva. This may precede frank dysphagia, which by all accounts is the most common complaint and becomes apparent when the esophageal lumen is narrowed to one-third of its normal diameter. For proximal esophageal tumors, increasing cough may be a sign of tracheoesophageal fistula. Chronic GI blood loss resulting from esophageal cancer may result in iron deficiency anemia.

Pathologic Characteristics

Esophageal cancer includes adenocarcinoma, SCC, mucoepidermoid carcinoma, small cell cancer, sarcoma, adenoid cystic carcinoma, and primary lymphoma. Adenocarcinoma is now more prevalent than SCC in non-Asian countries and primarily develops in the distal esophagus.[103] In general, SCC is found in the upper half of the esophagus, whereas adenocarcinoma predominates closer to the GEJ. This chapter focuses on carcinomas of the esophagus/GEJ, whereas other chapters in this book are dedicated to other types of malignancy of the esophagus/GEJ.

Staging and Prognosis

Esophageal cancer is a treatable disease but is rarely curable. Since the mid-1990s, the histologic type and location of cancer of the upper GI tract have changed. The incidences of proximal gastric, GEJ, and distal esophageal adenocarcinomas have steadily increased up until the last several years, where it now appears to have reached a steady state. The most current version of the AJCC TNM staging (8th edition, Tables 27–6, A–G) now includes primary tumors of the GEJ or proximal gastric cancer extending 2 cm into the stomach as part of esophageal cancer staging.[39]

Table 27–6A American Joint Cancer Committee TNM Staging System for Gastroesophageal Junction and Esophageal Cancers

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia, defined as malignant cells confined to the epithelium by the basement membrane
T1	Tumor invades lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Tumor invades the pleura, pericardium, azygos vein, diaphragm, or peritoneum
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc.
Regional Lymph Nodes (N)	
Nx	Regional nodes cannot be assessed
N0	No regional nodal metastasis
N1	Metastasis in 1–2 regional lymph nodes
N2	Metastasis in 3–6 regional lymph nodes
N3	Metastasis in ≥7 regional lymph nodes
Distant Metastases (M)	
M0	No distant metastases
M1	Distant metastases
Grade (G)	
GX	Grade cannot be assessed—stage grouping as G1
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated—stage group as G3 squamous
Location	
Upper	15 to <20 cm
Middle	25 to <30 cm
Lower	30–45 cm

Clinical staging uses EGD with EUS, CT, and FDG-PET. In patients with proximal esophageal cancer, additional bronchoscopy is recommended to evaluate potential tracheal invasion or document and palliate tracheoesophageal fistula. Among patients with disease extending into the stomach, most experts agree that laparoscopic peritoneal staging is also necessary to evaluate occult peritoneal seeding that is not well visualized with noninvasive modalities (Figs. 27–4 to 27–9).

In various studies, FDG-PET has been consistently shown to have better specificity than CT at diagnosing metastatic disease and LN status. PET serves the primary purpose of detecting occult metastases that are present in 15% to 20% of patients newly diagnosed with esophageal cancer.[104,106] Multiple studies have been performed in patients with esophageal cancer after preoperative treatment, with PET being examined for predicting prognosis.[104,106] and treatment response.[107] Fluorodeoxyglucose-PET can better reveal bone metastasis than bone scans[108] and commonly reflects images of multiple foci of intense uptake. Studies have shown significant correlations between FDG uptake and tumor invasion depth and LN metastasis and survival rates, with a high degree of accuracy in the neck and upper thoracic and abdominal regions.[109] Unlike with gastric cancer, FDG-PET results have been found to be important predictors of response and prognosis. In a retrospective analysis, Swisher et al reported the results of FDG-PET use in 103 consecutive patients with locally advanced esophageal cancer who

underwent preoperative chemoradiotherapy.[110] At surgery, 58 patients (56%) had experienced a pathologic response to chemoradiotherapy (surgical pathologic results ≤10% viable residual cancer cells). Pathologic response was associated with FDG-PET standardized uptake value (SUV) (3.1 vs 5.8, $P = .01$). A post-chemoradiotherapy FDG-PET SUV of 4 or higher had the highest accuracy and was an independent predictor of survival (HR 3.5; $P = .04$) on multivariate analysis.[110]

Perhaps the strongest endorsement for using FDG-PET as a predictor of response came from the Metabolic Response Evaluation for Individualization of Neoadjuvant Chemotherapy in Esophageal and Esophagogastric Adenocarcinoma (MUNICON-1) trial. Lordick et al*36* evaluated the feasibility and applicability of FDG-PET in clinical practice in 110 evaluable patients with locally advanced esophageal adenocarcinoma. Patients with adenocarcinoma of the esophagogastric junction types I and II (tumors extending to the esophagus 5 cm above and 2 cm below the GEJ) underwent 2 weeks of induction chemotherapy with platinum and 5-FU (FLP). Fluorodeoxyglucose-PET scans were obtained for all patients at baseline and after induction chemotherapy. Metabolic response

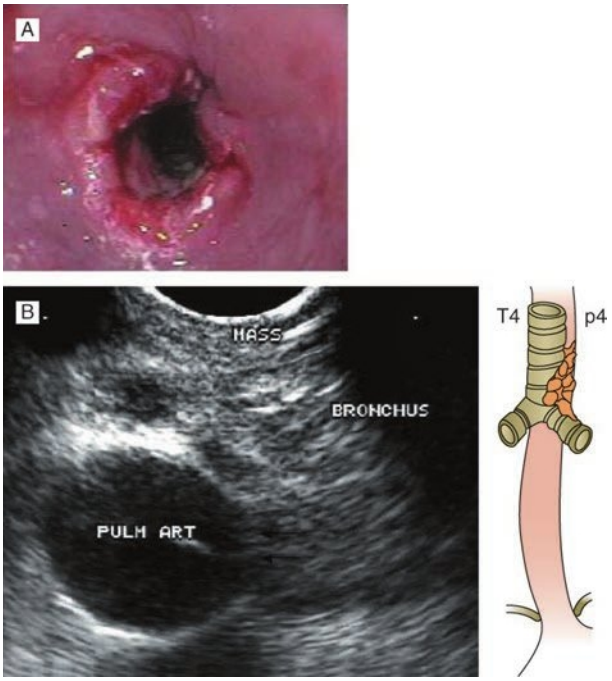

FIGURE 27–9 **A. Endoscopic image of T4 esophageal cancer. B. Endoscopic ultrasound image of the same tumor. (Reproduced with permission from http://www.massgeneral.org/gastro/endo_homepage.htm)**

was defined as an SUV decrease by 35% or more. Responders underwent more chemotherapy with FLP or folinic acid and fluorouracil plus cisplatin and paclitaxel, or folinic acid, 5-FU, and oxaliplatin (FOLFOX) for 12 weeks followed by surgery. Nonresponders discontinued further chemotherapy after the 2 weeks of initial induction chemotherapy and underwent surgery. In this study, there were 54 responders (metabolic response rate, 49%). One-hundred four patients (54 responders and 50 nonresponders) underwent surgery. At 2.3 years of follow-up, the median OS was not reached for responders and was 25.8 months (HR 2.13; $P = .015$) for nonresponders. The median event-free survival durations for responders and nonresponders were 29.7 months and 14.1 months, respectively (HR 2.18; $P = .002$). Major pathologic remissions (<10% residual tumor) were noted in 58% of responders and 0% of nonresponders.*36* In the MUNICON-1 study, the response to induction therapy was valuable for stratifying patients to appropriate therapy, further establishing the clinical utility of FDG-PET in limiting exposure to unnecessary toxicity and maximizing therapeutic benefits. The MUNICON-2 prospective trial was carried out to improve the clinical outcome of metabolic nonresponders using a salvage neoadjuvant radiochemotherapy. In this study, PET nonresponders received salvage neoadjuvant radiochemotherapy, whereas metabolic responders received neoadjuvant chemotherapy for 3 months before surgery. This prospective study showed the feasibility of a PET-guided treatment algorithm. However, by comparing the groups of nonresponding patients in the current trial and the previous published MUNICON I trial, increased histopathologic response was observed after salvage radiochemotherapy, but the primary end point of the study to increase the R0 resection rate was not met.[111]

Treatment

The gold standard for treating high-grade dysplasia and early or superficial esophageal cancer is esophagectomy. However, endoscopic mucosal resection (EMR)/endoscopic submucosal dissection, with or without photodynamic therapy, has become a popular alternative to surgery for early esophageal disease. Endoscopic mucosal resection has been reported in several small prospective case series to be effective, with an initial complete remission rate of 59% to 99%.[112,113] The ideal clinical characteristics for EMR are small (<2 cm diameter), solitary, flat lesions that are confined to the mucosa (T1a). Because EMR has a relatively high recurrence rate, it is recommended that BE and high-grade dysplasia or patients with early esophageal cancer be followed up endoscopically every 3 months during the first year and annually thereafter. Complications associated with EMR are bleeding (4%–46%), perforation (1%), and stricture (20%).[114]

Despite the recognized epidemiologic and clinical differences between ESCCs and adenocarcinomas, there is still inadequate evidence that treatment for esophageal cancer should be based on histologic type. Locally advanced cervical esophageal cancer is preferably managed with definitive chemoradiotherapy. For all other esophageal cancers, current evidence supports the use of preoperative chemoradiotherapy to enhance surgical survival outcome in patients with locally advanced resectable disease.[115] Surgery remains the best chance for long-term survival. Ongoing international clinical research with novel cytotoxic and targeted agents will continue to further define and improve survival outcomes of patients with locally advanced curable esophageal and GEJ cancers. Unfortunately, the main therapeutic goal is symptom palliation in patients with locally advanced, unresectable disease.

Resectable Disease

Surgery

Only 23% of patients with esophageal cancer present with clinically resectable localized disease.[116] Surgical resection is the mainstay of treatment for these patients[117] and should only be recommended as

upfront treatment in T1b/T2 tumors without nodal involvement by EUS. Recent data indicate that the overall 5-year survival rate of patients with esophageal cancer after curative surgery is about 25%.*42,43,*[118] Therefore, preoperative chemotherapy or preoperative chemoradiotherapy have become the mainstay strategies for treatment to improve surgical outcome, whereas definitive chemoradiotherapy has been recommended for patients with cervical tumors or unresectable disease.

Cancers of the middle or lower third of the esophagus (SCC or esophageal adenocarcinoma, except GEJ cancers) generally require total esophagectomy, which is a challenging procedure with a high complication rate. No uniform surgical approaches to curative resection exist, but the most common procedures in North America include transhiatal, transthoracic (Ivor-Lewis), and tri-incisional esophagectomy. For patients with potentially resectable disease, R0 resection is generally believed to be necessary to achieve durable survival.[119] R0 resection is defined as resection of the primary tumor with negative proximal, distal, and circumferential margins. Despite a lack of prospective randomized studies, there is a growing consensus that more extensive nodal dissection is needed; including the removal of all cancerous tissue from the mediastinum improves DFS and OS durations through better control of locoregional recurrence. Also, aggressive lymphadenectomy is generally recommended to increase the accuracy of pathologic staging. In the United States, en bloc resection of the mediastinal and upper abdominal LNs is considered standard for transthoracic esophagectomy, and three-field lymphadenectomy is not considered a standard treatment for patients with esophageal cancer.

Preoperative Chemotherapy

Preoperative chemotherapy theoretically increases the curative resection rates by downsizing and downstaging the primary tumor and LN metastases, reducing the local and distant relapse rates through suppression and elimination of micro-metastases, improving tumor-related symptoms with early initiation of antineoplastic therapy, and appraising in vivo the chemosensitivity of the primary tumor that will influence the choice of chemotherapy in the adjuvant setting. Preoperative therapy is hypothesized to result in tumor downstaging, which allows for higher R0 resection and pathCR rates.[120]

The two largest studies evaluating the role of preoperative chemotherapy were the US Intergroup trial (INT0113)[121] and UK Marsden Royal College (MRC)-OEO-2 randomized controlled trials.[122] Both studies determined the survival benefit of preoperative chemotherapy compared with surgery alone in patients with resectable ESCC and adenocarcinoma. Cisplatin plus 5-FU (CF) was administered in both studies. The two studies had completely divergent findings. INT0113 found no clinical/pathologic benefit or survival improvement with preoperative chemotherapy followed by surgery compared with surgery alone.[121] The median survival was 14.9 months for patients who received preoperative chemotherapy and 16.1 months for those who underwent immediate surgery (P = .53). The recent updated analysis of INT0113 confirmed the lack of benefit of preoperative chemotherapy.[123] The MRC-OEO-2 trial, however, reported a statistically significant improved R0 resection rate (78% vs 70%) and median OS time (17.2 vs 13.3 months) in patients who underwent preoperative chemotherapy.[122] Results of both INT0113 and OEO-2 studies did not help determine the role of preoperative chemotherapy in patients with resectable esophageal cancer. In the United Kingdom and other countries in Europe, preoperative chemotherapy has become the acceptable standard of care.

The three most recent randomized studies of preoperative and perioperative chemotherapy, FNCLCC,[60] UK MAGIC,[43] and UK FLOT trials[124–126] are the strongest validations of the benefits of preoperative and perioperative chemotherapy. These three studies are described in detail in the "Gastric Cancer" section of this chapter. In addition to the FLOT, MAGIC, and French trials, a third Japanese trial on patients with SCC (JCOG 9907) deserves mention because it rendered positive results. Patients were given two cycles of cisplatin and 5-FU (CF) preoperatively. Postoperatively, CF was administered to node-positive patients only. Of the above mentioned three trials, this one showed the highest 5-year survival rate in both arms.[127]

MRC-OEO-5 evaluated the use of preoperative chemotherapy, comparing two preoperative chemotherapy regimens, CF versus ECX (epirubicin, cisplatin, and capecitabine) in resectable esophageal adenocarcinoma.[128] In this study, 879 patients were randomized to receive two cycles of CF or four cycles of ECX before surgery. The median survival was 23.4 months in the CF group and 26.1 months in the ECX group (HR 0.90, P = .19). This trial showed that adding epirubicin to platinum-based therapy and more cycles of chemotherapy did not improve survival. The addition of targeted therapy to perioperative chemotherapy was also not helpful. The MRC ST03 trial*80* demonstrated that the addition of bevacizumab ECX chemotherapy did not prolong OS over chemotherapy alone. Table 27–7 lists the ongoing studies of locally advanced resectable gastric, GEJ, and distal esophageal adenocarcinomas.

Preoperative Radiation

Preoperative radiotherapy was studied in the early 1980s. However, in several phase 3 studies, a benefit similar to that of surgery alone was not shown. In a

Table 27–7 Key Esophageal Cancer Trials

Study	No. of Patients	Treatment Arm Control Arm	HR for OS (*P* value)	OS (%)
Pre- and Perioperative Chemotherapy				
Kelsen et al (INT-113)[121]	467	3 × CF → S S	0.75 (NR)	5-y OS: 36% vs 23%
Allum et al (MRC-OEO-2)[122]	802	2 × CF → S S	0.84 (.03)	5-y OS: 23% vs 17.1%
Ychou et al (ACCORD 7)[60]	169	2/3 × CF → S S	0.69 (.02)	5-y OS: 38% vs 24%
Alderson et al (MRC-OEO-5)[128]	897	2 × CF → S 4 × ECX → S	0.9 (0.19)	3-y OS: 39% vs 42%
Cunningham et al (MRC ST-03)[80]	1100	3 × ECX → S ECX, B → S	1.09 (.36)	3-y OS: 50.3% vs 48.1%
Ando et al (JCOG 9907)[127]	380	S → 2× CF 2 × CF → S	0.73 (.04)	5-y OS: 43% vs 55%
Preoperative Chemoradiotherapy				
Tepper et al (CALGB 9781)[129]	56	2 × CF; 50.4 Gy → S S	1.46-5.69 (NR)	5-y OS: 39% vs 16%
Shapiro et al (CROSS)[115]	366	5 × carboplatin/paclitaxel; 41.4 Gy → S S	0.657 (.003)	5-y OS: 47% vs 34%
Preoperative CT vs Preoperative CRT				
Stahl et al (POET)[130]	119	2.5 × CF, Leu → S 2 × CF, Leu → CE 30 Gy → S	0.67 (.07)	3-y OS: 27.7% vs 47.4%
Postoperative CT				
Ando et al (JCOG 9204)[131]	242	S S → 2 CF	(.13)	5-y OS: 52% vs 61%

B, bevacizumab; CE, cisplatin and etoposide; CF, cisplatin and 5-fluorouracil; CRT, chemoradiotherapy; CT, chemotherapy; ECX, epirubicin, cisplatin, and capecitabine; HR, hazard ratio; Leu, leucovorin; NR, not reported; OS, overall survival, S; surgery.

recent quantitative meta-analysis comprising five randomized trials and 1147 patients, it was again demonstrated that there is no improvement in survival with preoperative radiotherapy alone in potentially resectable esophageal cancer.[132,133]

Preoperative Chemoradiotherapy

In the United States, pre- or perioperative chemotherapy is not as common as preoperative chemoradiotherapy for locally advanced esophageal and GEJ cancers. Preoperative chemoradiotherapy has the goal to improve the pathCR rate, locoregional control, and survival.

The CALGB 9781 trial provided additional support for preoperative chemoradiotherapy, although it was stopped early because of a slow patient accrual rate. Fifty-six patients were randomly assigned to surgery alone (n = 26) or CF chemotherapy and concurrent radiotherapy (n = 30). At a median follow-up of 6 years, an intent-to-treat analysis showed a median OS duration of 4.5 versus 1.8 years (P = .002) in favor of trimodality therapy. The 5-year OS rates were 39% (95% CI 21%–57%) versus 16% (95% CI 5%–33%) in favor of trimodality therapy.[129] Gebski et al[134] reported improved survival with preoperative chemotherapy and chemoradiotherapy. The HR for all-cause mortality with preoperative chemoradiotherapy versus surgery alone was 0.81 (95% CI 0.70–0.93; P = .002), corresponding to a 13% absolute difference in survival at two years, with similar results for different histologic tumor types (SCC: HR 0.84, P = .04; adenocarcinomas: HR 0.75, P = .02). The HR for preoperative chemotherapy was 0.90 (95% CI 0.81–1.00; P = .05), which indicates a 2-year absolute survival benefit of 7%. There was no significant effect on all-cause mortality for preoperative chemotherapy in SCC (HR 0.88; P = .12), but there was a benefit in adenocarcinoma (HR 0.78; P = .014).[134] With chemoradiotherapy, evidence seems to suggest that treating physicians can expect a pathCR rate of 20% to 30%, a median OS

duration of 16 to 24 months, and a therapy-related mortality rate of 5% to 10%.

The Chemoradiotherapy for Oesophageal Cancer Followed by Surgery Study (CROSS) trial was a well-executed study that established level 1 evidence for preoperative chemoradiotherapy. Three-hundred sixty-eight patients with localized esophageal cancer (adenocarcinoma or squamous) were randomly assigned to receive either preoperative paclitaxel and carboplatin with concurrent radiation 41.4 Gy (n = 178) or surgery alone (n = 188). With a median follow-up time of 45.4 months, the median OS for preoperative chemoradiotherapy group was 49.4 months versus 24.0 months for the surgery-alone group (HR 0.657, 95% CI 0.495–0.871; P = .003). Five-year OS was again in favor of the chemoradiotherapy group (47%) versus the surgery-alone group (34%).[135] The complete resection rate was higher in the chemoradiotherapy group (92%) versus the surgery-alone group (69%), and 29% of patients in the chemoradiotherapy group had pathCR. In a subgroup analysis, the patients with SCC demonstrated the best outcomes (HR 0.453 for squamous cancer vs 0.732 for adenocarcinoma).[135,136]

The recently published RTOG 1010 study was designed to determine whether trastuzumab increases DFS when combined with trimodality treatment for patients with HER2-overexpressing esophageal adenocarcinoma.[137] This randomized phase 3 trial included patients with newly diagnosed stage T1N1–2, T2–3N0–2 adenocarcinoma of the esophagus involving the mid, distal, or esophagogastric junction and up to 5 cm of the stomach. All patients received chemotherapy of paclitaxel 50 mg/m2 and carboplatin (area under the curve = 2) weekly for 6 weeks, with radiation (50.4 Gy in 28 fractions) followed by surgery. Patients were randomly assigned 1:1 to receive weekly trastuzumab 4 mg/kg for week 1 and then 2 mg/kg weekly × 5 during CXRT then 6 mg/kg for one dose before surgery and 6 mg/kg every 3 weeks for 13 treatments after surgery. The median DFS time was no different at 19.6 months (13.5–26.2) for the CXRT+trastuzumab arm compared with 14.2 months (HR 0.97). The median OS time was 38.5 months for the CXRT+trastuzumab arm compared with 38.9 months for the CXRT arm (HR1.01). This study demonstrated that adding trastuzumab to standard chemotherapy was not better than standard chemotherapy alone in treating localized esophageal adenocarcinoma in patients with trimodality therapy.[137]

Preoperative Chemotherapy Versus Preoperative Chemoradiotherapy

Meta-analyses have been performed to further support the available evidence for preoperative therapy.[134,138,139] Cumulatively, these three meta-analyses determined that the most consistent significant survival benefit resulted from the combination of surgery and preoperative chemoradiotherapy and, to a lesser extent, preoperative chemotherapy.

Since these studies, results from the Preoperative Chemotherapy or Radiochemotherapy in Esophagogastric Adenocarcinoma (POET) trial, presented by Stahl et al,[130] have provided further support for three-step preoperative therapy, although the study was closed prematurely because of slow patient accrual. The POET trial was designed to evaluate the survival outcomes of patients treated with preoperative chemotherapy compared with preoperative chemoradiotherapy. One-hundred nineteen patients were randomly assigned to chemotherapy followed by chemoradiotherapy and surgery (n = 59) or chemotherapy followed by surgery (n = 60); the R0 resection rates were 72% and 70% (P = not significant), the pathCR rates were 16% and 2% (P < .001), and the N0 rates were 64% and 38% (P < .001), respectively. The 3-year OS rate trended toward improvement with induction chemotherapy, chemoradiotherapy, and surgery (47% vs 28% with chemotherapy and surgery; P = .07).[130] Patients in the chemoradiotherapy arm had a significantly higher probability of a pathCR (15.6% vs 2.0%). Postoperative mortality rates did not differ between the chemoradiotherapy and chemotherapy arms (10% vs 4%; P = .26). These results suggest that preoperative chemoradiotherapy confers a survival advantage over preoperative chemotherapy in distal esophageal and GEJ adenocarcinoma.

The use of induction chemotherapy before chemoradiotherapy and surgery has been evaluated in several phase 2 studies.73 Trimodality-eligible patients were randomized to receive no induction chemotherapy (Arm A) or induction chemotherapy (oxaliplatin/FU; Arm B) before oxaliplatin/FU/radiation. Surgery was attempted about 5 to 6 weeks after chemoradiation. The pathCR, postsurgery 30-day mortality, OS, and toxic effects rates were assessed. Results from this study showed that induction chemotherapy produces a nonsignificant increase in the pathCR rate and does not prolong OS.

In Europe and the United Kingdom, the treatment approach varies accordingly to tumor histology. For resectable SCC, patients are commonly treated with preoperative chemoradiotherapy,[140] whereas for resectable adenocarcinomas, either preoperative CRT or perioperative chemotherapy is administered. In the United States, preoperative chemoradiotherapy is the standard of care irrespective of histology.

Postoperative Therapy

Few studies have been performed to evaluate postoperative chemotherapy versus surgery alone. Reflecting the incidence of esophageal cancer during the 1980s and 1990s, these studies included more patients with squamous cell cancer than with adenocarcinoma; this

is a shortcoming of these early studies. In a study by Pouliquen et al, no survival improvement was found in the patients who were administered postoperative chemotherapy (CF).[141]

The second study, a randomized trial, JCOG 9204, compared the outcomes of patients who underwent surgery alone versus patients who underwent surgery followed by adjuvant CF. The 5-year DFS rates favored the postoperative chemotherapy group (55% vs 45%; $P = .037$). However, the difference in the 5-year OS rate was not statistically significant (61% vs 52%; $P = .13$). The duration of adjuvant therapy was suboptimal, and approximately 25% of patients assigned to the postoperative chemotherapy group failed to receive the full course of therapy.[131]

Another retrospective case-control study was designed to evaluate the effect of postoperative chemotherapy in 211 patients who underwent R0 esophagectomy with radical lymphadenectomy. Of 211 patients, 94 received postoperative chemotherapy, whereas the other 117 patients received surgery alone. The OS was compared between the two groups after they were stratified by the numbers of metastasis-positive LNs. In the subgroup of patients with more than eight positive LNs, postoperative chemotherapy significantly improved OS compared with surgery alone. Therefore, the authors suggested that postoperative chemotherapy was beneficial only in patients with more than eight metastatic LNs,[142] reducing the risk of relapse. However, postoperative chemotherapy did not improve OS compared with surgery alone.

Many studies have been performed to evaluate the role of postoperative radiotherapy versus surgery alone. In two studies conducted by Teniere et al,[143] postoperative radiotherapy did not improve survival. Results from two other randomized studies revealed conflicting findings. Xiao et al[144] demonstrated that postoperative radiotherapy improved the 5-year OS in patients with esophageal cancer with stage III disease. In contrast, Fok et al found shorter survival durations in patients who underwent postoperative radiotherapy as a direct result of irradiation-related death and the early appearance of metastatic disease.[145] Thus, the utility of postoperative radiotherapy may be limited. Of these studies, only the one by Zieren et al evaluated quality of life, which was found to be better in the surgery-alone group.

Malthaner et al[139] performed a meta-analysis of 34 randomized controlled trials and six meta-analyses in which patients with locally advanced esophageal cancer underwent pre- or postoperative chemotherapy, radiotherapy, or chemoradiotherapy. No significant difference in survival was observed in the postoperative radiotherapy group.

The available evidence suggests that postoperative chemotherapy or radiotherapy does not result in a benefit. However, few randomized comparisons have been performed with surgery alone versus surgery and postoperative treatment. Extrapolation of the INT-0116 study[42] (described in the gastric section) as supporting evidence for postoperative chemoradiotherapy in esophageal cancer should be performed with caution.

On the basis of the available evidence, patients with esophageal cancer gain limited survival benefit with postoperative chemotherapy and chemoradiotherapy after R0 resection. The limited contribution of postoperative therapy is probably caused by the moderate toxicity, which leads to treatment-related complications or an inability to complete therapy.

The limited ability to deliver therapy after surgery, as demonstrated by results from the INT-0116, MAGIC, and FLOT studies,[42,43] suggests that all effective therapy should be administered before surgery.

The utility of adjuvant checkpoint inhibitor after trimodality therapy in both adenocarcinoma and squamous cell carcinoma patients with esophageal or GEJ cancers is being evaluated in the CHECKMATE 577 study. Results are eagerly awaited.[146]

Definitive Chemoradiotherapy

The potential activity of chemotherapy against micro-metastases and its ability to act as a radiotherapy-sensitizing agent formed the basis for combining chemotherapy and radiotherapy to treat locally advanced cancer. In the RTOG 85-01 study, patients with locally advanced esophageal adenocarcinoma or SCC were randomly assigned to chemoradiotherapy with CF or radiotherapy alone. The 5-year OS rates were 0% and 26% for radiotherapy and chemoradiotherapy, respectively.[147]

A comprehensive review of the pattern of care for esophageal cancer in the United States from 1992 to 1994 surveyed 400 patients with locally advanced esophageal cancer treated at 63 institutions.[148] The study confirmed that using combined concurrent chemoradiotherapy as a nonoperative strategy to achieve superior survival and local tumor control was better than radiotherapy alone.[148] The report also suggested a trend toward survival improvement with chemoradiotherapy before surgery compared with chemoradiotherapy or surgery alone.

In the INT-0123 (RTOG 94-05) study, patients ($n = 236$) were administered concurrent CF (similar to RTOG 85-01) but were assigned randomly to different radiation doses, either 50.4 or 64.8 Gy. No association was found between higher radiation doses and higher median survival (13 vs 18 months for 50.4 vs 64.8 Gy, respectively) or 2-year survival (31% vs 40%, respectively). Higher radiation dose was also more toxic.[149] The reason for the failure of the higher radiation dose to improve survival is unclear.

The multi-institutional RTOG 0113 trial evaluated induction chemotherapy followed by definitive chemoradiotherapy in patients with localized unresectable esophageal cancer. The primary goal was to determine whether any approach would result in more than 78% 1-year OS, surpassing the historical 66% rate from RTOG 94-05. Seventy-two evaluable patients were randomly assigned to receive either induction with fluorouracil, cisplatin, and paclitaxel and then fluorouracil plus paclitaxel with 50.4 Gy of radiation (Arm A) or induction with paclitaxel plus cisplatin and then the same chemotherapy with 50.4 Gy of radiation (Arm B). Both arms of RTOG 0113 were associated with high morbidity, and the study did not meet its 1-year survival end point.[149]

Definitive Chemoradiotherapy Versus Chemoradiotherapy Plus Surgery

Stahl et al[130] performed a randomized comparison of chemotherapy followed by chemoradiotherapy and then surgery (surgical arm, $n = 86$) and chemotherapy followed by chemoradiotherapy and no surgery (nonoperative arm, $n = 86$) in 172 patients with locally advanced ESCC. The median follow-up duration was 6 years. The OS rates were similar for the surgical and nonsurgical arms ($P < .05$). The 2-year local PFS rate was higher in the surgical arm than the nonsurgical arm (64% vs 41%; HR 2.1; 95% CI 1.3–3.5; $P = .003$). The treatment-related mortality rate was significantly higher in the surgical arm (12.8% vs 3.5%; $P = .03$). The clinical tumor response to induction chemotherapy was the only independent prognostic factor for OS (HR 0.30; 95% CI 0.19–0.47; $P < .0001$). The results of this study suggested that adding surgery to chemoradiotherapy improves local tumor control but not survival in patients with locally advanced ESCC. Tumor response to induction chemotherapy is associated with a favorable prognostic group in these high-risk patients, regardless of treatment. Of course, the difficulty of incorporating these results into clinical practice is detecting residual disease or response after preoperative therapy.

Another randomized comparison in only responders to chemoradiotherapy (45 Gy conventional or 60 Gy split-course radiation) was conducted by Bedenne et al.[150] Patients with resectable ESCC were treated with two cycles of CF along with concurrent radiotherapy (conventional/split course). Patients who experienced a response ($n = 259$) were then randomly assigned to surgery or more chemoradiotherapy. The 2-year OS rates were 34% and 40% (HR 0.90; $P = .44$), the median OS durations were 18 and 19 months (P = not significant), the 2-year local control rates were 66% and 57% ($P < .01$), and the 3-month mortality rates were 9.3% and 0.8% ($P = .002$), respectively. The authors concluded that in patients who experience a response to chemoradiotherapy, surgery after chemoradiotherapy resulted in no added benefit over continued chemoradiotherapy.[150]

In a phase 3 study by the Chinese University Research Group for Esophageal Cancer (CURE), investigators from China are comparing the survival benefits of esophagectomy versus chemoradiotherapy. From 2000 to 2004, 80 patients were randomly assigned to esophagectomy ($n = 44$) or chemoradiotherapy ($n = 36$). A two- or three-stage esophagectomy with two-field lymphadenectomy was performed. Chemoradiotherapy consisted of CF and concurrent 50 to 60 Gy of radiation. Tumor response was assessed by EGD, EUS, and CT. Salvage esophagectomies were performed for incomplete response or recurrence. The median follow-up time was 1.4 years. No difference in the early cumulative survival rate was found between the two groups (RR 0.89; 95% CI 0.37–2.17; $P = .45$), nor was there a difference in DFS. Patients treated with surgery only had a slightly higher recurrence rate in the mediastinum, whereas those treated with chemoradiotherapy had a higher rate in the cervical or abdominal region.[151]

Surgery is the foundation of treatment for locally advanced resectable esophageal cancer. Early results from European studies suggested that patients with ESCC will not benefit from surgery after chemoradiotherapy.[152] The caveat of the nonsurgical approach to solid tumors is detecting minimal residual disease. Therefore, until more confirmatory evidence and clinical tools become available for detecting minimal residual disease or molecular or imaging predictive markers in patients who require surgery after preoperative therapy, the treatments for squamous cell cancer and adenocarcinoma will remain similar.

MD ANDERSON PRACTICE TIPS

RESECTABLE GASTRIC CANCER

- All patients with newly diagnosed invasive cancer undergo staging, which includes endoscopic assessment of the location and size of the primary tumor and EUS staging, CT, and/or PET/CT. Patients with cervical or proximal esophageal cancer also undergo bronchoscopy as part of a recommended staging workup.
- Staging laparoscopy is performed in some patients with cardia cancer, but the decision is made on a case-by-case basis.

- Patients with localized disease are discussed at the weekly Esophageal Multidisciplinary Tumor Board.
- Patients with locally advanced cervical esophageal cancer are treated with primary definitive chemoradiotherapy, even those with resectable disease. Salvage surgery is considered only in patients with persistent or locally recurrent disease.
- Currently at MDACC, treatment modalities for locally advanced resectable esophageal cancer include chemoradiotherapy and then surgery. For GEJ adenocarcinoma, postoperative chemoradiotherapy and perioperative chemotherapy are additional options available to patients. With the results of the CROSS trial, we now recognize that a minimum dose of 41.4 Gy may be sufficient in the preoperative setting, although our preference is to use a higher dose (50.4 Gy).

Figure 27–3A summarizes the MDACC approach to resectable gastroesophageal cancer.

ADVANCED AND METASTATIC GASTRIC, GASTROESOPHAGEAL JUNCTION, AND ESOPHAGEAL CANCERS

The prognosis of patients with advanced or metastatic gastric, GEJ, and esophageal cancers is poor; thus, clinicians should be cognizant of the patient's quality of life and weigh the risks and benefits of therapy. The overall 5-year survival rate of metastatic gastric and esophageal cancer patients is less than 5%. The standard of care for advanced disease is systemic chemotherapy. Different frontline combination chemotherapy regimens are available, but no head-to-head comparison has been performed for most of these; thus, the optimal choice is not obvious, and treatment remains regionally variable.

The medical treatment of metastatic gastric and esophageal cancer is primarily palliative and confers a modest effect on OS. Multiple agents are active in the treatment of gastric cancer, including fluoropyrimidines (5-FU, capecitabine, and S-1), anthracyclines, platinum agents, taxanes, irinotecan, and some targeted therapies such as trastuzumab for human epidermal growth factor receptor 2 (HER2)-overexpressing gastric cancers. Combination regimens are associated with higher response rates and, according to one meta-analysis, are also associated with increased survival when compared with single-agent chemotherapies.[153]

First-Line Therapy

Only a minor amount of level 1 evidence exists for the treatment of gastric cancer in the first-line setting. In fact, only docetaxel,[154] cisplatin/oxaliplatin,[155] and trastuzumab[156] are supported by high-level evidence.

A phase 3 trial involving 445 patients with metastatic cancer randomly assigned patients to receive CF or CF plus docetaxel. The investigators found that the addition of docetaxel was superior in terms of response rate (37% vs 25%; $P = .01$), time to tumor progression (5.6 vs 3.7 months; $P < .001$), and OS (9.2 vs 8.6 months; $P = .02$).[154] One could question the clinical significance of a less than 1 month absolute improvement in OS, particularly in the context of significant toxicities, most notably a high rate of febrile neutropenia (30%). Importantly, this regimen should not be used in patients who have a reduced performance status.

The third randomized phase 3 trial enrolled 305 patients in Japan to either S-1 alone or S-1 and cisplatin. Median OS was significantly longer in patients assigned to S-1 plus cisplatin (13.0 months) than in those assigned to S-1 alone (11.0 months; HR for death, 0.77; 95% CI 0.61–0.98; $P = .04$). Progression-free survival was significantly longer in patients assigned to S-1 plus cisplatin than in those assigned to S-1 alone (median PFS, 6.0 vs 4.0 months; $P < .0001$).[157] This trial provided evidence for the superiority of the addition of cisplatin when compared with a fluoropyrimidine alone and established the use of a fluoropyrimidine in addition to a platinum as a reasonable treatment option.

Trastuzumab was the first targeted agent with documented clinical activity in the advanced gastric and gastroesophageal cancer setting. This treatment is useful in the HER2-enriched population; however, only approximately 20% of gastric cancers and 30% of gastroesophageal cancers overexpress HER2, so that a relatively small proportion of patients benefit from the treatment. The ToGA trial randomly assigned 584 patients whose tumors overexpressed HER2 by immunohistochemistry (IHC) or fluorescence in situ hybridization to receive a fluoropyrimidine (5-FU or capecitabine) plus cisplatin with or without trastuzumab. The chemotherapy was administered every 3 weeks for six cycles, and trastuzumab was administered every 3 weeks until disease progression.[156] The investigators found that the addition of trastuzumab to chemotherapy increased OS from 11.1 to 13.8 months (HR 0.74, 95% CI 0.60–0.91; $P = .0046$). The secondary end points of PFS (6.7 vs 5.5 months; $P = .0002$) and

response rate (47.3% vs 34.5%; $P = .0017$) were also improved. On extended follow-up, the HR of OS for the addition of trastuzumab has decreased to 0.80,[158] indicating that although real, the response to trastuzumab may be short lived. The difference in median OS was reduced from 2.7 months to merely 1.4 months, representing an approximate 50% decrease in the effect of trastuzumab, which suggests that only a few patients benefit. Based on this trial, the combination of trastuzumab and chemotherapy has become the standard of care in patients whose tumors overexpress HER2.

In contrast to the positive results with trastuzumab in HER2-overexpressing gastroesophageal cancers, bevacizumab failed to demonstrate an OS benefit when it was added to a combination of cisplatin and fluoropyrimidine in patients with advanced gastric and GEJ adenocarcinoma.[159] A total of 774 patients were randomly assigned, and the median OS was 12.1 months with bevacizumab plus fluoropyrimidine-cisplatin and 10.1 months with placebo plus fluoropyrimidine-cisplatin (HR 0.87, 95% CI 0.73–1.03; $P = .1002$). Both median PFS (6.7 vs 5.3 months; HR 0.80, 95% CI 0.68–0.93; $P = .0037$) and overall response rate (46.0% vs 37.4%; $P = .0315$) were significantly improved with bevacizumab versus placebo.[159] In a preplanned subgroup analysis, the investigators were able to show that a benefit in terms of OS existed for "Pan-American" patients but not for European and Asian patients. This might point to differences in tumor biology but is also dependent on other factors. A subsequent retrospective biomarker analysis of the AVAGAST trial showed that patients with high baseline plasma VEGF-A levels and low baseline expression of neuropilin-1 seemed to have an improved OS. For both biomarkers, subgroup analyses demonstrated significance only in patients from non-Asian regions.[160] It is important to note that neither of these biomarkers has been validated. Unlike the ToGA trial, the AVAGAST trial did not use a biomarker-enriched patient population, underscoring the importance of appropriate patient selection in randomized controlled trials and the use of predictive biomarkers to direct care. Similarly, the AVATAR trial, which included an all Asian patient population, did not show any survival benefit of adding bevacizumab to the cisplatin-capecitabine combination.[161]

Equally disappointing results were also reported from two *EGFR*-targeting trials: the Erbitux (cetuximab) in Combination with Xeloda (capecitabine) and Cisplatin in Advanced Esophagogastric Cancer (EXPAND) and Revised European American Lymphoma (REAL-3) trials.[162,163] A biomarker analysis of the REAL-3 trial did not identify any biomarkers whose presence predicted resistance to modified epirubicin, oxaliplatin, and capecitabine (EOC) and panitumumab; however, only a few biomarkers were evaluated in this study.[164]

The role of lapatinib, a dual *EGFR* and HER2 tyrosine kinase inhibitor (TKI), was investigated in combination with capecitabine plus oxaliplatin (CapeOx) in 545 patients with HER2-positive advanced/metastatic gastroesophageal adenocarcinomas in the TRIO-013/LOGiC trial. The addition of lapatinib to CapeOx did not improve efficacy (OS and PFS) among untreated patients with HER2-positive metastatic gastric cancer.[165] Similarly, the concept of dual HER2 inhibition was studied in the JACOB trial. The JACOB trial was a double-blinded, placebo-controlled, randomized, multicenter, international phase 3 trial evaluating the efficacy and safety of adding pertuzumab to trastuzumab and chemotherapy in first-line treatment of HER2-positive metastatic gastric cancer/GEJ cancer. Unfortunately, adding pertuzumab to trastuzumab and chemotherapy did not significantly improve OS in patients with HER2-positive metastatic gastric or GEJ cancer compared with placebo.[166]

The KEYNOTE 062 study assessed whether in a PD-L1–positive (defined as CPS ≥1), HER2-negative advanced gastric or GEJ adenocarcinoma patient population pembrolizumab was noninferior to cisplatin-based chemotherapy and whether the addition of pembrolizumab to chemotherapy affected outcomes.[167] The investigators found that in patients with a CPS of 1 or higher, pembrolizumab was noninferior to chemotherapy, with a median survival of 10.6 versus 11.1 months (HR 0.91). For patients with a PD-L1 CPS of 10 or more, the survival with pembrolizumab was superior to chemotherapy (HR = 0.69); the median OS was 17.4 months for those receiving pembrolizumab compared with 10.8 months for those receiving chemotherapy. In the combination-therapy arm, the addition of pembrolizumab to chemotherapy added nothing in terms of OS or PFS when compared with chemotherapy alone regardless of patient CPS status. As of this writing, the CHECKMATE-649 (NCT02872116) study addressing the question of whether the addition of nivolumab to standard of care FOLFOX chemotherapy increases OS is ongoing and will soon be reported. The nivolumab/ipilumimab arm of this study was stopped early after an item analysis. Recently, the JAVELIN Gastric 100 study[168] addressed whether maintenance avelumab prolonged OS in patients with metastatic HER2-negative gastric or GEJ cancer in patients who received first-line oxaliplatin-based chemotherapy and did not progress. Reported study results found no difference in OS of patients with PD-L1 1 or higher with a median OS of 16.2 months in avelumab versus 17.2 months in the chemotherapy arm (HR 1.13; $P = .635$). This demonstrates that there is no role for maintenance avelumab in patients who do not progress on standard chemotherapy.

In summary, the standard of care in the first-line setting remains a combination of fluoropyrimidine and platinum-containing chemotherapy, with the addition of trastuzumab in the HER2-enriched population. The results of targeted therapy trials have mostly been disappointing, but none of these trials looked at an appropriately biomarker-enriched population. For immunotherapy, CPS appears to be a better biomarker than PD-L1 score; however, testing methodology and optimal cutoffs need to be better established in gastroesophageal cancers.

Second-Line Therapy

The validity of the use of second-line chemotherapy and its benefit in gastric cancer has long been questioned; however, all recently published trials demonstrated an OS prolongation, albeit very modest, when chemotherapy was compared with best supportive care (BSC).[169–172] A small German phase 3 study compared the efficacy of irinotecan plus BSC to BSC alone in patients with advanced gastric or GEJ adenocarcinoma.[170] Only 40 patients were randomly assigned to treatments, and the study closed early due to poor accrual. The HR for death was 0.48, with a 95% CI of 0.25 to 0.92, favoring the active treatment with irinotecan ($P = .023$). The median survival time was 4.0 months (95% CI 3.6–7.5) in the irinotecan arm and 2.4 months (95% CI 1.7–4.9) in the BSC arm.[170] There were no documented responses to irinotecan in this trial.

The second trial, COUGAR-02, randomized 186 patients to docetaxel plus BSC versus BSC alone. Docetaxel significantly improved OS compared with BSC alone, with a median OS of 5.2 months (95% CI 4.1–5.9) for docetaxel and 3.6 months (95% CI 3.3–4.4) for BSC (HR 0.67, 95% CI 0.49–0.92; $P = .01$).[171] Another study that demonstrated an OS benefit for patients treated with chemotherapy (either docetaxel or irinotecan) versus BSC was published by Kang et al.[173] Median OS was 5.3 months among 133 patients in the chemotherapy arm and 3.8 months among 69 patients in the BSC arm (HR 0.657, 95% CI 0.485–0.891; one-sided $P = .007$). There was no median OS difference between docetaxel and irinotecan (5.2 vs 6.5 months; $P = .116$).*79*

The role of angiogenesis inhibition as a target in gastric cancer was investigated in the Ramucirumab Monotherapy for Previously Treated Advanced Gastric or Gastro-Oesophageal Junction Adenocarcinoma (REGARD) trial, which randomly assigned 355 patients to receive ramucirumab or placebo.[169] This study demonstrated a marginal improvement in median OS (5.2 months in the ramucirumab group and 3.8 months in the placebo group; HR 0.776, 95% CI 0.603–0.998; $P = .047$). Interestingly, the average patient in the study treated with ramucirumab received treatments for 2 weeks longer than the average patient treated with placebo. In the published Ramucirumab in Metastatic Gastric Adenocarcinoma (RAINBOW) trial, ramucirumab was added to weekly paclitaxel as a second-line therapy in 665 patients with advanced or metastatic gastric cancer, demonstrating a significant improvement in both PFS and OS over paclitaxel alone.[172] A statistically significant prolongation of OS was demonstrated (HR 0.81, 95% CI 0.68–0.96; $P = .017$). Median OS times were 9.6 and 7.4 months in the ramucirumab-plus-paclitaxel arm and placebo-plus-paclitaxel arm, respectively. The PFS was also significantly longer for patients receiving ramucirumab plus paclitaxel (HR 0.64, 95% CI 0.54–0.75; $P < .001$) with an overall good safety profile, further supporting its role in combination with chemotherapy.

In the second-line setting, targeted HER2 therapy with TKIs has been a failure.[174,175] Lapatinib has been investigated in a large 420-patient study (TyTAN trial), which randomly assigned HER2-positive patients to lapatinib plus paclitaxel (L+P) versus paclitaxel alone. Median OS was 11.0 months for L+P and 8.9 months for paclitaxel alone in the intent-to-treat population (HR 0.84; $P = .2088$). In a preplanned subgroup analysis, median OS in the HER2 IHC 3+ subgroup was 14.0 months for the combination therapy and 7.6 months for paclitaxel alone (HR 0.59; $P = .0176$).[175] Interestingly, it has recently been demonstrated that although the study mandated IHC HER2 positivity, 35% of patients in the TyTAN trial had tumors classified as IHC 0/1.[175] Antibody-drug conjugates represent a promising class of drugs because of their efficient drug delivery to antigen-expressing tumor cells. Trastuzumab emtansine (T-DM1) is an antibody-drug conjugate comprised of trastuzumab linked to the tubulin inhibitor emtansine by a stable linker. In the GATSBY trial, second-line T-DM1 failed to prolong OS compared with taxane in previously treated HER2-positive gastric cancer.[176]

Equally disappointing, the UK Gefitinib for Oesophageal Cancer Progressing After Chemotherapy (COG) trial in patients with adenocarcinoma of the esophagogastric junction types I/II (tumors extending to the esophagus 5 cm above and 2 cm below the GEJ) in the second-line setting randomized 449 patients to receive gefitinib or placebo.[177]

Multiple studies highlight the importance of identification and targeting of driver mutations and their usefulness in the creation of appropriate biomarkers to direct care.[178,179] *MET* amplification and/or overexpression of its protein product has long been implicated in the pathogenesis of gastric cancer, supporting its role as a poor prognostic factor.*45* Hepatocyte growth factor/MET-targeted treatments were evaluated in patient-selected phase 3 trials (RILOMET-1 and MET

Gastric).[180,181] Both antibodies (rilotumumab and onartuzumab) failed to improve survival in gastric cancer that was IHC-positive for MET expression.

The role of poly (adenosine diphosphate–ribose) polymerase (PARP) inhibitors in gastric cancer was investigated in a phase 2 study in which 124 patients who progressed on fluoropyrimidines (second-line metastatic setting) were randomly assigned to receive olaparib plus paclitaxel versus paclitaxel alone.[182] There was no improvement in PFS, but the addition of olaparib significantly improved OS (HR 0.56, 95% CI 0.35–0.87; P = .010). The subsequently performed phase 3 trial yielded negative results, unfortunately.[183] Overall survival did not differ between treatment groups in the overall patient population (median OS 8.8 months in the olaparib group vs 6.9 months in the placebo group; HR 0.79; P = ·026) or in the ataxia telangiectasia-mutated protein-negative population (12.0 months vs 10.0 months; HR 0.73; P = .25).[183]

The role of immunotherapy has also been assessed in second-line therapy for gastroesophageal cancers. The KEYNOTE-061 trial also failed to show a survival benefit for pembrolizumab over paclitaxel in the second-line setting in patients with a PD-L1 CPS (a proportional assessment of PD-L1 staining on tumor and immune cells) expression >1.[184] Of note, in a post hoc analysis, patients with CPS scores of 5 or more and 10 or more did appear to see benefit. These disappointing results add weight to the hypothesis that only a minority of patients benefit from single-agent immunotherapy. The phase 3 KEYNOTE-181[185] study evaluating pembrolizumab versus physician's choice chemotherapy in patients with advanced esophageal/GEJ adenocarcinoma and SCC who had progressed after first-line therapy failed to meet its primary end point of OS in the intention-to-treat population of patients with a CPS of 1 or more, with median OS of 7.1 months in both arms (HR 0.89; P = .056). They found that in the subgroup of patients with a CPS of 10 or higher, the median survival was 9.3 versus 6.7 months (HR 0.69; P = .0074). In a press release, the FDA granted approval for nivolumab in unresectable advanced, recurrent, or metastatic ESCC after prior fluoropyrimidine- and platinum-based chemotherapy. The approval is based on the phase 3 ATTRACTION-3 trial in which patients treated with nivolumab (n = 210) demonstrated superior OS versus those treated with taxane chemotherapy (n = 209) (investigator's choice of docetaxel or paclitaxel) (HR 0.77, 95% CI 0.62–0.96; P = .0189). The median OS was 10.9 months (95% CI 9.2–13.3) for nivolumab compared with 8.4 months (95% CI 7.2–9.9) for docetaxel or paclitaxel.[186] Nivolumab is the first approved immunotherapy in this setting regardless of tumor PD-L1 expression level.[187]

Third-Line Therapy

Apatinib is a small-molecule multitargeted TKI with activity against VEGFR. After showing improved PFS and OS in heavily pretreated patients with metastatic gastric cancer in a phase 2 trial,[188] apatinib was evaluated in a phase 3 trial in 271 patients with advanced gastric cancer.[189] Patients had prior failure to second-line chemotherapy and were stratified according to the number of metastatic sites (≤ or >2 sites). This trial met its primary end point, showing significant improvement in OS and PFS. The median OS time was 6.5 months for apatinib and 4.7 months for placebo (HR 0.71, 95% CI 0.54–0.94; P = .015), and the median PFS was 2.6 months for apatinib and 1.8 months for placebo (HR 0.44; 95% CI 0.33–0.61; P < .0001). This trial further supports the angiogenesis inhibition as a target in this disease.

In addition to treatment with standard cytotoxic chemotherapy and targeted therapy, immune checkpoint inhibitors with antiprogrammed cell death protein 1 monoclonal antibodies (PD-1 inhibitors) have emerged as a therapeutic option in the metastatic setting. As of this writing, the PD-1 inhibitor, pembrolizumab, is approved for all patients with mismatch repair–deficient tumors after failure of first-line cytotoxic chemotherapy. In KEYNOTE-059 Cohort 1, a multicenter, open-label, single-arm phase 2 trial conducted at 67 sites in 17 countries, 259 patients (after failing two or more lines of chemotherapy including cisplatin and 5-FU; patients with HER2-positive tumors must have received treatment with trastuzumab) received a fixed dose of 200 mg pembrolizumab in a 3-weekly cycle. Pembrolizumab showed an objective response rate of 11.6% (95% CI 8.0%–16.1%), with complete response of 2.3% (95% CI 0.9%–5.0%). The response rate was higher in the patients with PD-L1–positive tumors (PD-L1–positive vs PD-L1–negative: 15.5% vs 6.4%). A total of seven (4%) tumors were microsatellite instable–high and the response rates were higher, with an overall response rate of 57.1%. Median PFS was 2.0 months and median OS was 5.6 months. Based on these results, the FDA has approved pembrolizumab as the third-line treatment for PD-L1–positive gastric adenocarcinoma.[190]

Nivolumab, an immune checkpoint inhibitor, was evaluated in the phase 3 ATTRACTION-2 study[191] in patients with gastric or GEJ cancer treated with two or more prior chemotherapy regimens. Patients were randomly assigned (2:1) to receive 3 mg/kg nivolumab or placebo intravenously every 2 weeks. Nivolumab was associated with a significant OS benefit *versus* placebo (OS 5.32 *vs* 4.14 months; P < .0001; 12-month OS 26.6% *vs* 10.9%). Nivolumab reduced mortality risk by 37% compared with placebo. The survival advantage was persistent over time with nivolumab and

irrespective of PD-1/PD-L1 expression. Nivolumab is currently not approved in the United States for metastatic GEJ or gastric cancer.[191]

TAS-102 (trifluridine/tipiracil) is an oral combination drug of two active compounds: trifluridine, a thymidine analog (nucleoside antitumor agent), and tipiracil hydrochloride, a thymidine phosphorylase inhibitor, in a ratio of 1:0.5. In the international phase 3 randomized control trial, the TAGS study, 507 patients with advanced/metastatic gastric adenocarcinomas (including adenocarcinoma of the GEJ) were randomly assigned to TAS-102 or placebo in a 2:1 ratio. In patients with prior gastrectomy, OS (6.0 months vs 3.4 months, HR 0.57, 95% CI 0.41–0.79) and PFS (2.2 months vs 1.8 months, HR 0.65, 95% CI 0.49–0.85) were more favorable among the TAS-102 group versus those receiving placebo. Moreover, the patients who did not have gastrectomy also showed OS (HR 0.80, 95% CI 0.60–1.06) and PFS (HR 0.65, 95% CI 0.49–0.85) benefit to treatment with TAS-102.[192] More patients in the TAS-102 arm achieved disease control compared with the placebo group (44% vs 14%; $P < .0001$).[192]

Table 27–8 lists major phase 3 trials for advanced/metastatic esophageal, GEJ, and gastric cancer involving chemotherapy agents, and Table 27–9 lists trials involving targeted agents in the first-, second-, and third-line settings.

Supportive Measures for Advanced Gastric, Gastroesophageal Junction, and Esophageal Cancers

The goal of symptom palliation is to optimize quality of life. Current or potential signs or symptoms that affect quality of life should be assessed during the initial evaluation of patients with unresectable disease. Available treatment options include palliative radiotherapy without concurrent chemotherapy*197*; chemotherapy; endoscopic palliation with luminal dilation, stents, or laser or chemical ablation; and palliative surgery. Palliative surgery is rarely performed because it is rare that the potential benefits clearly outweigh the risks of surgery. Several special issues to consider in this group of patients include (1) problems specifically associated with primary disease, (2) nutrition, (3) diagnosis and treatment of tracheoesophageal fistulas, and (4) management of oral secretions.

All patients, especially those who present with more than 15% weight loss from their normal baseline, should undergo formal nutritional evaluation, and alternative nutritional support methods should

Table 27–8 Major Phase 3 Gastric Cancer Trials Involving Chemotherapy Agents in the Advanced/Metastatic Setting

Trials	No. of Patients	Treatment Arms	HR for OS (*P* value)	Primary End Point Comparison in Months
Advanced Gastric Cancer: First Line				
Van Cutsem et al (V325 study group)[154]	445	DCF vs CF	TTP: 1.47 (< .001) OS: 1.29 (.02)	TTP: 5.6 vs 3.7 OS: 9.2 vs 8.6
Cunningham et al[155]	1002	ECF vs ECX vs EOF vs EOX	0.80 (.02)	OS: 9.9 vs 9.9 vs 9.3 vs 11.2
Koizumi et al (SPIRITS)[157]	305	S-1 + cisplatin vs S-1	0.77 (.04)	OS: 13.0 vs 11.0

Shitara et al (TAGS)[192]	507	TAS-102 vs placebo	0.69 (.00029)	OS: 5.7 vs 3.6

[a]HR reduced to 0.8 on follow-up analysis.
BSC, best supportive care; CapeOx, capecitabine and oxaliplatin; CF, cisplatin and 5-fluorouracil; CX, cisplatin and capecitabine; EOC, epirubicin, oxaliplatin, and capecitabine; HR, hazard ratio; mEOC, modified epirubicin, oxaliplatin, and capecitabine; OR, objective response (CR+PR); OS, overall survival; PFS, progression-free survival; TAS-102, trifluridine/tipiracil.

be considered. Adequate nutrition and hydration are crucial to ensure that patients complete the full course of therapy. Jejunostomy feeding tubes (J-tubes), which are inserted primarily via a surgical procedure, can be considered in patients with gastric and GEJ cancer; they can be placed during the initial laparoscopic evaluation. Percutaneous gastrostomy feeding tubes, placed by endoscopic (percutaneous endoscopic gastrostomy) or radiologic (G-tube) guidance, can be considered for esophageal cancer. The continued use of jejunostomy, gastrostomy, or nasogastric feeding tubes is considered the first choice if nutrition cannot be supported orally.

Patients with advanced gastric, GEJ, and esophageal cancers might be candidates for definitive chemoradiotherapy. Chemotherapy agents used in combination with radiotherapy include cisplatin, paclitaxel, carboplatin, oxaliplatin, or 5-FU. Patients with borderline performance status may not be candidates for definitive chemoradiotherapy, even with consistent nutritional support via feeding tubes. Therapy should be based on the patient's most pressing symptoms. Malnutrition should be addressed, whenever feasible, with gastrostomy or a jejunostomy tube. Upper GI bleeding and pain can be palliated with radiotherapy, alone or with endoscopic cauterization. Finally, effective chemotherapy can directly improve symptoms such as dysphagia and pain, as well as indirectly improve nutrition and minimize bleeding risk and aspiration.

Although genetic profiling of tumors (next-generation sequencing) has become a more widely used tool in the treatment of gastric, GEJ, and esophageal cancers, patients are often found to have multiple and nontargetable mutations. Even when a potentially targetable mutation is found and the patient is treated with a given drug, we have found that responses are rare, likely because of our poor knowledge of driver mutations. However, with the advent of more targeted treatments in combination with cytotoxic agents or immunotherapy, we emphasize the enrollment of patients into available clinical trials.

Figure 27–3A and B summarize the MDACC approach to advanced gastric, GEJ, and esophageal cancer.

MD ANDERSON PRACTICE TIPS

ADVANCED GASTRIC, GASTROESOPHAGEAL JUNCTION, AND ESOPHAGEAL CANCERS

- Our approach in the metastatic setting is to provide palliation of symptoms and prolongation of life.
- In HER2-positive gastric cancer, there is an OS benefit with the addition of anti-HER2 therapy to first-line chemotherapy.
- A reasonable option in the first-line setting is a platinum-based doublet with the addition of docetaxel depending on the performance status of the patient.
- In the second line, we use ramucirumab combined with paclitaxel; however, in patients with severe neuropathy, irinotecan-based chemotherapy is also an alternative.
- Since the approval of pembrolizumab in PD-L1–positive gastric cancer, our approach is to use immunotherapy in patients with PD-L1–positive tumors (CPS >1) that have progressed on two lines of chemotherapy.
- Additional options for treatment include TAS102.

28 Pancreatic Cancer

Jonathan D. Mizrahi
Anirban Maitra
Robert A. Wolff

KEY CONCEPTS

- Pancreatic cancer has a five-year survival of 10%, and it is expected to become the second leading cause of cancer death in the United States by 2030.
- Modifiable risk factors for pancreatic cancer include tobacco use, obesity, diabetes mellitus (particularly new-onset diabetes), and chronic pancreatitis. Age and family history are well-established, nonmodifiable risk factors.
- *KRAS* mutations and *p16* inactivation are near universal genomic events identified in pancreatic cancers, and histologically, pancreatic adenocarcinomas are characterized by a dense, collagenous stroma.
- High-quality multidetector computed tomography imaging is the gold-standard diagnostic and staging modality, because it can classify pancreatic cancers as resectable, borderline resectable, locally advanced, or metastatic.
- The only potentially curative treatment for pancreatic cancer is surgical resection, which is an option for only 15% to 20% of patients, because most patients are diagnosed at an advanced stage.
- Recent advances in combination chemotherapy, particularly FOLFIRINOX and gemcitabine plus nab-paclitaxel, have increased survival for patients with advanced pancreatic cancer; FOLFIRINOX also improves survival in the adjuvant setting.
- Precision medicine is slowly emerging in pancreatic cancer

When clinicians use the term *pancreatic cancer*, they refer to adenocarcinoma of the pancreas, one of the most challenging malignancies facing oncologists, patients, and caregivers today. This disease is characterized by significant morbidity and a poor prognosis. At the MDACC, we manage pancreatic cancer using a multidisciplinary approach. For patients with localized disease, we generally employ a stepwise multimodality approach. For most patients with locally advanced disease and all patients with metastatic disease, palliation is a high priority. This chapter summarizes our current knowledge about pancreatic cancer, including its epidemiology, risk factors, molecular biology, diagnosis and staging, and clinical strategies for therapy.

HARD FACTS ABOUT PANCREATIC CANCER

Pancreatic adenocarcinoma, the most common pancreatic neoplasm, is an aggressive and often rapidly fatal malignancy. In the United States, it represents 3% of all cancer cases but accounts for 7.5% of all cancer deaths.[1] As of this writing, it is the third leading cause of cancer-related deaths, ranking behind lung and colorectal cancers. The 5-year survival rate has marginally improved over the past few decades (2% in 1974–1976, 6% in 2014) and has recently reached 10% for the first time.[2,3] Over the next decade, deaths caused by pancreatic cancer are projected to increase dramatically, overtaking colorectal cancer as the second leading cause of cancer-related death.

EPIDEMIOLOGY

There are approximately 56,000 new cases of pancreatic cancer each year in the United States and 459,000 cases worldwide.[4] Incidence rates are highest in industrialized societies and Western countries. Of note, the risk of pancreatic cancer among Blacks, in whom pancreatic cancer mortality rates are higher

than most other ethnic groups in the United States, is considerably higher than the rates for African Blacks.[5] The risk of developing pancreatic cancer is low in the first three to four decades of life but increases sharply after the age of 50 years. The average age at the time of diagnosis is 72 years; it is uncommon in persons younger than 40 years. However, there has been an increasing interest in early-onset pancreatic cancer (usually defined as age of onset before 50 years). Our group has recently reported that patients with early-onset pancreatic cancer are more apt to have germline mutations in DNA damage repair pathway genes compared with patients considered to have later onset.[6]

RISK FACTORS FOR PANCREATIC CANCER

Both genetic and environmental factors have been implicated in the risk of pancreatic cancer development. Table 28–1 summarizes these risk factors.

Tobacco

Cigarette smoking is one of the better-established lifestyle risk factors for pancreatic cancer, albeit the odds ratio is lower than that of lung cancer. Overall, cigarette smoking is estimated to account for roughly 25% to 30% of pancreatic cancer cases.[7]

Diabetes Mellitus

Diabetes has been implicated both as an early manifestation of pancreatic cancer and as a predisposing factor. As many as half of pancreatic cancer patients report a history of new-onset diabetes (NOD) or worsening hyperglycemia, and an additional one quarter report impaired glucose tolerance.[8] In these cases, the occult pancreatic cancer is responsible for inducing hyperglycemia, likely through altering peripheral insulin resistance. Changes in glycemic control can occur as early as 36 months before clinical diagnosis, providing an opportunity for earlier detection. However, because only around 1% of NOD is caused by an underlying pancreatic cancer, further enrichment of this high-risk population is needed to conduct meaningful surveillance. Our team is currently leading a multicenter prospective NOD cohort that will accrue 10,000 patients with NOD or hyperglycemia and follow them for the development of incidental pancreatic cancer. Longitudinal collection of biospecimens for biomarker studies aims to better define and enrich this population for pancreatic cancer risk.[9]

Body Mass Index

Epidemiologic studies have also implicated a high body mass index as increasing the risk for pancreatic cancer.[10] Numerous molecular mechanisms—both local (inflammatory mediators produced by abdominal adipocytes within the peri-pancreatic milieu) and systemic (secreted adipokines and hyperinsulinemia)—are

Table 28–1 Acquired and Genetic Risks Factors Associated with Pancreatic Cancer

Acquired Risk Factors	Relative Risk	Comments
Tobacco smoking	2–5	Risk increases with increasing exposure
Diabetes mellitus	2	Not all authorities concur; many patients have altered glucose metabolism on presentation
High body mass index	2	
Chronic pancreatitis	13–18	Not all authorities concur with this degree of increased risk
Inherited Disorders	**Relative Risk**	**Known Defects**
Hereditary pancreatitis	10–53	PRSS1
FAMMM syndrome	22	p16INK/CDKN2
HNPCC	8	MLH1, MSH2, MSH6
Peutz-Jeghers syndrome	13–30	LBK1/STK11
Familial adenomatous polyposis	4–5	APC
Li-Fraumeni syndrome	?	p53
Familial breast and ovarian cancer	3–5	DNA repair pathways, BRCA2

FAMMM, familial atypical mole and melanoma; HNPCC, hereditary nonpolyposis colon cancer.

postulated to contribute toward the increased risk of pancreatic cancer in obesity.[11,12] For example, studies in preclinical models from MDACC have shown the influence of obesity-associated lipocalin-2 levels in accelerating pancreatic carcinogenesis.[13]

Diet

Positive associations have been discovered between pancreatic cancer and meat and carbohydrate intake.[14] However, there is no consensus on the contribution of dietary fat. Epidemiologic studies of pancreatic cancer have shown a protective role for high fruit and vegetable intake.

Chronic Pancreatitis

Early clinical studies have suggested an association between chronic pancreatitis and pancreatic cancer. Studies have suggested that hereditary pancreatitis, in particular, may affect the risk. Mutations of several genes can be associated with hereditary pancreatitis, of which *PRSS1*, encoding for cationic trypsinogen, is the most common.[15]

Familial Pancreatic Cancer and Other Genetic Syndromes

Approximately 10% of patients with pancreatic cancer harbor a germline mutation that predisposes them to pancreatic cancer.[16,17] Notably, only about half of these patients report a family history of pancreatic cancer, and therefore, the National Comprehensive Cancer Network (NCCN) and the American Society for Clinical Oncology (ASCO) both recommend universal germline testing for all patients.[18,19] Known cancer predisposition syndromes that are associated with increased risk of pancreatic cancer include hereditary nonpolyposis colorectal cancer, ataxia-telangiectasia, Peutz-Jeghers syndrome, familial breast and ovarian cancer, and familial atypical multiple-mole melanoma. The most common class of genes associated with familial predisposition to pancreatic cancer are those whose protein products are involved in the cellular DNA repair response, including *BRCA2*, *BRCA1*, *ATM*, and *PALB2*. Of these, BRCA1/2 and PALB2 proteins are key components of homologous recombination through the repair of DNA double-strand breaks. The poly(ADP-ribose) polymerase (PARP) enzyme is integral for single-stranded DNA repair, and inhibition results in DNA breaks that require intact BRCA proteins for repair. Therefore, in the presence of mutant BRCA1/2 or PALB2 proteins, PARP inhibition results in synthetic lethality. As we discuss later, the PARP inhibitor, olaparib, became the first biomarker-based therapy approved for pancreatic cancer based on its clinical benefit in the maintenance setting in germline *BRCA*–mutated patients with disease control on initial platinum-based chemotherapy.[20,21]

MOLECULAR EVENTS IN HUMAN PANCREATIC CARCINOGENESIS

With the advent of next-generation sequencing platforms, several publicly funded initiatives such as the International Cancer Genome Consortium and The Cancer Genome Atlas have comprehensively mapped the genomic landscape of pancreatic cancer across hundreds of tumors.[22–24] These large-scale efforts have not only identified the major recurrent alterations in pancreatic cancer, but also less frequently altered mutations, many of which are "actionable."[25] As much as one quarter of patient tumors may harbor potentially actionable mutations and this information can be returned to the oncologist in a feasible timeframe.[26,27]

Oncogenes in Pancreatic Cancer

Oncogenic mutations of *KRAS* are the defining genetic feature of pancreatic cancer, occurring in about 90% of cases.[24] *KRAS* mutations most commonly involve codon 12 and are usually either a glutamine-to-valine ($KRAS^{G12V}$) or glutamine-to-aspartic-acid ($KRAS^{G12D}$) alteration. The uncommon $KRAS^{G12C}$ mutations are observed in only about 1.5% of pancreatic cancer.[28]

Of note, around 10% of cases are wild-type KRAS. In these cases, it is not uncommon to find alternative drivers, including *NRG1*, *ALK*, or *NTRK* fusions that drive cancer progression,[29] and for which targeted agents are readily available.[30–32] Therefore, the absence of a demonstrable *KRAS* mutation in confirmed pancreatic adenocarcinoma should prompt interrogation for these alternative drivers.[33,34]

Tumor Suppressor Genes in Pancreatic Cancer

The most common recurrently altered tumor suppressor genes in pancreatic cancer are *TP53*, *CDKN2A/p16*, and *DPC4/SMAD4*.[24] *TP53* is the most commonly mutated gene in human cancer, and somatic alterations are present in about 75% of pancreatic cancers. Nearly all pancreatic cancers harbor anomalies of the cyclin-dependent kinase inhibitor gene *CDKN2A/p16*. DPC4/SMAD4 alterations are observed in approximately 55% of pancreatic cancers. In solid tumors, *DPC4/SMAD4* aberrations are somewhat specific for advanced pancreatic cancer.[35]

Potentially Actionable Gene Mutations in Pancreatic Cancer

As of this writing, the most clinically relevant are genes encoding for proteins involved in DNA damage response and repair, including *BRCA2*, *BRCA1*, *PALB2*, *CHEK2*, *ATM*, *RAD51*, among others.[22,24] Although germline mutations of these genes occur in the context of familial pancreatic cancer, approximately 15% of cases harbor somatic loss of function mutations and such cases could be targets for DNA repair targeted therapies, such as PARP inhibitors. Approximately 1% of pancreatic cancer cases harbor mutations in genes involved in a particular class of DNA repair known as mismatch repair, including *MLH1*, *MSH2*, *PMS2*, and *MSH6*, and the corresponding tumors have an exceptionally high tumor mutation burden (so-called "hypermutators").[36] Hypermutator tumors are susceptible to immune checkpoint inhibitor immunotherapy and can be offered this in the first or second line based on recent FDA directives.[37] Finally, one needs to mention the class of genes that encode for protein involved in chromatin regulation (such as *ARID1A*, *PBRM1*, *KDM6A*, *MLL3*, among others) that are cumulatively mutated in 15% to 25% of cases.[38,39] In other solid tumors, there are emerging data to suggest the potential for using immunotherapy combinations against these tumors.[40,41]

Transcriptomic Subtypes of Pancreatic Cancer

Currently, the most widely accepted classification scheme assigns pancreatic cancers into so-called "classical" and "basal-like" subtypes.[24,42] The "classical" phenotype is characterized by the expression of the endodermal transcription factors GATA6 and HNF4A, both of which are absent in the "basal-like" tumors.[43,44] In contrast, basal-like, sometimes called "squamous subtype," is characterized by an aggressive natural history, and emerging data suggest that the basal-like tumors are resistant to FOLFIRINOX.[45]

Pancreatic Cancer Stroma

No discussion of the molecular pathology of pancreatic cancer is complete without alluding to the stroma and immune cell types that comprise the complex tumor microenvironment (TME) in this disease. A credible review of the pancreatic cancer TME is beyond the scope of this chapter, and the reader is pointed to several recent reviews on this topic.[46–48] A few highlights are emphasized. First, the pancreatic cancer stroma is comprised of a multitude of cell types and extracellular matrix proteins.[46] Second, the most common nonimmune cell type is the cancer-associated fibroblast (CAF), and recent single-cell RNA sequencing studies have identified at least three distinct types of CAFs,[49,50] with potentially distinct tumor-promoting versus tumor-suppressive roles. This is important because generic strategies to target the pancreatic cancer CAFs (eg, using small-molecule inhibitors targeting the Hedgehog pathway) have been counterproductive,[51] underscoring the distinct roles played by various CAF populations in constraining or promoting the neoplastic process. Third, the pancreatic cancer TME is characterized by high interstitial pressure, which has been ascribed to the deposition of extracellular matrix proteins like hyaluronic acid and other glycosaminoglycans,[52] and is implicated in reducing the delivery of systemic chemotherapy to the tumor milieu. Although preclinical studies supported the efficacy of reducing interstitial pressure by targeting hyaluronic acid with a pegylated hyaluronidase and facilitating the influx of therapeutic agents,[53,54] the phase 3 clinical trial of this agent (PEG-PH20), in combination with cytotoxic chemotherapy, failed to improve survival in metastatic disease, again reinforcing the complexities of stromal biology in pancreatic cancer.

PATHOLOGY

Pancreatic acinar cells account for approximately 80% of the cell number and volume of the gland; islet cells account for 1% to 2%. The ductal system is composed of single-layer, cuboidal epithelial cells representing 10% to 15% of the gland's structure, with a sparse interlacing network of blood vessels, lymphatics, nerves, and collagenous stroma. In carcinoma, this architecture is markedly altered. The predominant histologic feature is a desmoplastic (fibrous) stroma with atrophic acini, usually preserved islet cell clusters, and a haphazard growth of cancerous ducts (Fig. 28–1). The diagnosis of ductal adenocarcinoma rests on the identification of mitoses; nuclear and cellular pleomorphism; and evidence of perineural, vascular, or lymphatic invasion.[55] Intraductal precursor lesions in the surrounding pancreatic parenchyma are common with two major subtypes. The first and most common (~90% of cancers arise from these precursors) are the microscopic pancreatic intraepithelial neoplasia or PanIN lesions. Histologically, PanIN lesions are graded as "low" and "high" grades. High-grade PanINs often harbor many of the genetic alterations found in frank carcinomas.[56] The macroscopic precursors of ductal adenocarcinomas are mucinous cysts of the pancreas, presenting either as intraductal papillary mucinous neoplasms or mucinous cystic neoplasms.[57] Analogous to PanINs, the cystic lesions also demonstrate low- and high-grade epithelial dysplasia, culminating in invasive neoplasia.

FIGURE 28–1 **Photomicrograph of ductal adenocarcinoma of the pancreas with well-preserved islet cells and pancreatic architecture above and infiltrating tumor with poorly formed glandular structures below.**

Almost all malignant neoplasms of pancreatic origin (95%) arise from the exocrine portion of the gland, with ductal adenocarcinomas being the most common.[58] Pancreatic neuroendocrine tumors arising from the islets of Langerhans are much more infrequent, and primary nonepithelial tumors (eg, lymphomas or sarcomas) are extremely rare. The histologic classification of exocrine pancreatic neoplasms is presented in Table 28–2.

CLINICAL PRESENTATION

The clinical presentation of pancreatic cancer is primarily dependent on the location of the tumor within the pancreas. The majority (85%) develop within the pancreatic head. About 10% are located in the pancreatic body, and 5% are located in the tail. Nonspecific, poorly localized, epigastric or back pain is the most common initial presentation. It is usually caused by invasion or compression of the celiac, splanchnic, or mesenteric plexi. Tumors in the head or neck typically cause pain in the epigastric area or in the right upper quadrant of the abdomen. Cancers of the body may cause unremitting, severe back pain, and tumors in the pancreatic tail may be associated with left upper quadrant pain.

Painless jaundice, another common presentation, is generally associated with tumors in the pancreatic head or uncinate process. When the tumor does not arise in proximity to the intrapancreatic portion of the bile duct, diagnosis may be delayed and characterized by abdominal pain or back pain without jaundice.

Acute pancreatitis, although uncommon, can be caused by a ductal adenocarcinoma in patients with no other reason for acute pancreatitis (lack of gallstones, no history of alcohol or precipitating drugs).[59] Symptoms of chronic pancreatitis are relatively common, including diarrhea, bloating or constipation, abdominal distention, and weight loss. Patients with tail lesions often remain asymptomatic until the development of signs or symptoms of metastatic disease.

DIAGNOSIS AND STAGING

Pancreatic cancer can be difficult to diagnose, particularly in patients with nonspecific complaints. Circuitous workups and interventions are not uncommon and may include upper endoscopy, which may be misleading and demonstrate mild esophagitis, gastritis, or duodenitis, with or without evidence of *Helicobacter pylori*. Patients complaining of right upper quadrant pain may undergo ultrasonography, potentially revealing gallstones, prompting cholecystectomy. For patients presenting with complaints of back pain, a musculoskeletal evaluation is commonly done. Most patients ultimately undergo cross-sectional body imaging with the discovery of a pancreatic mass.

For patients who present with obstructive jaundice, suspicion of pancreatic cancer is sufficiently high that the diagnostic workup usually proceeds in an orderly fashion with directed imaging studies. These usually include abdominal ultrasonography, computed tomography (CT) scan of the abdomen, or both.

Tissue Acquisition

With rare exception, all patients seen at MDACC are advised to undergo biopsy to confirm the presence of malignancy and type if it is not performed before referral. Cross-sectional imaging, (our preference is dual-phase multidetector CT), should always be performed before interventional endoscopic or other invasive procedures to prevent procedure-related inflammatory changes, which may confound assessment of the tumor's potential for resection. In patients who present with obstructive jaundice and radiographic evidence of a localized pancreatic mass, endoscopic retrograde cholangiopancreatography and endoscopic ultrasound (EUS) with biopsy are often performed concurrently. EUS-guided biopsies are preferred over percutaneous biopsies in patients who may be candidates for surgical resection to decrease the risk of peritoneal or needle-track seeding, which has been reported among patients undergoing transcutaneous ultrasound– or CT-directed biopsies.[60] Alternatively, when CT or magnetic resonance imaging clearly demonstrates an unresectable, locally advanced cancer, CT- or ultrasound-guided transcutaneous biopsy may substitute for EUS-guided aspiration. If a patient presents with obstructive jaundice and biliary stricture without radiographic evidence of a pancreatic mass, EUS examination is also advised. EUS can also be useful in the evaluation of regional lymph nodes and offers an opportunity for biopsy if the primary tumor is technically difficult to biopsy.

When there is clear radiographic evidence of metastatic disease and an obvious pancreatic mass, we prefer biopsy of a metastatic site, such as the liver. This confirms both the diagnosis and the presence of metastatic disease with one procedure. In addition, core-needle biopsies of metastatic sites can generally be obtained safely and provide sufficient tissue for molecular profiling. Just as the NCCN and ASCO recommend germline testing for patients with pancreatic cancer, the NCCN also encourages molecular and genomic profiling of tumor tissue whenever feasible.[61]

Misdiagnosis of Pancreatic Cancer

It is not uncommon for patients to be misdiagnosed with pancreatic cancer. The most common mistake we see is in the setting of bulky peripancreatic adenopathy mimicking a pancreatic mass. Adenocarcinomas of the pancreas do metastasize to regional lymph nodes, but these are typically small to medium sized. Bulky lymph nodes are more often seen in other pancreatic neoplasms such as acinar cell carcinomas or pancreatic neuroendocrine tumors. Tumors of the esophagus, stomach, duodenum, and sometimes the colon can lead to bulky peripancreatic lymph nodes. Lymphoma, non–small-cell lung cancer, and carcinomas of unknown primary origin may also lead to bulky peripancreatic lymphadenopathy and be mistaken for a primary pancreatic neoplasm. Thin-cut, contrast-enhanced dynamic-phase CT will usually rule out the presence of a primary mass in the pancreas in this setting. Another helpful radiographic finding may be the presence or absence of atrophy of the pancreatic body and tail. Although commonly seen with adenocarcinomas, this finding is usually absent in the setting of neuroendocrine and acinar cell tumors.

High-Quality Computed Tomography

At MDACC, the single most important imaging modality is dynamic-phase CT. This technique is used to objectively define (anatomically) potentially resectable disease and allows for imaging of the pancreas and surrounding vascular structures in arterial and venous phases of intravenous contrast. For optimal pretreatment staging, a CT report in a patient with suspected pancreatic cancer should include the following:

1. The presence or absence of a primary tumor in the pancreas or periampullary region
2. The presence or absence of peritoneal and hepatic metastases
3. Description of the patency of the superior mesenteric vein (SMV) and portal vein (PV) and the relationship of these veins to the tumor
4. Description of the relationship of the tumor to the superior mesenteric artery (SMA), celiac axis, and hepatic artery

Objective radiographic criteria can be used to define a potentially resectable primary tumor of the pancreatic head or uncinate process (Fig. 28–2). The MDACC criteria include: (1) no extrapancreatic disease; (2) a patent SMV and PV (assuming the technical ability to resect and reconstruct this venous confluence); and (3) a definable tissue plane between the tumor and regional arterial structures, including the celiac axis and SMA. A recent meta-analysis has estimated the positive predictive value for resectability based on contrast-enhanced CT imaging is 81%.[62] CT of the chest is now routinely part of our staging workup. Bone scans and brain imaging are rarely indicated and should not be part of routine staging.

Positron Emission Tomography

Positron emission tomographic (PET) scans are not a routine part of our staging. However, they are sometimes

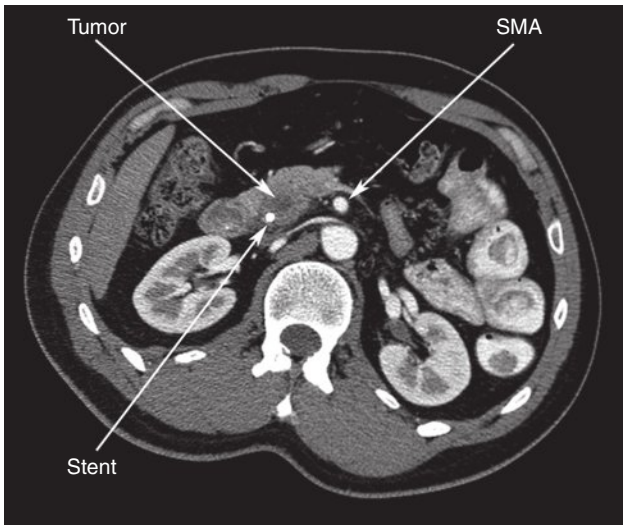

FIGURE 28–2 Computed tomographic image of tumor within the pancreatic head. Note the stent in the bile duct and the subtle low-density mass within the head. The superior mesenteric artery (SMA) has a fat plane completely surrounding it. This defines a potentially resectable tumor.

obtained in the setting of equivocal radiographic findings, such as indeterminate lesions in the liver or lungs. Note that small lesions (<1 cm) may be ^{18}F-fluorodeoxyglucose (FDG)-PET–negative, even when metastatic disease is present.[63] We also find ^{18}FDG-PET useful to evaluate for isolated local recurrence when a patient has undergone previous resection and subsequently exhibits a rising CA19-9 with soft tissue changes in the surgical bed indeterminate for fibrosis or recurrence.

Serum CA19-9 Determinations

CA19-9 measures the specific carbohydrate moiety of the mucin MUC-1.[64] This is the most commonly elevated tumor marker in pancreatic cancer, but it is not specific and may be elevated in other gastrointestinal tumors. Most retrospective analyses generally suggest that a high preoperative CA19-9 level (>500–1000 IU/mL) implies more advanced disease. Serial measurements of CA 19-9 during a course of neoadjuvant therapy is increasingly used to predict who among those with resectable or borderline resectable disease will derive the most benefit from surgical resection.[65,66] Conversely, in patients undergoing surgery as initial therapy, when postoperative CA19-9 levels do not normalize within 8 to 12 weeks postoperatively, early relapse with poor prognosis often ensues.[67] Decreasing CA19-9 levels of 50% or more during induction systemic chemotherapy has been correlated with improved survival.[68] A small subset of patients will have undetectable CA 19-9 levels based on lack of the enzyme fucosyltransferase needed to produce the CA 19-9 antigen, seen in patients who are Lewis antigen–negative (5%–7% of general population).[69]

The TNM System Versus Clinically Oriented Staging

The tumor, node, metastasis (TNM) staging system for pancreatic cancer is outlined in Table 28–3. For patients undergoing resection (who represent the small minority of patients with pancreatic cancer), the TNM system is somewhat useful in providing prognostic information.

TREATMENT STRATEGIES FOR PANCREATIC CANCER

At MDACC, patients are initially staged clinically as having potentially resectable, borderline resectable, locally advanced/unresectable, or metastatic disease (Fig. 28–3). For patients with potentially resectable disease and no contraindications to surgery based on frailty or comorbidities, surgery with curative intent should be pursued. As discussed later, we favor neoadjuvant therapy followed by surgery, over upfront surgery and adjuvant therapy. Patients with metastatic disease and adequate performance status (PS) usually receive systemic therapy. For patients presenting with locally advanced disease, treatment should be individualized and usually initially involves systemic therapy.

Resectable Pancreatic Cancer

It is widely known that surgery holds the only hope of cure for patients with pancreatic cancer. Most cases of resectable pancreatic cancers are comprised of small tumors located in the head of the pancreas. These are removed with a Whipple procedure,[70] more appropriately described as a pancreaticoduodenectomy.

There are two distinct approaches to the management of a patient with potentially resectable pancreatic cancer: (1) proceed with upfront surgery and, if possible, deliver adjuvant therapy for 6 months postoperatively; or (2) deliver neoadjuvant therapy and, if appropriate, proceed with surgical resection thereafter (Fig. 28–4).

Modern Adjuvant Therapy for Resected Pancreatic Cancer

Despite our preference for neoadjuvant therapy over upfront surgery and adjuvant therapy, the majority of patients with resectable pancreatic cancer undergo a surgery-first approach. For those who recover well and have no clinical evidence of early relapse, 6 months of systemic adjuvant therapy remains the standard of

Table 28–3 TNM Criteria for Pancreatic Adenocarcinoma TNM Definitions

No evidence of primary tumor	**T0**	Complete pathologic response to neoadjuvant therapy may result in T0 tumor
Tumor <2 cm in greatest dimension	**T1**	T1 tumors would generally be resectable based on high-quality imaging
Tumor >2 and <4 cm in greatest dimension	**T2**	T2 tumors may be resectable or borderline resectable (nonmetastatic)
Tumor >4 cm in greatest dimension	**T3**	T3 often with extrapancreatic extension and may be borderline resectable
Tumor involves the CA, HA, or SMA	**T4**	Encasement of these vessels define locally advanced disease; <180° = borderline resectable
No regional lymph node metastasis	**N0**	Negative lymph node involvement in 60% of cases after neoadjuvant therapy
Metastasis in one to three regional LNs	**N1**	Positive lymph node involvement occurs in 57% cases with upfront surgery
Metastases in four or more regional LNs	**N2**	Positive lymph node involvement occurs in 57% cases with upfront surgery
No distant metastasis	**M0**	
Distant metastasis	**M1**	Common metastatic sites would include the liver, lung, and peritoneum

LN, lymph node.

care. Since the last edition of this text, results using adjuvant therapy for pancreatic cancer have improved. However, as discussed further below, not all of the improvement in survival observed over time is completely attributable to the improvement of systemic therapy in the adjuvant setting.

A comprehensive history of adjuvant therapy for pancreatic cancer is beyond the scope of this text and focused on the delivery of 5-FU–based chemoradiation which, taken together, were inconclusive as to its survival benefit.[71–73] Gemcitabine monotherapy was subsequently shown to improve disease-free survival (DFS) and overall survival (OS) over surgery alone in a trial conducted by Charité Onkologie (CONKO). CONKO 001 was a randomized phase 3 trial that compared 6 months of gemcitabine with observation alone after curative intent surgery. Investigators showed a significant improvement in DFS and OS with the use of gemcitabine postoperatively (13 and 22.8 months, respectively) compared with surgery alone (6.9 and 20.2 months).[74] Subsequently, the European Society of Pancreatic Cancer (ESPAC) reported on their results in the ESPAC-4 trial, which randomly assigned surgically resected patients to adjuvant gemcitabine with or without capecitabine.[75] The chemotherapy doublet demonstrated an improvement in OS (28 vs 25.5 months; $P = .032$).

More recently, the results of the PRODIGE-24/CCTG study established another new standard of care for the adjuvant setting.[76] Patients were randomized to either 6 months of modified 5-FU, leucovorin, irinotecan, and oxaliplatin (mFOLFIRINOX) or gemcitabine. The combination chemotherapy arm significantly improved DFS from 12.8 to 21.6 months and median OS from 35 to 54.4 months. Despite the impressive survival data from the PRODGE-24/CCTG study, it is

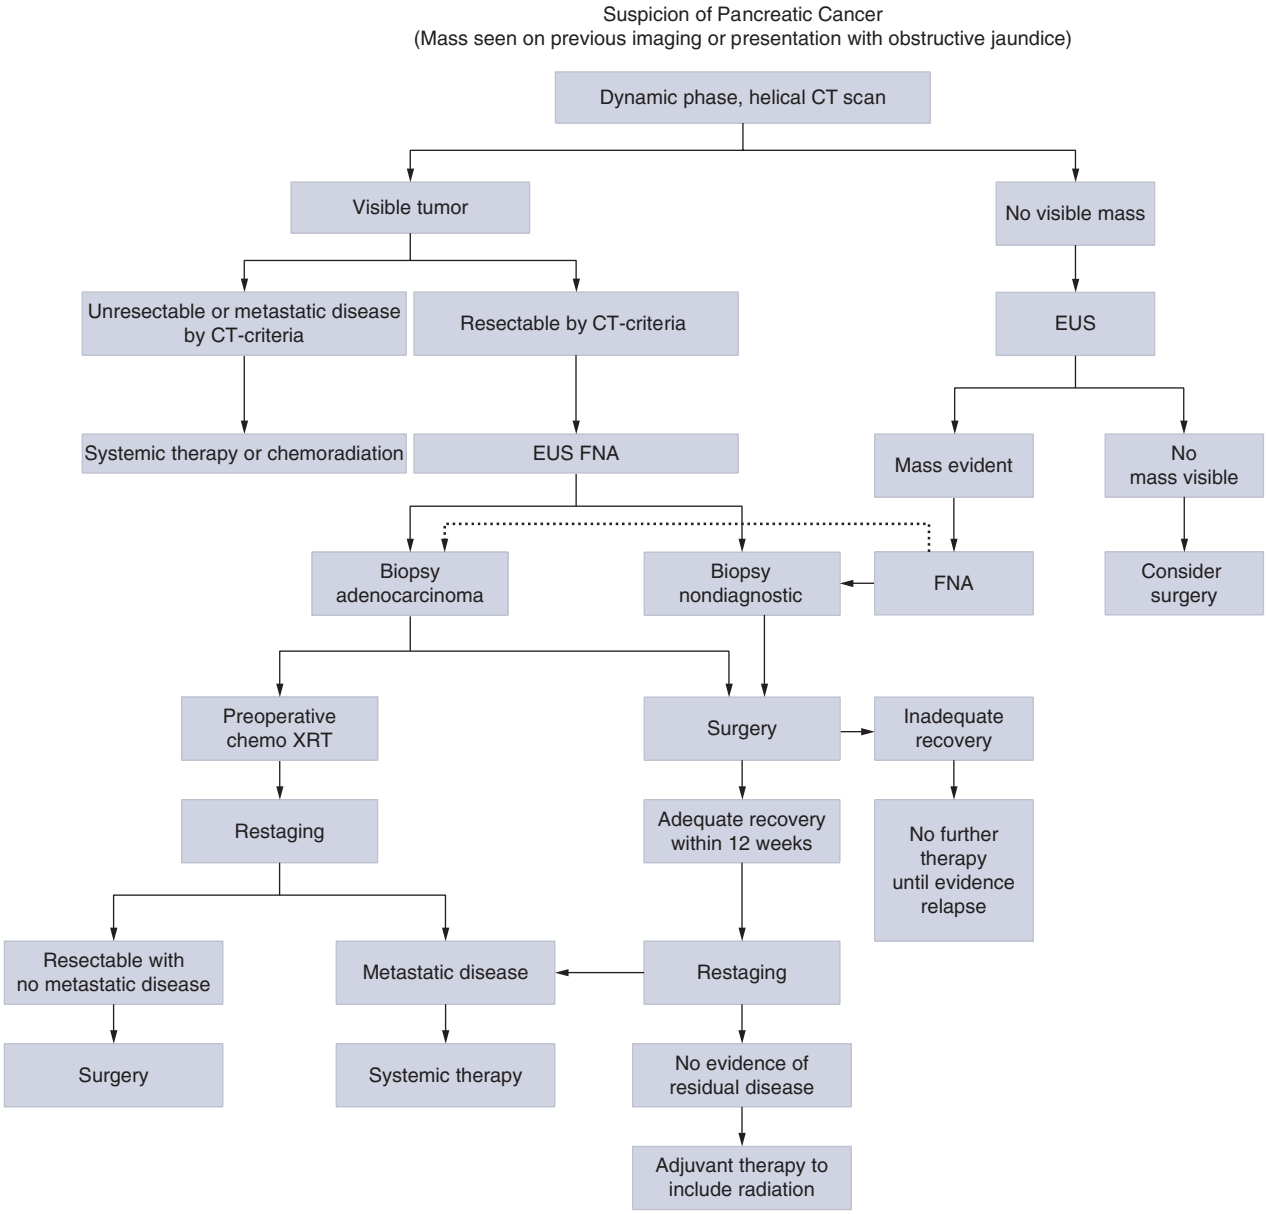

FIGURE 28–3 **General algorithm for diagnostic workup and management of newly diagnosed pancreatic cancer.**

important to recognize that the study patients represented a very select cohort. For example, patients with postoperative CA 19-9 levels greater than 180 U/mL within 21 days of random assignment were excluded. Moreover, enrollment was limited to patients with a World Health Organization PS of 0–1.

The most recent trial of adjuvant therapy for pancreatic cancer was the Adjuvant Pancreatic Adenocarcinoma Clinical Trial (APACT), which compared the combination of gemcitabine and nab-paclitaxel with gemcitabine for 6 months.[77] The primary end point of the study was independently assessed DFS. The results, presented at the ASCO annual meeting in 2019, demonstrated no significant improvement in DFS for the combination over single-agent gemcitabine. Of note, however, there was some improvement in OS for patients receiving gemcitabine and nab-paclitaxel compared with those receiving gemcitabine alone (40 vs 36 months), but this did not meet statistical significance and was not the primary end point.

Table 28–4 summarizes the results of the recently completed adjuvant trials. Note that the survival of patients randomly assigned to gemcitabine has steadily increased from 22.8 months in 2013 to 25 months in 2017 and up to about 35 months in 2018–2019. This suggests that patient selection for trial enrollment has become increasingly stringent from the early 2000s to the present time. Moreover, treatment options

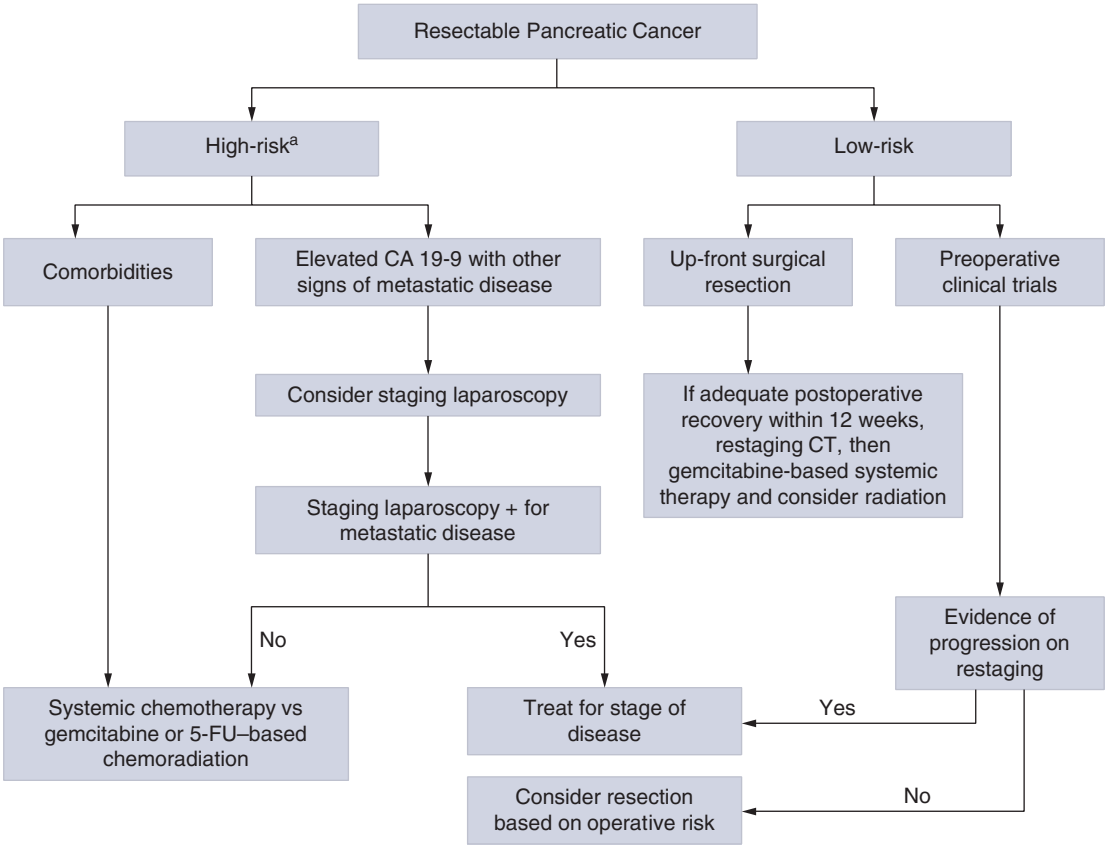

FIGURE 28–4 **Treatment algorithm for the management of resectable pancreatic cancer. [a]High-risk clinical features: suspicion of metastatic disease; CA19-9 >1000 with normal bilirubin; comorbidities suggesting high operative risk.**

available at the time of relapse have slowly expanded during this same time interval.

Challenges Associated with Upfront Surgery Followed by Adjuvant Therapy

In most centers, upfront surgical resection is the mainstay of treatment for potentially resectable pancreatic cancer. However, careful analysis of results from a surgery-first approach uncovers significant potential flaws in sequencing therapy this way.

1. *Surgical morbidity and mortality remain quite high after pancreaticoduodenectomy and impact the delivery of adjuvant therapy.*

Potentially resectable pancreatic cancer is often diagnosed in patients in their 60s to 70s and, given the known risk factors for pancreatic cancer, many patients may have a prior history of tobacco use, diabetes, or obesity, or they may present in a deconditioned state. Any of these comorbidities can increase the risk of postoperative complications, hamper recovery, and reduce the chances of receiving adjuvant therapy. An analysis performed by the American College of Surgeons National Surgical Quality Improvement Program evaluating data from the National Cancer Data Base (NCDB) has reported a rate of serious postoperative complications of 23%. For patients with no serious postoperative complications, the rate of adjuvant therapy delivery was 62%; for those with at least one postoperative complication, the delivery of adjuvant therapy was only 44%.[78] Pancreatic cancer surgery can also result in death. Among roughly 15,000 patients who underwent curative intent surgery for pancreatic cancer, 30-day mortality was only 3.4%, whereas 90-day mortality was twice that, at 7.5%.[79]

2. *Positive surgical margins are associated with inferior prognosis and are quite frequent with upfront surgery.*

Pancreatic cancer is notorious for being locally invasive, and surgical margins at the time of surgical resection are often microscopically positive (R1 resection). In modern trials of adjuvant therapy, the frequency of R1 resections among enrolled patients varies widely between 17% and 60% (Table 28–4). Prospective and retrospective analyses have shown that R1 resections are associated with worse survival compared with R0 resections.[80–82] In ESPAC-4, survival was superior for patients undergoing R0 resection compared with those having an R1 resection, irrespective of assigned therapy, as shown in Table 28–4.[75]

While some have advocated for postoperative radiation as a component of adjuvant therapy for patients

Table 28–4 Results of Upfront surgery in modern adjuvant therapy trials.

Study Year	Number of Patients	Number of Patients Enrolled Per Site Per Year	R1 Resection Rate	Median Survival (Months)	
				Control Arm	Experimental Arm
CONKO 001 2013	364	0.64	17	Observation 20.2	Gemcitabine 22.8
ESPAC 4 2017	730	1.32	60	Gemcitabine Full Cohort 25.5 R0 27.9 R1 23.0	Gemcitabine + capecitabine Full Cohort 28.0 R0 39.5 R1 23.7
PRODIGE/ CCTG 2018	493	1.90	43	Gemcitabine 35.0	FOLFIRINOX 54.4
APACT 2019[a]	866[b]	Not stated	24	Gemcitabine 36.2	Gemcitabine + nab-paclitaxel 40.5

[a]1226 patients were screened for enrollment, 360 (29%) failed screening; of these, 200 (17%) failed based on presence of postoperative radiographic evidence of persistent or metastatic disease, or postoperative CA 19-9 level >100 U/mL.
[b]The primary end point was independently assessed disease-free survival; overall survival was not the primary end point of this trial.

who undergo an upfront R1 resection,[83,84] our view is that neoadjuvant therapy is a more logical strategy to reduce the risk of a positive resection margin.[85]

3. *Upfront surgery results in persistent disease or metastases within the immediate postoperative period.*

The preliminary report of the APACT trial did report on screen failures for enrollment. A total of 1266 patients were evaluated for enrollment in this randomized phase 3 trial, but only 866 (71%) were enrolled. Of the 366 screen failures, 200 (17%) were ineligible based on postoperative radiographic evidence of persistent or metastatic disease, or a postoperative serum CA 19-9 level greater than 100.[77]

In summary, upfront surgery is associated with significant morbidity and mortality, it often leaves microscopic residual disease, and it puts the patient at risk for early relapse in the immediate postoperative period. Thus, based on current estimates, of the patients who undergo upfront surgery with curative intent, as much as 40% to 50% do not receive adjuvant therapy, proven to be a necessary component of treatment.[78]

MDACC Approach to Adjuvant Therapy

As will be discussed in more detail, our institutional bias is to deliver neoadjuvant therapy before considering surgery. Nevertheless, we have a subset of patients who are advised to undergo surgery first as part of their overall treatment plan. In addition, patients present to MDACC in the postoperative period seeking our opinion about a specific plan for adjuvant therapy.

In these circumstances, our approach has several facets.

1. *Assessment of postoperative recovery*

First and foremost, ensuring adequate recovery from surgery is an important step in determining whether the patient has recuperated adequately to consider adjuvant therapy. Patients should be ambulatory and capable of self-care with minimal assistance. At MDACC, adjuvant therapy is generally initiated 8 to 10 weeks postoperatively, although we accept a full 12 weeks of postoperative recovery as the outer bound for embarking on adjuvant therapy. This is based on analysis of results from patients treated on ESPAC trials of adjuvant therapy, which showed no difference in survival for those patients beginning adjuvant therapy at 6 to 8 weeks compared with those starting treatment 12 weeks postoperatively.[86] Moreover, for those patients who did not receive a full six cycles of adjuvant therapy, improved survival was demonstrated if treatment was initiated later (>8 weeks), implying that premature initiation of adjuvant therapy may be detrimental.

2. *Assessment of disease status*

Before initiating adjuvant therapy, patients undergo restaging studies that include measurement of serum tumor markers and CT imaging of the abdomen and pelvis. A specific cutoff for CA 19-9 suggesting persistent disease has not been established, but a postoperative level of 200 or higher should cause concern for the presence of gross residual disease. We recommend postoperative imaging as the patient approaches adequate recovery from surgery, usually 8 to 10 weeks postoperatively.

A. A specific plan for adjuvant therapy

Assuming the patient has adequate recovery and no clinical, biochemical or radiographic evidence of disease on postoperative assessment, the patient's performance status is the primary factor in determining the specific recommendations.

A.Modified (m)FOLFIRINOX:

For patients with very good PS (ECOG 0–1) and no contraindications to treatment with this combination, such as baseline peripheral neuropathy, mFOLFIRINOX delivered once every 2 weeks for six cycles (24 weeks) is the preferred regimen. Note that in the original report of this regimen as adjuvant therapy, the dose of irinotecan was reduced from 180 mg/m^2 to 150 mg/m^2, which improved overall tolerance to the treatment.[76] In the case of progressive peripheral neuropathy during treatment, we have a low threshold to reduce the dose or omit oxaliplatin completely for the remainder of the planned 6 months.

b. Gemcitabine and Capecitabine

For patients with ECOG PS 1–2, treatment with gemcitabine and capecitabine delivered over 24 weeks is generally recommended. In our experience, many patients do not tolerate a 28-day cycle of this regimen (3 weeks on, 1 week off), and if patients have unacceptable toxicity or develop progressive intolerance, we generally switch to treatment on a 21-day cycle. Regardless of cycle length, adjuvant therapy is usually given over 24 weeks.

3. *The Role of Radiation in Resected Pancreatic Cancer*

As a general rule, although final surgical pathology is prognostic, it is not typically used as a major factor in adjuvant treatment planning. The exception to this applies to patients who undergo an R1 resection. In that setting, systemic therapy for at least 4 months is advised. At that juncture, patients may be offered repeat imaging, and if there is no interval development of metastatic disease, chemoradiation may be considered to complete adjuvant therapy. Decisions about the role of postoperative chemoradiation are made by consensus during our weekly multidisciplinary pancreatic cancer conferences.

Neoadjuvant Therapy for Potentially Resectable Disease

At MDACC, our strong preference is for neoadjuvant therapy to be followed by surgery in the appropriate setting. This preference is based on the potential drawbacks associated with upfront surgery outlined previously. Neoadjuvant therapy followed by surgery offers some distinct theoretic advantages over immediate surgery and adjuvant therapy.

- Neoadjuvant therapy allows delivery of chemotherapy or chemoradiation to a relatively well-perfused tumor bed and provides early treatment to microscopic metastases.

Table 28–5 Analyses of R0 Resection Rate and Lymph Node Involvement with Upfront Surgery and Adjuvant Therapy Versus Neoadjuvant Therapy and Surgery

Author Study Details Year	Number of Patients	R0 Resection Rate (%)		Negative Lymph Node Rate (%)	
		Upfront Surgery	Neoadjuvant Therapy	Upfront Surgery	Neoadjuvant Therapy
Roland MDACC/Single Institution 2013	307	85	92	26	50
Youngwirth NCDB 2017	18,243	78	85	43	59
Mokdad NCDB/Propensity Matching 2017	15,237	76	83	23	52
Versteijne Meta-Analysis 2018	3484	67	87	35	56
Versteijne PREOPANC Randomized Trial 2020	246	40	71	22	67

- It can generate meaningful locoregional treatment effect, increasing the chance of a margin-negative resection and reducing the likelihood of positive lymph nodes (Table 28–5).
- It allows for observation of the tumor's underlying biology over time and facilitates the identification of patients with interval development of metastatic disease, sparing them a major surgical procedure which will not be of benefit.
- Neoadjuvant therapy also provides an opportunity to observe the patient's tolerance to nonsurgical treatment and allow for adjustments in its duration or intensity to maximize the patient's chances for recovery from preoperative treatment before surgical intervention.
- Neoadjuvant therapy allows for prehabilitation, which may involve gradual weight loss, improvements in nutrition and glucose control, and exercise to increase cardiovascular and physical fitness.[87]

We have been conducting neoadjuvant trials in potentially resectable pancreatic cancer at MDACC since the early 1990s.[88–92] Our data demonstrated that preoperative therapy is associated with high rates of R0 resections and relatively low local failure rates compared with adjuvant therapy. Subsequent analysis of our survival results in patients undergoing surgery after preoperative therapy has demonstrated increases in OS over time from 1990 to 2014 using four successive time periods, with median OS improving from 24.1 months from 1990 to 1999 to 43 months in 2010 to 2014.[93]

A growing number of comparisons between the use of neoadjuvant therapy followed by surgery and upfront surgery with or without adjuvant therapy have been conducted (Table 28–5).[94–98] All of these analyses conclude that neoadjuvant therapy is more likely to result in an R0 resection compared with upfront surgery and increase the likelihood of negative lymph nodes on final pathology. These analyses have been limited by a lack of randomized data comparing neoadjuvant therapy and subsequent surgery with upfront surgery and adjuvant therapy. The exception is the recently published PREOPANC trial conducted at 16 centers in the Netherlands, summarized in Table 28–5.[98] This study allowed enrollment of patients with resectable or borderline resectable disease (the latter to be discussed below). The study enrolled 246 patients between 2013 and 2017. Patients were randomly assigned to receive three courses of gemcitabine, with the second course given in conjunction with radiation to a dose of 36 Gy delivered over 15 fractions, followed by surgery, followed by four courses of postoperative gemcitabine; or to upfront surgery and six cycles of adjuvant gemcitabine. Based on the intent-to-treat analysis, patients who were assigned to neoadjuvant therapy had a slightly better median OS of 16.0 months compared with 14.3 months for those patients assigned to upfront surgery (P = .096). However, among the patients who underwent surgical resection, there was a clear survival advantage for patients who had received preoperative treatment, 35.2 months versus 19.2 months (P = .029). The PREOPANC trial, although negative for improvement in OS based on intent to treat, showed a survival advantage for those undergoing curative resection and has paved the way for more robust efforts to assess the value of neoadjuvant therapy compared with upfront surgery in pancreatic cancer. Furthermore, investigation of the relative contributions of chemotherapy and chemoradiation in neoadjuvant trials is ongoing.

MDACC Approach to Neoadjuvant Therapy in Patients with Resectable Disease

Patients who are identified before referral as having localized disease are initially seen by one of our surgical oncologists to assess PS and comorbidities and confirm adenocarcinoma from outside specimens or from biopsies obtained here. Routine laboratory studies are obtained to include complete blood counts and coagulation studies, a comprehensive metabolic panel, hemoglobin A1C, and serum tumor markers, specifically carcinoembryonic antigen, CA 19-9, and CA 125. High-quality dynamic-phase pancreatic protocol CT imaging of the chest, abdomen, or pelvis is obtained and reported in a templated format described earlier in the chapter. Patients clinically staged as having potentially resectable disease and considered to be surgical candidates are presented to multidisciplinary pancreatic cancer conferences to consider enrollment in a clinical trial or to develop a preliminary plan for off-protocol therapy.

Outside of a clinical trial, if neoadjuvant therapy is recommended, therapy is generally a well-defined course of induction systemic therapy consisting or 3 to 4 months of mFOLFIRINOX or gemcitabine/nab-paclitaxel. Restaging studies are performed every 2 months during induction chemotherapy. If no interval metastases are noted on restaging, long-, medium-, or short-course capecitabine-based chemoradiation (50.4 Gy over 28 fractions, 36 Gy over 12 fractions, or 30 Gy over 10 fractions, respectively) is delivered. Decisions about the induction chemotherapy are left to the discretion of the treating oncologist and are generally based on comorbidities and PS. Patients with ECOG PS 0–1 are usually treated with mFOLIRINOX and patients with ECOG PS 1–2, or with comorbidities, more often receive gemcitabine and nab-paclitaxel. In terms of the radiation dose and schedule, this is primarily the purview of the treating radiation oncologist with input from the surgeon and medical oncologist. Whenever possible, we advise our patients to receive neoadjuvant chemoradiation at MDACC. However,

we allow the delivery of off-protocol induction chemotherapy in collaboration with the patient's referring oncologist.

Borderline Resectable Pancreatic Cancer

In the late 1990s and early 2000s, the negative prognostic implications of an R1 resection were increasingly appreciated. This coupled with improvements in cross-sectional imaging allowed for the identification of tumors abutting but not encasing critical arterial structures surrounding the pancreas (celiac trunk and SMA). Such tumors were recognized as putting patients at risk for an R1 resection with upfront surgery and, in many centers, were considered locally advanced and unresectable. However, as we and others developed experience with neoadjuvant chemoradiation and observed significant treatment effect on final pathology, it was noted that a subset of patients having tumors with vessel abutment could undergo R0 resection after a period of neoadjuvant therapy. In that context, the concept of borderline resectable pancreatic cancer emerged.[99]

As of this writing, there is variability in definitions of borderline resectable disease, but for the purposes of this text, a borderline resectable tumor is one that puts the patient at high risk for an R1 resection with upfront surgery. A growing number of single-institution reports of neoadjuvant therapy for borderline resectable tumors are being published. Multi-institutional and cooperative group trials specifically designed for patients with borderline resectable disease are now being conducted, with some results already published.[100] Although there is no standard approach to neoadjuvant therapy for borderline resectable disease, some general observations are becoming evident.

1. *Neoadjuvant therapy followed by surgery for borderline resectable disease appears to offer a survival advantage over upfront surgery and adjuvant therapy.*

Using the NCDB, investigators analyzed outcomes of patients with borderline resectable disease treated with upfront surgery and adjuvant therapy and compared them with similar patients treated with neoadjuvant and subsequent surgery.[101] Median OS was superior using a neoadjuvant approach compared with upfront surgery (25.7 vs 19.6 months; $P < .0001$). Moreover, R0 resections were higher using neoadjuvant therapy and the rate of node-positive disease was lower.

2. *Induction gemcitabine/nab-paclitaxel or FOLFIRINOX with or without subsequent chemoradiation are the most common neoadjuvant regimens being reported recently.*

Two studies have reported on clinical outcomes after neoadjuvant therapy and subsequent surgery using FOLFIRINOX compared with gemcitabine and nab-paclitaxel.[102,103] Based on these results, there is no firm conclusion regarding the superiority of one regimen over the other.

3. *The role of radiation in the neoadjuvant treatment of borderline resectable disease is unclear.*

Radiation as a component of neoadjuvant therapy has yet to be firmly established because there are no well-designed randomized trials published to date. There are reports that neoadjuvant chemoradiation may improve R0 and pN0 resections compared with neoadjuvant chemotherapy alone, but no survival advantage has yet been demonstrated .[104] PREOPANC2 is a randomized clinical trial that will compare systemic gemcitabine and gemcitabine-based chemoradiation with FOLFIRINOX alone in patients with resectable and borderline resectable pancreatic cancer.[98] In addition, the Alliance for Clinical Oncology Trial A021501 is comparing FOLFIRINOX × 7 doses followed by SBRT with FOLFIRINOX × 8 doses followed by surgery.[105] Results from these and other trials may clarify the role of neoadjuvant radiation in borderline resectable disease.

MDACC Approach to Borderline Resectable Disease

Whenever possible, patients with borderline resectable pancreatic cancer are enrolled in clinical trials. Outside of a clinical trial, patients with borderline resectable pancreatic cancer are treated using a tailored approach, taking into account PS, comorbidities, baseline CA 19-9 measurements, and presence of indeterminate liver, lung, or peritoneal lesions (Fig. 28–5).

In general, patients with PS 0–1 and no contraindications to FOLFIRINOX are treated with this regimen. Induction chemotherapy is usually delivered over a longer interval (4+ months) compared with patients with potentially resectable disease (3–4 months). For patients with PS 1, comorbidities, or contraindications to FOLFIRINOX, we usually administer gemcitabine and nab-paclitaxel for a similar time frame. We have found that normalization of CA 19-9 levels after completion of neoadjuvant therapy (which for us usually involves chemoradiation after induction chemotherapy), improves the likelihood of a major pathologic response at the time of surgery and increases the chance of long-term survival.[65,66] Therefore, serial CA 19-9 measurements are obtained as patients receive induction chemotherapy. If a patient's clinical or marker response to the first two cycles (8 weeks) of frontline neoadjuvant FOLFIRINOX is considered suboptimal, we will consider a switch in chemotherapy to gemcitabine and nab-paclitaxel. Based on a retrospective analysis, this strategy ultimately allowed surgical resection in 40% to 50% of patients who did not respond to initial FOLFIRINOX.[106] We do not currently know whether a switch to FOLFIRINOX will also salvage the patient's candidacy for surgery if initial treatment with gemcitabine and nab-paclitaxel treatment is ineffective.

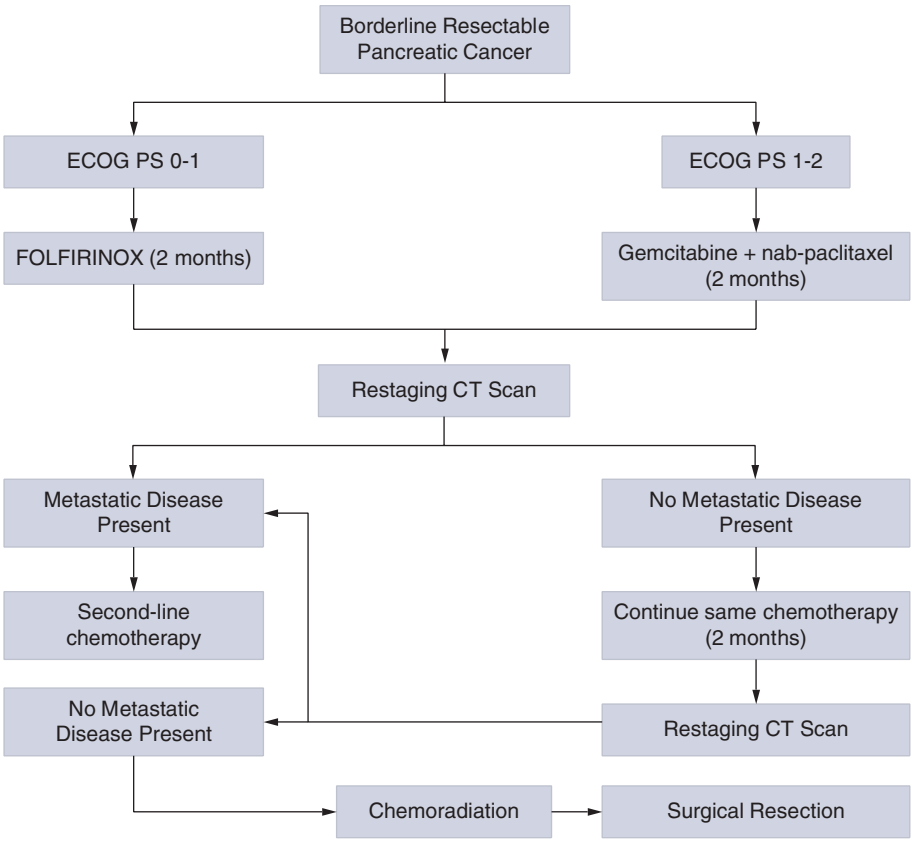

FIGURE 28–5 **Treatment algorithm for the management of borderline resectable pancreatic cancer.**

Neoadjuvant therapy in borderline resectable disease serves to identify the subset of patients with favorable response who should undergo an attempt at surgical resection. Thus, maintaining or improving fitness for surgery remains a priority during neoadjuvant therapy. We take a two-pronged approach. First, we have found that modest de-escalation of FOLFIRINOX or gemcitabine and nab-paclitaxel intensity is well tolerated, generates anticancer effects, and minimizes toxicity that could compromise a patient's surgical candidacy.[107] Second, we have increasingly used formalized prehabilitation as part of our neoadjuvant program to assist patients with nutritional modifications, gradual intentional weight loss, and to provide specific recommendations for exercise to increase cardiovascular fitness and muscle strength.

Management of Patients with Locally Advanced Disease

Patients are defined as having locally advanced pancreatic cancer when there is radiographic evidence of SMA or celiac artery encasement, occlusion of the SMV-PV confluence, or significant involvement of the common hepatic artery originating from the celiac trunk. There should be no clinical or radiographic evidence of metastatic disease. Currently, roughly half of all patients present with locally advanced disease. As with resectable pancreatic cancer, an understanding of certain principles aid in decision making.

- *Locally advanced pancreatic cancer poses unique challenges.* Local tumor progression with worsening pain, new or recurrent biliary obstruction, PV thrombosis, or gastric outlet obstruction represent difficult treatment problems.
- *Assessment of response to therapy can be difficult.* These tumors may be composed of small nests of adenocarcinoma surrounded by large areas of desmoplasia (Fig. 28–6). Even when cytotoxic therapy is effective, the desmoplastic component of the residual mass may not regress, and the overall tumor mass may appear unchanged.
- *All surgical interventions should be considered carefully and based on patient PS and life expectancy.* Palliative nonsurgical procedures may produce results similar to those of aggressive surgery.

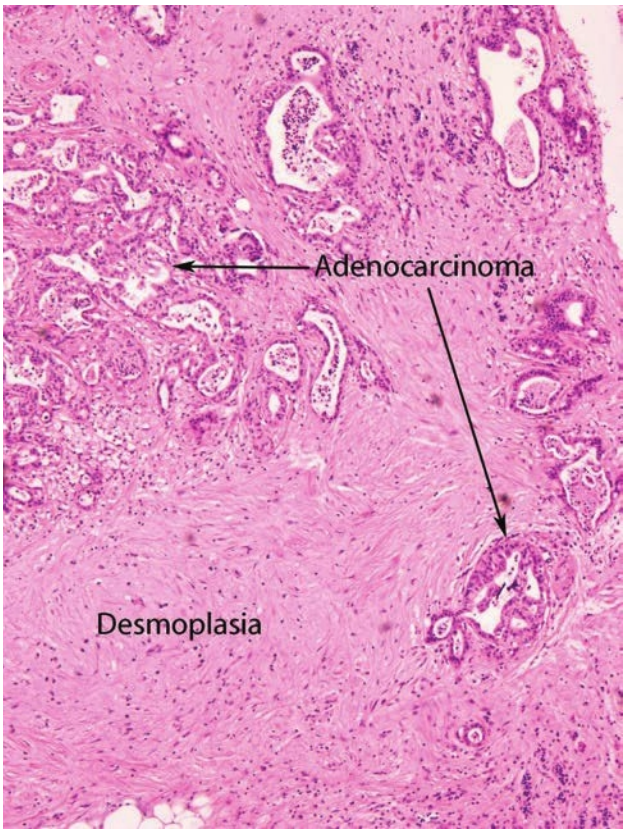

FIGURE 28–6 Photomicrograph of ductal adenocarcinoma of the pancreas with intense desmoplastic reaction. Even if the tumor cells regress in response to therapy, a residual fibrotic mass may remain. This confounds assessment of response to therapy using standard radiographic criteria.

The Evolution of Therapy for Locally Advanced Disease

Concurrent chemoradiation had historically been the initial treatment approach for patients with locally advanced pancreatic cancer. After approval of gemcitabine in 1997, a common practice for management of locally advanced disease was to deliver 5-FU–based chemoradiation followed by systemic gemcitabine as tolerated until disease progression.

Induction Chemotherapy Followed by Chemoradiation

The old paradigm of chemoradiation followed by chemotherapy was challenged by analyses suggesting that induction chemotherapy followed by chemoradiation might be a better strategy.[108–110] Two of these studies showed that approximately 30% of patients with locally advanced pancreatic cancer would develop metastatic disease within 2 to 4 months of starting systemic therapy. This implied that such patients had aggressive tumor biology negating any benefit from local therapy, and therefore the initial use of systemic therapy would serve to identify patients with favorable biology, making them attractive candidates for local control.

Systemic Therapy Alone for Locally Advanced Disease

The strategy of systemic therapy followed by consolidative chemoradiation was challenged by the results of LAP 07.[111] In this trial, patients were randomly assigned to gemcitabine or gemcitabine plus erlotinib (100 mg/d) for 4 months. Participants with controlled disease after induction chemotherapy were subsequently randomly assigned to further chemotherapy for 2 more months or to chemoradiation (54 Gy) with capecitabine 1600 mg/m^2/d). All treatment then ceased. Of the 442 patients initially randomly assigned, 269 patients (61%) entered the second-round randomization phase, thus identifying the subset of patients with unfavorable tumor biology unlikely to benefit from local control. Median OS in the chemotherapy arm was 16.5 months compared with 15.2 months for the chemoradiation group (hazard ratio [HR] 1.03, 95% CI 0.79–1.34; P = .83). It appeared neither radiation nor erlotinib improved survival in this population. However, the administration of radiation delayed the reinitiation of anticancer therapy for progressive disease (3.7 months for the chemotherapy arm, 6.1 months for chemoradiation; P = .02). This potential for a longer chemotherapy-free interval after consolidating chemoradiation may be of value to patients and has been used to justify continued studies of consolidating chemoradiation after a period of systemic therapy. As of this writing, for patients with good PS (ECOG 0–1), the NCCN Pancreatic Cancer Guidelines subcommittee endorses induction chemotherapy (for 4–6 months) for patients with locally advanced disease. If the patient remains with locally advanced, nonmetastatic disease, chemoradiation or SBRT are accepted as subsequent therapeutic options.

MDACC Approach to Locally Advanced Pancreatic Cancer

For patients with adequate PS (ECOG ≤2), outside of a clinical trial, our general approach is to initiate therapy with gemcitabine and nab-paclitaxel rather than FOLFIRINOX. This is based in part on our off-protocol approach to treatment with gemcitabine/nab-paclitaxel (given day 1 and 15 every 28 days) which we find quite tolerable for the majority of our patients.[107] This allows us to consider second-line FOLFIRINOX or 5-FU with liposomal irinotecan if no benefit is observed with first-line gemcitabine and nab-paclitaxel

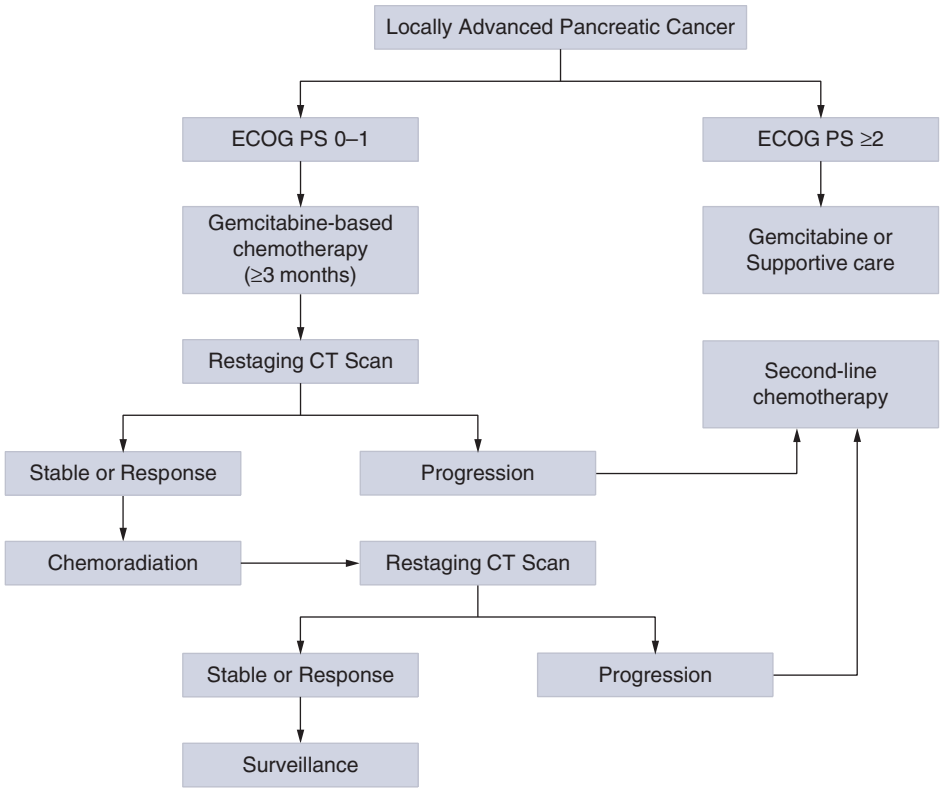

FIGURE 28–7 **Treatment algorithm applied to the management of patients with locally advanced pancreatic cancer.**

and provides another active regimen if interval metastatic disease develops (Fig. 28–7).

The exception to the use of gemcitabine and nab-paclitaxel as frontline therapy in locally advanced disease pertains to patients who are more likely to be reconsidered for surgery after a period of neoadjuvant therapy. These patients usually have PS 0 and limited comorbidities to allow for aggressive neoadjuvant therapy and subsequent surgery. Support for this approach comes from retrospective data reported from the Johns Hopkins Hospital. A total of 415 LAPC patients were included in the study, and 84 patients ultimately underwent resection of the primary tumor (20%) after neoadjuvant therapy. FOLFIRINOX-based therapy and SBRT correlated with increased probability of resection ($P = .006$). Resected patients had better PS, smaller median tumor size ($P = .029$), and lower median CA 19-9 values ($P < .001$. Patients who underwent surgical resection had significant higher median OS compared with those who did not (35.3 vs 16.3 months; $P < .001$).[112] A more recent report also supports FOLFIRINOX (combined with losartan) followed by chemoradiation as a strategy to allow a subset of patients with locally advanced disease to ultimately undergo surgery with curative intent.[113] Our approach is similar for these patients and we generally administer FOLFIRINOX for at least 4 months. For patients who demonstrate a clinical, biochemical, or radiographic response to systemic therapy, we favor consolidating chemoradiation, particularly when surgical resection remains a possibility.

Outside of a clinical trial, we generally administer capecitabine as the radiosensitizer, based on results from the SCALOP trial, a randomized phase 2 trial performed in the United Kingdom. Patients with locally advanced pancreatic cancer who did not have disease progression after 12 weeks of induction chemotherapy with gemcitabine plus capecitabine were randomly assigned to either gemcitabine (300 mg/m^2/week) or capecitabine (830 mg/m^2 twice daily on days of radiotherapy) concurrently with radiation (50.4 Gy in 28 fractions).[114] Median OS was 17.6 months in the capecitabine arm compared with 14.6 months in the gemcitabine arm (adjusted HR 0.68; $P = .185$).[115] Furthermore, for patients who receive chemoradiation we consider maintenance therapy using capecitabine for at least 3 months after completion.

Whenever possible, patients with stable disease or response after a period of systemic therapy, are encouraged to enroll in clinical trials using novel radiosensitizers or radioprotectants.

Of note, if patients do not derive any significant clinical, biochemical, or radiographic response from first- and/or second-line induction chemotherapy, we

generally do not pursue chemoradiation as an alternative strategy. This is also true for patients who remain with relatively high CA 19-9 levels after a trial of systemic therapy. It is our perception that patients with chemoresistant disease harbor tumors that are likewise radioresistant.

For patients with poor PS, supportive care is encouraged, and systemic therapy and radiation are usually contraindicated. In the subgroup of patients with significant pain related to the primary tumor, aggressive use of opioids is initiated, with emphasis on slow-release, long-acting formulations. When poor tolerance to opioids or inadequate pain control occurs with their administration, celiac or splanchnic nerve block is recommended. If adequate pain control is achieved, patients with improving PS can be reconsidered for anticancer therapy.

Localized and Locally Advanced Pancreatic Cancer Summary

Clinical and autopsy data have repeatedly proven that adenocarcinoma of the pancreas is both a locally invasive disease and a systemic disease, and it is estimated that 20% of patients who die as a result of pancreatic cancer succumb to progressive local disease. As a general rule, in patients with localized disease (potentially or borderline resectable, and locally advanced disease), systemic therapy remains the foundation of anticancer therapy and in our view should be delivered before surgery. When appropriate, an array of local therapies should be considered in patients who demonstrate disease response or prolonged local disease stabilization. This might involve ultimate surgical resection, various radiation techniques, or other locally ablative techniques such as irreversible electroporation (if applied properly by experienced clinicians).[116] Moreover, as our systemic therapy continues to evolve and improve, durable local disease control will become increasingly relevant for better patient outcomes.

Management of Metastatic Disease

Compared with patients having other common malignancies, such as cancer of the colon or breast, patients with advanced pancreatic cancer often have more tumor-related symptoms and functional compromise. Therefore, palliation must be a primary goal of therapy. Management of metastatic disease should be guided by the following principles:

- The disease course may be quite dynamic, and the clinical status of a patient can change quickly. Patients therefore require frequent reassessment, regardless of whether they are undergoing cytotoxic therapy.
- Responses to therapy are rarely observed in patients with poor PS or high tumor burden, and combination therapy in these patients is associated with increased toxicity.
- When metastatic disease is confined to the lungs, its course may be more indolent.
- Although newer cytotoxic chemotherapy regimens have improved survival for patients with advanced disease, further advances in the treatment for pancreatic cancer are desperately needed, and patients with good PS should be encouraged to participate in clinical trials.

Gemcitabine-Based Therapy for Advanced Pancreatic Cancer

Gemcitabine

Gemcitabine was the first FDA-approved drug for advanced pancreatic cancer based on a randomized trial. The study compared weekly gemcitabine with bolus weekly 5-FU in previously untreated patients.[117] Patients treated with gemcitabine achieved a higher response rate (5.4% vs 0%) and improvement in median OS compared with those treated with 5-FU (5.65 vs 4.41 months; $P = .0025$). The 1-year survival rate for gemcitabine-treated patients was 18% compared with 2% for those treated with 5-FU. Importantly, more clinically meaningful effects on disease-related symptoms were recorded with gemcitabine therapy compared with 5-FU treatment (24% vs 5%).

Gemcitabine Doublet Therapy

After gemcitabine's approval in 1997, a number of gemcitabine doublets were tested. These trials generally combined gemcitabine with another cytotoxic agent: 5-FU, cisplatin, irinotecan, oxaliplatin, and docetaxel.[118–123] Most doublets showed some modest improvement in objective response rate (15%–20% vs gemcitabine at 10%); alas, no meaningful improvement in survival was observed using cytotoxic doublet therapy in unselected patients.

Similar to cytotoxic doublets, no significant progress has been made combining gemcitabine with molecular targeted agents.[124–129] More recently, the focus of investigation has been aimed at the tumor microenvironment. Early ventures into this arena have likewise been disappointing. Only erlotinib, an oral EGF-R inhibitor, which led to a slightly longer median survival compared with gemcitabine alone (6.24 vs 5.91 months; $P = .038$),[130] has demonstrated improved efficacy in combination with gemcitabine. This is likely explained by the lack of a predictive biomarker for any of the drugs tested and the relative impotence of single-agent gemcitabine as delivered in clinical trials (1000 mg/m^2 over 30 minutes).

Gemcitabine and Capecitabine

In contrast to other cytotoxic drugs, capecitabine, the orally bioavailable fluorinated pyrimidine, has shown modest added benefit compared with treatment with gemcitabine alone. In a phase 3 trial, Cunningham and colleagues randomly assigned patients to receive gemcitabine versus gemcitabine plus capecitabine.[131] The addition of capecitabine to gemcitabine significantly improved overall response rate (19.1% vs 12.4%) and progression-free survival (HR = 0.78) ($P < .03$ and .004, respectively). The combination also showed a trend toward improved OS ($P = .08$). The NCCN Pancreatic Cancer Guidelines subcommittee continues to include this doublet as a reasonable regimen to deliver in patients with advanced disease.

Gemcitabine and Nab-Paclitaxel

In September 2013, the FDA first approved a gemcitabine-based combination chemotherapy regimen with nab-paclitaxel as a standard treatment for advanced pancreatic cancer. This was based on a phase 3 study showing an OS advantage of gemcitabine plus nab-paclitaxel over gemcitabine alone (8.5 months vs 6.7 months; HR for death 0.72; 95% CI 0.62–0.83; $P < .001$).[132] The 1-year survival rates were 35% versus 22%, respectively. The response rate according to independent review was 23% versus 7% in the two groups ($P < .001$). Patients in the combination arm did have increased neutropenia, fatigue, and neuropathy. Importantly, enrollment allowed patients with Karnofsky Performance Status score of at least 70% and suggested that this combination could be used safely in patients with compromised functional status. The gemcitabine and nab-paclitaxel combination therefore is an attractive drug regimen for patients with advanced disease having some degree of frailty or comorbidities, which make triplet drug therapy less attractive.

Gemcitabine and Cisplatin: Good for DNA Damage Repair Deficiency?

As experience with gemcitabine was growing, we and others found that some subsets of patients with advanced disease appeared to have some dramatic responses to gemcitabine and cisplatin. In a retrospective review of clinical data sets from MDACC and the Johns Hopkins group, patients with family or pedigree history of cancer had superior OS when treated with gemcitabine and a platinum analogue over gemcitabine monotherapy. This was especially true in patients with three or more relatives with a history of breast, ovarian, or pancreatic cancers (HR 0.49, 95% CI 0.30–0.80; $P = .003$). As the number of relatives with these cancers increased, the OS rate improved for individuals receiving first-line platinum therapy (HR 0.76, 95% CI 0.65–0.89; $P = .0004$), which was not the case for those receiving other therapies ($P = .98$).[133] Based on preclinical data and such clinical observations, it has been hypothesized that for patients with a strong family history of breast, ovarian or pancreatic cancer, germline mutations of BRCA or other DNA damage repair pathway genes would be more common and more likely sensitive to gemcitabine and platinum therapy. This has been supported by a recent randomized phase 2 trial in which germline BRCA- or PALB2-mutated patients received gemcitabine and cisplatin with or without velaparib.[134] The addition of veliparib did improve the objective response rate from 65% to 74% but this did not reach statistical significance. Nevertheless, the median OS of patients enrolled in this trial was impressive, ranging from 15.5 to 16.4 months. Thus, a strong family history of breast, ovarian, and/or pancreatic cancer, or a documented germline mutation in BRCA1/2 or PALB2 may serve as a predictive biomarker to treatment with gemcitabine and cisplatin. Over time, investigation of platinum-containing regimens in the setting of other mutated DDR genes, such as PALB2, ATM, or ATR, should expand the number of patients who may benefit from this doublet.

Triplet Chemotherapy for Advanced Pancreatic Cancer

FOLFIRINOX

In 2011, investigators in France tested a three-drug chemotherapy regimen consisting of oxaliplatin, irinotecan, fluorouracil, and leucovorin (FOLFIRINOX) and compared it with gemcitabine in patients with metastatic pancreatic cancer with ECOG PS 0–1.[135] There were 342 patients enrolled and randomly assigned to receive FOLFIRINOX (oxaliplatin, 85 mg/m^2 body surface area; irinotecan, 180 mg/m^2; leucovorin, 400 mg/m^2; and fluorouracil, 400 mg/m^2 given as a bolus followed by 2400 mg/m^2 given as a 46-hour continuous infusion every 2 weeks) or gemcitabine. The median OS was 11.1 months in the FOLFIRINOX group compared with 6.8 months in the gemcitabine group (HR for death 0.57, 95% CI 0.45–0.73; $P < .001$). The objective response rate was also markedly improved in the FOLFIRINOX group, 31.6% versus 9.4% ($P < .001$). FOLFIRINOX is approved for use as frontline therapy in patients with advanced pancreatic cancer having ECOG PS 0–1 and in that population is considered a standard of care.

Gemcitabine, Nab-Paclitaxel, and Cisplatin

Very recently, a gemcitabine triplet combination has been similarly reported as highly active, with overall acceptable toxicity in patients with metastatic disease. This regimen builds on gemcitabine and nab-paclitaxel with the addition of cisplatin for treatment of patients

with advanced disease. In a multicenter phase 1b/2 trial, patients were treated with standard doses of nab-paclitaxel plus gemcitabine plus various doses of cisplatin, 25–50 mg/m^2, on days 1 and 8 of a 21-day cycle.[136] Among the 25 enrolled patients, there were two complete responses (8%), 15 partial responses (62%), four stable disease (17%), and three progressive disease (12%). Median progression-free survival was 10.1 months, with a median OS of 16.4 months. Moreover, 16 patients (64%) were alive at 1 year, 10 (40%) at 2 years, 4 (16%) at 3 years, and 1 (4%) at 4-plus years. On a cautionary note, fatal events occurred in three patients (12%); two were thought to be treatment related. A larger phase 2 trial of this regimen is now underway (NCT03915444).

Second-Line Chemotherapy

Nanoliposomal irinotecan has gained approval in the second-line setting for patients with metastatic pancreatic cancer who received prior gemcitabine-based therapy based on the results of the phase 3 NAPOLI-1 study.[137] In this trial, 417 patients whose disease had progressed on gemcitabine-based chemotherapy were randomized to one of three arms: (1) 5-FU + leucovorin, (2) nanoliposomal irinotecan, or (3) combination of 5-FU + leucovorin + nanoliposomal irinotecan. Median OS in the triplet-therapy group with 5-FU + leucovorin + nanoliposomal irinotecan was 6.1 months, compared with 4.2 months in the 5-FU + leucovorin group (HR 0.67; $P = .012$).

Second-line options for systemic chemotherapy are based largely on a patient's PS at the time of progression. Previously treated patients should be encouraged to participate in clinical trials where available. Outside of a clinical trial, for patients who are treated with first-line gemcitabine plus nab-paclitaxel, those who retain a good PS are usually offered 5-FU + leucovorin + nanoliposomal irinotecan. Rarely, patients with excellent PS may be considered for second-line FOLFIRINOX, although data on the triplet regimen in the pretreated setting are limited. For patients whose disease progresses on first-line FOLFIRINOX and who maintain an adequate PS, gemcitabine plus nab-paclitaxel is an appropriate second-line option.[138]

Future Directions in Systemic Therapy for Pancreatic Cancer

Modern Targeted Therapy in Pancreatic Cancer

For years, targeted therapy in pancreatic cancer proved disappointing predominantly based on the lack of predictable biomarkers. More recent investigations of target therapy have yielded somewhat more positive results.

Targeting Mutations in DNA Repair Proteins

Up to 25% of patients with pancreatic cancer may harbor mutations in genes that play a role in the DNA damage repair (DDR) response.[139–142] The most studied among these are germline BRCA1 and BRCA2 mutations, which occur in as much as 7% of patients with pancreatic cancer.[143,144]

Patients whose tumors are deficient in DDR proteins display heightened susceptibility to DNA-damaging agents, including platinum chemotherapy and radiotherapy. Recent therapeutic focus on inhibitors of PARP, a crucial component of the homologous recombination pathway for single-strand DNA breaks, has identified this class of drugs as being particularly effective in patients with DDR mutations. Early-phase studies evaluating the PARP inhibitors olaparib and rucaparib revealed promising activity in pretreated patients with pancreatic cancer with germline or somatic BRCA1 and BRCA2 mutations.[145,146] Most prominently, the phase 3 POLO trial randomly assigned 154 patients with metastatic pancreatic cancer with germline BRCA1 or BRCA2 mutations whose disease had not progressed on at least 16 weeks of first-line platinum-based chemotherapy to maintenance therapy with either placebo or olaparib.[20] The median PFS in the maintenance olaparib arm was significantly longer than in the placebo arm (7.4 vs 3.8 months, HR 0.53; $P = .004$). As of this writing, there has been no difference in OS between the groups. In December 2019, olaparib was granted FDA approval as a maintenance therapy for this population.[21]

NTRK Fusions

Fusions in the *NTRK* gene are rare but clinically significant molecular events, occurring in up to 1% of patients with pancreatic cancer. This aberration has been demonstrated in case reports to be a potent target with the TRK inhibitor, entrectinib.[147] In 2019, the FDA approved entrectinib in a tumor-agnostic setting for the treatment of patients with advanced solid tumors harboring *NTRK* fusions.[148] As tumor molecular profiling becomes increasingly used, medical oncologists should be aware of this population who have the potential to derive dramatic benefits from targeted therapy.

Stromal Re-engineering and Targeted Therapy

The traditional view of pancreatic cancer stroma has been as a hindrance to delivery of chemotherapy and accounting for the adverse prognosis associated with this cancer. Hedgehog inhibitors were particularly effective in causing stromal depletion.[149] This theory, however, was disproven in the clinical setting, with randomized trials of two hedgehog inhibitors, IPI-926 and vismodegib, failing to improve survival when added to gemcitabine compared with gemcitabine alone. Kalluri et al, from MDACC, recently showed that stromal depletion in genetically engineered mouse models resulted in accelerated tumor growth. In addition, they showed that stromal-depleted pancreatic

cancers were sensitive to the CTLA-4 (cytotoxic T lymphocyte-associated antigen 4) antibody ipilimumab.[150] Similar findings were reported by Rhim et al, who demonstrated that stroma is protective in pancreatic cancer, and deletion of sonic hedgehog accelerated tumor growth; this effect was again reproduced by treatment with smoothened inhibitor.[151] Stroma as a target for therapy continues to be investigated in the clinic.

A recently investigated stromal component is the extracellular matrix component hyaluronan. Enzymatic depletion of hyaluronan by the pegylated hyaluronidase (PEGPH20) resulted in inhibition of cancer growth and prolonged survival when combined with gemcitabine in preclinical studies.[54] Despite early provocative results, PEGPH20 combined with gemcitabine and nab-paclitaxel failed to demonstrate any clinical benefit over treatment with gemcitabine/nab-paclitaxel alone.[152] Even more troubling, in a phase 1b/2 trial conducted by SWOG, PEGPH20 combined with FOLFIRINOX, led to significantly inferior survival compared with FOLFIRINOX alone. The median OS in the mFOLFIRINOX arm was 14.4 months (95% CI 10.1–15.7) versus 7.7 months (95% CI 4.6–9.3) in the experimental arm.[153]

Immunotherapy for Pancreatic Cancer

Immunotherapy has finally come of age, and immune targeting is rapidly changing the course of several cancers. Both innate and adaptive immune systems are involved in the immunosurveillance mechanisms, which include cytotoxic CD8 T-cells, T helper 1 (Th1) cells, dendritic cells, tissue macrophages (M1), and natural killer cells. Cancers must escape these surveillance mechanisms to flourish and degrade health.[154] Preclinical models of pancreatic cancer have informed us that immunosuppressive tumor-associated macrophages, regulatory T-cells, along with scarce effector T-cells (CD8+) occur at even the earliest preinvasive stages and persist through the development of invasive cancer. High concentrations of CD8+ T-cells, when infrequently present in pancreas cancer, are associated with a good prognosis.[155]

Early efforts using modern immunotherapy, specifically checkpoint inhibitors were disappointing. Ipilimumab was investigated in 27 cases of pancreatic adenocarcinoma, and one delayed response occurred.[156] An anti–PD-L1 antibody was studied in an expansion cohort of pancreatic cases ($n = 14$) without any therapeutic responses.[157] These data have highlighted the fact that predictive criteria for checkpoint inhibitors are needed. As of this writing, the only biomarker for potential response to checkpoint inhibition is microsatellite instability, a hallmark of hereditary nonpolyposis colon cancer.[37] Current immunotherapy approaches for pancreatic cancer have taken a variety of forms to include harvest of tumor-infiltrating lymphocytes or leukapheresis of circulating T-cells for ex vivo expansion and reinfusion with or without checkpoint inhibitors or other immune mediators. In addition, some investigators have been evaluating the combination of cytotoxic chemotherapy with checkpoint inhibition with or without a CD40 agonist. Other strategies include integration of cytotoxic checkpoint inhibitors and other immune mediators, pancreatic cancer vaccines, adoptive T-cell transfer, monoclonal antibodies acting at the immune checkpoint level, cytokines, and regulatory T-cell depletion. None of these strategies has a proven benefit thus far and more rigorous preclinical models will be required to accelerate progress with immunotherapy in pancreatic cancer.

MD Anderson Approach to Metastatic Disease

Metastatic pancreatic cancer is characterized by anorexia, cachexia, and pain. Therefore, palliation must always be a major focus for this group of patients and is facilitated by a multidisciplinary approach. Symptomatic relief of biliary obstruction and pain should be addressed before the consideration of systemic therapy. If pain is not well controlled with oral or transdermal opioids, or if these agents are poorly tolerated, patients should undergo an evaluation with an interventional pain specialist to consider celiac or splanchnic plexus neurolysis. In addition to aggressive pain control efforts, other supportive measures should be considered, including appetite enhancers, antidepressants, and central nervous system stimulants.

Biliary obstruction should be relieved by nonsurgical means whenever possible, and we advocate the insertion of expandable metal stents rather than polyethylene biliary stents. Occasionally, percutaneous biliary drainage may be required in the setting of extrahepatic biliary obstruction.

When a patient develops gastric outlet obstruction, we try to estimate the prognosis at that juncture. If life expectancy is greater than 12 weeks, surgical intervention for definitive gastric bypass is considered. For patients with end-stage metastatic disease, the use of duodenal stents is encouraged. For patients with intractable symptomatic ascites, it is important to realize that this may not be caused by carcinomatosis and frequently results from PV or SMV thrombosis. Moderate ascites secondary to portal hypertension may respond to diuretics, including spironolactone, whereas large volume ascites, malignant or otherwise requires repeated paracentesis or an indwelling peritoneal catheter for symptomatic relief. Gastroparesis is another commonly occurring problem that requires promotility agents and dietary and behavioral modification.

MDACC Approach to Systemic Therapy for Advanced Pancreatic Cancer

Systemic therapy for metastatic disease should be actively discouraged in patients with poor PS (ECOG >2) or significant metastatic burden. End-of-life discussions are appropriate at the time of diagnosis. For the majority of patients with newly diagnosed disease, we recommend germline genetic testing and, if feasible, molecular profiling is obtained whenever sufficient tissue is available. When possible, patients with good PS should be treated with systemic therapy in a clinical trial. Off protocol, patients with ECOG PS 0–1 and no contraindications to treatment with FOLFIRINOX are generally advised to receive this regimen as first-line therapy. After progression on FOLFIRINOX, gemcitabine-based regimens like gemcitabine plus nab-paclitaxel are considered. After gemcitabine and nab-paclitaxel, FOLFOX or single-agent capecitabine are preferred. For patients with ECOG PS 1–2, we generally favor gemcitabine and nab-paclitaxel. At the time of disease progression, for those with preserved PS, treatment in a clinical trial is preferred. When this is not available or feasible, treatment with infusional 5-FU and liposomal irinotecan, FOLFIRI, or FOLFOX are all reasonable.

For patients who are not candidates for multiagent chemotherapy, gemcitabine as first-line therapy can be recommended with careful monitoring. At MDACC, our off-protocol approach is to deliver FDR gemcitabine (600–750 mg/m^2) at a rate of 10 mg/m^2 per minute, weekly. Adding erlotinib yields marginal benefit and is not as relevant with the availability of more modern therapy. Nevertheless, when gemcitabine monotherapy is advised, the addition of erlotinib is not unreasonable.

When an objective response or stable disease is observed, chemotherapy is usually continued until there is radiographic or clinical evidence of disease progression, with restaging studies generally performed every 8 to 12 weeks. However, when FOLFIRINOX is being delivered, shifting to a period of maintenance therapy with FOLFIRI or capecitabine may avoid functional impairment from progressive peripheral neuropathy. Gemcitabine-platinum doublets are now generally offered only to patients with BRCA-associated pancreatic cancer.

Summary: Metastatic Disease

Clinically meaningful advances in the treatment of metastatic pancreatic cancer have occurred in the past 5 years. These developments have changed the treatment paradigm for patients with advanced disease, and more patients are experiencing modest improvements in survival and quality of life. Continued efforts to enroll patients with advanced disease into well-designed clinical trials should remain a high priority for oncologists. Finally, attention to palliation should always be a major focus of clinical care.

MD ANDERSON PRACTICE TIPS

- When there are no contraindications to intravenous contrast dye, we prefer high-quality multidetector CT imaging for diagnosis and staging of pancreatic cancer, because it can classify pancreatic cancers as resectable, borderline resectable, locally advanced, or metastatic. Furthermore, our clinicians are comfortable reviewing CT imaging over magnetic resonance imaging and generally rely on CT imaging for restaging purposes.
- On presentation, we recommend germline genetic testing of patients diagnosed with pancreatic cancer, especially those with a family history of breast, ovarian, pancreas, or colon cancer.
- When choosing a site to biopsy for tissue confirmation, we prefer to biopsy a metastatic site versus the tumor in the pancreas. This generally provides more tissue for molecular profiling compared with tissue obtained from fine-needle aspiration of the pancreatic primary.
- Whenever feasible, if insufficient tumor tissue is available for interrogation, we will obtain circulating tumor DNA assay (liquid biopsy) as an alternative to mutational profiling.
- At MDACC, serum tumor markers (most commonly CA 19-9) are routinely followed every 2 to 4 weeks as surrogate markers of response or resistance to therapy. In some patients in whom CA 19-9 levels are undetectable or normal, we have found serum carcinoembryonic antigen or CA 125 levels may occasionally serve as alternative markers.
- Outside a clinical trial, we deliver FOLFIRINOX and gemcitabine/nab-paclitaxel every 2 weeks.
- For patients with localized disease, presentation to our multidisciplinary pancreatic cancer conference is encouraged for input from specialists in medical, surgical, and radiation oncology. Similarly, for patients with limited metastatic disease, input from specialists in radiation oncology, interventional radiology, and surgical oncology is obtained in conference format.

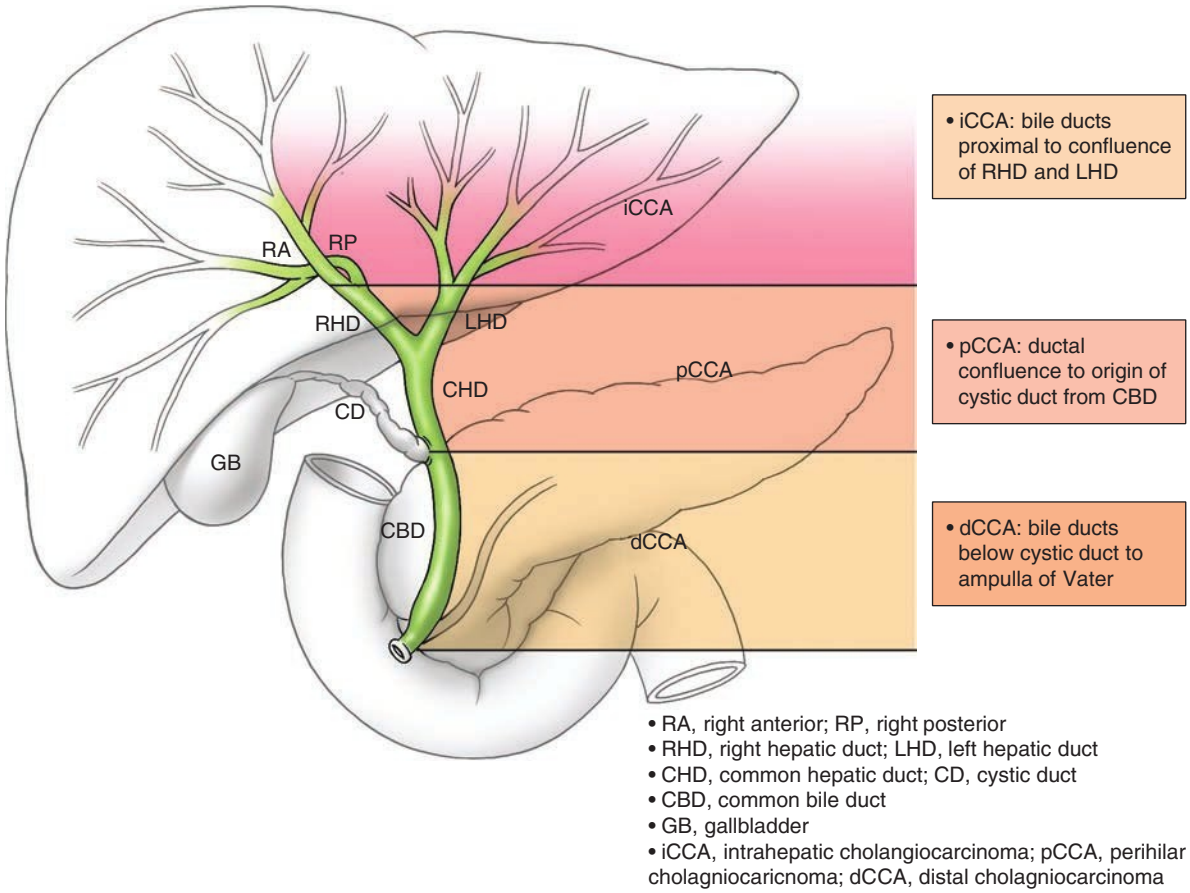
29 Biliary Tract Cancer

Shalini Makawita
Sunyoung Lee
Yun Shin Chun
Millicent A. Roach
Eugene J. Koay
Milind Javle

KEY CONCEPTS



- Biliary tract cancers are rare tumors (prevalence <6/100,000 persons/year) with significant geographic variability.
- Risk factors include cholelithiasis, polyps, porcelain gallbladder, chronic inflammatory states such as inflammatory bowel disease, primary sclerosing cholangitis and nonalcoholic steatohepatitis, genetic syndromes (Peutz-Jeghers or Gardner syndrome), and chronic infection (*Salmonella typhi* carriers, *Opisthorchis viverrine,* and *Clonorchis sinensis,* particularly in Southeast Asia, hepatitis B and C).
- Five-year overall survival rates post R0 resection range from 40% to 50%. High-risk features include positive lymph nodes/margins, vascular invasion, and multifocal disease.
- In localized disease, a multimodality approach is often used:
- In early-stage intrahepatic cholangiocarcinoma, surgical resection with nodal dissection is followed by adjuvant capecitabine or gemcitabine-cisplatin; radiation therapy is given postoperatively for positive margins.
- Neoadjuvant chemotherapy is considered for high-risk features.
- In clinical practice, combination chemotherapy (gemcitabine-cisplatin or gemcitabine-capecitabine) is used adjuvantly, particularly in node-positive disease or R1 resection.
- Systemic therapy in metastatic disease is guided largely by molecular profiling and actionable targets. *FGFR, IDH1, HER2,* and *BRAF* alterations are among the most enriched, and numerous clinical trial options are available for these patients.
- Cholangiocarcinoma has low rates of high microsatellite instability and programmed cell death ligand 1 positivity. It remains overall a "cold tumor," though methods to improve immune cell infiltration and predict responders to immunotherapy are underway.

INTRODUCTION

Biliary Tract Cancers

Biliary tract cancers include gallbladder carcinoma and cholangiocarcinoma, both of which arise from the ductal epithelium. Cholangiocarcinomas are further classified based on their anatomic site as intrahepatic, perihilar, and distal types (Fig. 29–1). Intrahepatic cholangiocarcinoma (ICC) occurs in the bile ducts proximal to the confluence of the right and left hepatic ducts. Perihilar cholangiocarcinoma includes the ductal confluence up to the origin of the cystic duct from the common bile duct, whereas distal cholangiocarcinoma includes the bile duct below the cystic duct origin to the ampulla of Vater. The incidence of these anatomic types varies—perihilar cholangiocarcinoma occurs most frequently, followed by the extrahepatic distal and intrahepatic types. Cholangiocarcinoma has been subclassified by the Liver Cancer Study Group of Japan according to the growth pattern and macroscopic appearance of the tumor into three types as mass-forming, periductal-infiltrating, and intraductal growth types.[1] The mass-forming type has an expansive pattern of growth, whereas the periductal-infiltrating type of tumor extends toward the portal pedicle. The intraductal type spreads along the mucosal layer and is associated with abundant mucin production.

At a microscopic level, cholangiocarcinoma is adenocarcinoma consisting of tubules, acini, solid nests, or trabeculae embedded within a desmoplastic stroma.[2] Other types are exceedingly rare and include

FIGURE 29–1 An overview of cholangiocarcinoma subtypes based on anatomic location. (Reproduced with permission ©2020 The University of Texas MD Anderson Cancer Center.)

adenosquamous and squamous carcinomas that arise in metaplastic epithelium and from liver cysts. Adenocarcinoma, particularly ICC, is radiologically indistinguishable from metastatic tumors from other sites, including those of the stomach, pancreas, lung, or breast. A pattern of immunohistochemical staining is used to distinguish cholangiocarcinoma from other tumor types. The tumor cells typically express cytokeratins AE1/AE3,7, and 19, and epithelial membrane antigen, and display a cytoplasmic positivity for carcinoembryonic antigen (CEA). The absence of a membrane staining for polyclonal CEA and hepatocyte antigen (HepPar 1) aids in distinguishing ICC from hepatocellular carcinoma (HCC) with the pseudoglandular pattern. Other important immunohistochemistry characteristics that distinguish cholangiocarcinoma from other common malignancies are depicted in Table 29–1.[3,4] Most cholangiocarcinomas, particularly the perihilar type have a high degree of desmoplasia, leading to treatment resistance.

Gallbladder malignancies are almost exclusively adenocarcinoma. Rare variants have been described, including papillary adenocarcinoma, mucinous adenocarcinoma, clear cell adenocarcinoma, and signet cell carcinoma. Aggressive histologies of the gallbladder carcinoma include small cell/high grade neuroendocrine carcinoma and squamous histology. These are discussed in detail elsewhere.[5,6]

Epidemiology

Biliary tract cancers are described as rare cancers (a prevalence of less than 6/100,000 persons per year). There is significant geographic heterogeneity in the incidence and prevalence of these cancers worldwide, likely secondary to environmental exposures and genetic susceptibilities. The peak age at diagnosis of cholangiocarcinoma is in the seventh decade of life, and there is a slightly higher incidence in males compared with females. The global incidence of cholangiocarcinoma is depicted in Table 29–2.[7,8]

Several recent studies indicate that the incidence of ICC is rising. Saha et al[9] examined the Surveillance, Epidemiology, and End Results data to assess 40-year

Table 29–1 Pattern of Immunohistochemical Staining in Cholangiocarcinoma

Positive	
AE1/AE3 (or other broad-spectrum keratins, eg, pankeratin)	Diffuse, moderate to strong staining
CK7	Diffuse, moderate to strong staining in most ICC (>90%).
CK17/CK19	Diffuse, moderate to strong staining in most ICC (>80%).
Albumin in situ hybridization (ISH)	Focal to diffuse, moderate to strong staining in most ICC (>90%).
MOC31	Focal to diffuse, moderate to strong staining in most cholangiocarcinoma.
Negative	
CK20	Negative in most ICC. Focal or multifocal, moderate staining can be seen more (<50%) in ICC that arises from large bile ducts. This mirrors the expression in hilar and ECC.
CDX2	Negative in most ICC. Focal or multifocal, weak to moderate staining can be seen (<30%).
TTF1	Negative in most ICC.
GATA3	Negative in most ICC. Focal or multifocal, weak expression can be seen (<10%). If there is diffuse, strong staining for GATA3, other carcinomas, eg, breast and bladder, would have to be excluded.
HepPar-1/arginase-1/glypican-3	Negative in most ICC. If there is robust staining, HCC or combined HCC and cholangiocarcinoma would be a consideration.
SMAD4 (DPC4)	Negative, ie, intact staining, in most ICC.
PAX8	Negative in most ICC.
ER/PR/BRST-2 (GCDFP15)	Negative in most ICC.
NKX3.1/PSA	Negative in ICC.

Table 29–2 Global Incidence Rates of Cholangiocarcinoma

Region	Age- standardized Incidence Rate/100,000 Population
Thailand — North	85
Thailand — South	5.7
China	7.6
South Korea	8.8
Japan	3.5
Germany	3
United Kingdom	2.2
United States	1.6
Australia	0.4
Canada	0.4

trends in the age-standardized incidence of ICC and extrahepatic cholangiocarcinoma (ECC) between 1973 and 2012. They reported that the incidence of ICC increased from 0.44 to 1.18 cases per 100,000 persons, representing an annual percentage change (APC) of 2.30%; this trend has accelerated during the past decade to an APC of 4.36%. In contrast, the incidence of ECC increased modestly from 0.95 to 1.02 per 100,000 persons during the 40-year period (APC, 0.14%). The incidence of cancer of unknown primary origin with histologic features potentially consistent with cholangiocarcinoma decreased by 51% between 1973 and 2012 (APC, –1.87%). Gallbladder carcinoma on the other hand has a different geographic distribution, with high incidence rates reported in South Asia, Latin America, East Asia, and Eastern Europe. The highest mortality rate of gallbladder carcinoma in the world, 35 per 100,000 inhabitants, is found in Southern Chile, which is inhabited by Mapuche Indians.[10] Countries with the top five highest age-standardized incidence rates per 100,000 for males are Bolivia (12.8%), Thailand (9.0%), Republic of Korea (8.4%), Chile (6.6%), and Nepal (6.0%). In the US, an estimated 5000 patients are diagnosed with gallbladder carcinoma annually.[11] There is a strong female predominance with two-thirds of cases and deaths occurring among women. Native American and Alaska Natives have the highest incidence and death rates in the country (3.2 cases and 1.6 deaths per 100,000 people). Gallbladder carcinoma incidence rates are decreasing among all racial and ethnic groups except non-Hispanic Blacks. The incidence rate increased 2.2% per year among non-Hispanic Black men and women in the last decade.[12]

Gallbladder Carcinoma: Risk Factors

The principal risk factor for gallbladder carcinoma is gallstone disease/cholelithiasis. The association between gallstones and cancer has been proven by case-control studies, autopsy studies, and screening surveys. However, the risk of cancer in cholelithiasis is very low at 1%, although 90% of gallbladder carcinoma cases are associated with gallstones. It has been postulated that the chronic inflammation resulting from gallstones leads to epithelial dysplasia and adenocarcinoma. Gallstone size has been correlated with cancer risk, especially with stone size smaller than 3 cm, and the vast majority are composed of cholesterol.[13] These stones are positively correlated with age, female gender, multiparity, genetic factors, high body mass index, and family history of gallstones. Gallbladder diseases like adenomyomatosis, polyps, and porcelain gallbladder are associated with a high risk of cancer.

Other conditions associated with gallbladder carcinoma include inflammatory bowel disease, including Crohn disease and ulcerative colitis, Peutz-Jeghers syndrome, multiple familial polyposis (Gardner syndrome), and anomalous pancreatobiliary junction, particularly in East Asia. Chronic infections, including *Salmonella typhi* carrier state has also been linked with gallbladder carcinoma, independent of the presence of gallstones.[14]

Cholangiocarcinoma: Risk Factors

Cholangiocarcinoma is rare in the Western world, but more common in Asia. In most cases in the West, this disease is rare, sporadic, and without an identifiable risk factor. Higher incidence in Asia is caused by a greater risk of liver fluke infections with *Opisthorchis viverrini* and *Clonorchis sinensis*, particularly in Southeast Asia. Hepatolithiasis and choledochal cysts are also more likely to be associated with cholangiocarcinoma in Asian countries.[15] Other infectious risk factors include hepatitis B in Asia and hepatitis C in the West. Other important factors include primary sclerosing cholangitis (PSC) associated with inflammatory bowel disease, cirrhosis, alcoholism, obesity, fatty liver disease, and smoking. Cirrhosis and nonalcoholic steatohepatitis are most commonly associated with ICC, whereas liver fluke infections are more likely to be associated with perihilar cholangiocarcinoma.[16]

In the Western countries, PSC is an important risk factor for cholangiocarcinoma. The annual incidence of cholangiocarcinoma in PSC is around 1%, with a reported lifetime incidence of 20%.[17] The median time from PSC diagnosis to detection of cholangiocarcinoma is relatively short, at 4 to 6 years. There are no clear predictive factors identifiable in patients with PSC that correlate with an increased risk of cancer, and there are inconsistent data regarding cirrhosis as a risk factor in this setting. Given the high risk, most guidelines recommend surveillance with annual or biennial imaging (ultrasound, magnetic resonance imaging, or magnetic resonance cholangiopancreatography) and laboratory workup including CA 19-9 levels.[18]

Genetic Epidemiology of Biliary Cancers

As discussed above, biliary cancers have unique epidemiologic trends, and considerable research has ensued to identify a genetic basis of these cancers. The largest experience in this field is a genome wide association study from Tata Memorial Hospital, in Mumbai, India.[19] The study included 1042 patients with gallbladder carcinoma and 1709 control patients and demonstrated significant single-nucleotide polymorphisms (SNPs) in the chromosomal region containing the hepatobiliary phospholipid transporter genes, *ABCB1* and *ABCB4*. A smaller Japanese genome wide association study noted that the SNP rs7504990 in the deleted in colon cancer (*DCC*) gene is associated with an increased risk of gallbladder carcinoma.[20] Other genomic variations noted in gallbladder carcinoma include variations in cytochrome P450 enzymes, some of which play a key role in estrogen metabolism, which may explain the female predominance.[21] Bile acids are important for cholesterol homeostasis and the polymorphisms of CYP7A1, which encodes for a rate-limiting step in the bile acid synthesis pathway and may lead to gallbladder carcinogenesis.[22]

It is believed that cholangiocarcinoma may be related to dysregulation of genes involved in inflammation. Genomic variation in the interleukin (IL)-6 receptor (IL-6R), rs8192284 in exon 9 of IL-6R is associated with liver fluke–related cholangiocarcinoma in Thailand. SNPs in IL-8 gene and IL-1 receptor antagonist have been associated with susceptibility to biliary tract cancers.[23] Although the above variants individually have a low risk, collectively these may be important for prediction of individual risk and for future surveillance strategies.

STAGING

Staging of biliary tract cancers requires high-quality, multiphasic computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen and pelvis to evaluate the extent of primary tumor and identify metastases, particularly in the lymph nodes, liver, and peritoneum. CT of the chest, with or without contrast, should be performed to evaluate for pulmonary and lymph node metastases. For patients with biliary obstruction, high-quality cross-sectional imaging should be performed before placement of biliary

stents, which can interfere with tumor visualization. Positron emission tomography (PET)/CT may be considered when CT or MRI findings are equivocal.

Staging laparoscopy as a standalone procedure is not routinely recommended. For patients scheduled for surgical resection of biliary tract tumors, staging laparoscopy has been shown to identify an unresectable disease in 17% of patients, with a higher yield in patients with gallbladder carcinoma and elevated serum CA 19-9.[24] Therefore, diagnostic laparoscopy before open resection can be considered for patients at risk for radiologically occult metastases, particularly peritoneal implants.

The eighth edition of the American Joint Committee on Cancer Staging Manual has separate staging systems for gallbladder carcinoma, ICC, perihilar bile duct cancer, and distal bile duct cancer (Table 29–3).[25] For gallbladder carcinoma, the T category is based on the depth of invasion into the gallbladder wall and extension to surrounding structures. For ICC, tumor size, number, and vascular invasion define the T stage. The T category for perihilar cholangiocarcinoma reflects the central location of these tumors, which can invade the portal vein, hepatic artery, and contralateral bile duct and/or vasculature. For distal cholangiocarcinoma, the T stage is based on the depth of tumor invasion, measured in millimeters.

In biliary tract cancers, regional lymph nodes are defined as those in the hepatoduodenal ligament. With the exception of ICC, the N category is separated by the number of positive regional nodes, with N1 defined as one to three regional nodes and N2 as four or more regional nodes. M1 disease includes distant lymph node metastases, including aortocaval and celiac lymph nodes.

SURGERY FOR BILIARY TRACT CANCERS

The goals of surgery are to evaluate for radiologically occult distant metastases which contraindicate surgery, resect the primary tumor with negative margins, and perform regional lymphadenectomy for adequate staging. Preoperative biopsy is not mandatory before surgery and can be difficult to obtain, particularly in patients with malignant biliary strictures. Transperitoneal biopsy is contraindicated in patients with perihilar cholangiocarcinoma who may otherwise be candidates for liver transplantation because of the risk of peritoneal seeding.[26] In most patients, suspicious clinical presentation and radiologic features, with or without elevated CA 19-9, are sufficient for preoperative diagnosis. In rare patients, a differential diagnosis of immunoglobulin (Ig)G4-associated cholangitis (IAC) presents a diagnostic and therapeutic dilemma. IAC is a fibroinflammatory disorder characterized by IgG4-positive plasma cell infiltration of the bile duct wall and elevated serum IgG4 levels in 74% of patients.[27] Concurrent autoimmune pancreatitis is found in 92% of patients. Imaging features of IAC include long, multifocal strictures and smooth margins of the bile duct lumen.[28] In contrast, cholangiocarcinoma is characterized by a solitary, irregular lesion with eccentric thickening of the bile duct wall.

Estimated 5-year overall survival (OS) rates after R0 resection are reportedly 43%, 40%, 48.5%, and 44% in gallbladder carcinoma, ICC, perihilar cholangiocarcinoma, and distal bile duct cancer, respectively.[29–32] Predictors of worse survival after surgery include lymph node metastases, positive resection margin, vascular invasion, and multifocal disease. Contraindications to surgery include distant metastases, local invasion into critical vasculature that cannot be reconstructed, poor performance status, and insufficient functional liver remnant volume. In selected patients with locally advanced disease or poor prognostic factors, such as lymph node metastases or multifocal diseases, neoadjuvant therapy may be considered, particularly in the setting of a clinical trial. Systemic therapy before surgery may allow assessment of tumor biology, treatment of micrometastases, downsizing of tumors, and increased chance of R0 resection.[33,34]

Gallbladder Cancer

Among patients undergoing definitive surgery for gallbladder carcinoma, 61% of patients are diagnosed incidentally with cancer after laparoscopic cholecystectomy for a presumed benign gallbladder disease.[29] For T1a tumors, simple cholecystectomy is sufficient. For incidentally diagnosed T1b–T3 tumors, reresection, also termed *radical cholecystectomy*, is recommended. Radical cholecystectomy entails resection of the gallbladder bed, typically partial hepatectomy of segments 4B/5, and hepatoduodenal ligament lymphadenectomy. Bile duct resection is reserved for patients who otherwise would have a positive cystic duct margin. Routine resection of port sites from prior laparoscopic cholecystectomy is not recommended.[35]

Intrahepatic Cholangiocarcinoma

Major or minor hepatectomy may be required for R0 resection of ICC, depending on the anatomic extent of a disease. ICC often presents as a large mass invading the hepatic vein, inferior vena cava, and/or portal vein, requiring extended resection. Criteria for resectability of hepatic tumors include adequate vascular inflow and outflow, biliary drainage, and sufficient functional remnant liver volume.[36] For patients with inadequate liver volume, portal vein embolization is a strategy that induces hypertrophy of the remnant liver to enable safe hepatectomy.

Table 29–3 Staging System[a]

Stage		Disease site			
		Gallbladder cancer	**Intrahepatic cholangiocarcinoma**	**Perihilar bile duct**	**Distal bile duct**
I	IA	T1N0: Invades lamina propria or muscular layer	T1aN0: Solitary tumor ≤ 5 cm without vascular invasion	T1N0: Tumor confined to bile duct, with extension up to muscle layer or fibrous tissue	T1N0: Invades bile duct wall with depth < 5mm
	IB		T1bN0: Solitary tumor >5 cm without vascular invasion		
II	IIA	T2aN0: Invades perimuscular connective tissue on peritioneal side without involvement of serosa (visceral peritoneum)	T2No: Solitary tumor with intrahepatic vascular invasion, or multiple tumors, with or without vascular invasion	T2N0: Invades beyond wall of bile duct to surrounding adipose tissue or adjacent hepatic parenchyma	T1N1: 1-3 regional nodes, or T2N0: invades bile duct wall with depth 5-12 mm
	IIB	T2bN0: Invades perimuscular connective tissue on hepatic side without extension into the liver			T2N1, or T3N0; invades bile duct wall with depth >12 mm, or T3N1
III	IIIA	T3 N0: Tumor perforates serosa and/or directly invades liver and/or other adjacent organ or structure, ie., extrahepatic bile duct, colon	T3N0: Tumor perforating visceral peritoneum	T3N0: Invades unilateral branches of portal vein or hepatic artery	T1-3,N2: ≥ 4 regional nodes
	IIIB	T1-3, N1: 1-3 regional lymph nodes	T4N0: Direct invasion of local extrahepatic structures, or any T, N1: regional lymph node metastasis	T4N0: Invades main PV or branches bilaterally, or CHA, or unilateral 2nd-order biliary radicles with contralateral PV or HA involvement	T4, any N: Tumor involves celiac axis, superior mesenteric artery, and /or common hepatic artery
	IIIC	–	–	Any T, N1: 1-3 regional nodes	–
IV	IVA	T4, N0-1: Tumor invades main portal vein or hepatic artery, or invades ≥ 2 extrahepatic organs or structures	Any T, any No, M1	Any T, N2: ≥ 4 regional nodes	Any T, any N, M1
	IVB	T1-4, N2: 4 ≥ regional nodes, or M1		Any T, any N, M1	

[a]Text describes underlined T or N category.
CHA, common hepatic artery; HA, hepatic artery; PV, portal vein.
Data from Edge SB, Byrd DR, Byrd DR, et al: AJCC Cancer Staging Manual, 8th ed. New York, NY: Springer; 2017

Perihilar Cholangiocarcinoma

Perihilar cholangiocarcinoma, also termed *hilar cholangiocarcinoma* or *Klatskin tumor*, is technically challenging to resect because of its central location and frequent involvement of the portal vein, hepatic artery, and second-order bile duct tributaries of both hepatic ducts. Major hepatectomy and bile duct resection with reconstruction are required, and in some patients, vascular resection and reconstruction are needed. Preoperative biliary drainage and normalization of serum bilirubin are necessary before major hepatectomy. Endoscopic biliary stents carry a risk of ascending cholangitis, whereas percutaneous transhepatic biliary drainage is associated with a risk of peritoneal seeding.[37,38] For patients with potentially resectable tumors, consultation with a hepatobiliary surgeon and high-quality axial imaging are recommended before placement of biliary stents.

In patients with unresectable tumors, liver transplantation after neoadjuvant therapy is associated with a post-transplant 5-year recurrence-free survival rate of 65%.[39] Eligibility criteria for liver transplantation include radial diameter smaller than 3 cm and absence of a metastatic disease, including nodal metastases.

Distal Bile Duct Cancer

The standard surgical procedure to achieve margin-negative resection and adequate lymph node harvest is pancreaticoduodenectomy (PD), which is associated with significant morbidity and mortality. In highly selected patients with localized mid–bile duct cancer who are not candidates for PD, segmental bile duct resection with lymphadenectomy has been shown to result in comparable survival as PD.[40]

RADIATION THERAPY

Previous studies have shown that the majority of patients with unresectable ICC die from liver failure caused by vascular compromise (portal vein or hepatic vein obstruction) or biliary obstruction.[41,42] In a retrospective study of 362 patients with unresectable ICC, local tumor progression led to liver failure in 89% patients, half of whom died from tumor-related biliary obstruction and the rest from vascular compromise or a combination of both.[43] Although a higher proportion of patients with ECC die from extrahepatic disease than those with ICC, local tumor-related complications remain an important factor in patient survival.[42] For both ICC and ECC, radiation therapy (RT) plays an important role in achieving local control of the primary tumor.

In recent decades, multiple advances in radiation delivery technologies have made the delivery of high doses of radiation to the upper abdomen safe and effective through multiple radiation modalities: stereotactic body RT (SBRT), intensity-modulated RT (IMRT), proton therapy, and image-guided radiation, which have been reviewed previously.[44–47]

Growing Evidence for Radiation Therapy in the Treatment of Biliary Cancers

Through a series of clinical trials, RT techniques, dose constraints, and specific indications were established that have demonstrated that RT can effectively ablate small liver tumors.[48] Traditional SBRT can achieve excellent results for small hepatic tumors (<5 cm), but it may not be an effective strategy for large liver tumors (>7 cm). The ablative doses are defined as those that can achieve 2-year local tumor control rates greater than 90% and are termed *stereotactic ablative RT*. Studies have shown that SBRT in 3 to 5 fractions can lead to high biliary stricture rates and toxicity to the central hepatobiliary tract and should be avoided.[49] An RT dose of 58 Gy in 15 fractions is considered safe for the biliary tree. Delivery of lower RT doses has resulted in inadequate tumor control in primary ICC and proven insufficient for liver metastases.[50]

In a retrospective study involving 34 patients with 42 lesions, including 31 unresectable ICC and 11 hilar cholangiocarcinomas treated with a median SBRT dose of 30 Gy in three fractions, an actuarial 4-year local control of 79% was achieved.[51] The median OS was 17 months, and the median progression-free survival (PFS) was 10 months. However, 12% (4/34) of patients experienced grade III adverse effects, including duodenal ulceration, cholangitis, and liver abscess.[51] A phase 2 trial of 128 patients included 46 patients with ICC, 35 with HCC, and 47 with colorectal liver metastases.[52] All patients received high-dose conformal RT with a median dose of 60.75 Gy (1.5 Gy per fraction, twice daily) and concurrent hepatic artery floxuridine. The median OS was 15.8 months for all patients, and 13.3 months for patients with ICC.

A retrospective dose-response analysis of patients treated with definitive IMRT for unresectable ICC at MDACC identified 79 patients, most of whom had large tumors (median size 7.9 cm).[41] Eighty-nine percent of patients (n = 70) had received systemic chemotherapy before RT. The median RT dose was 58.05 Gy (range 35–100) in 3 to 30 fractions, with median biologic equivalent dose (BED) of 80.5 Gy. The 1-year and 3-year OS rates were 87% and 44%, respectively, and the median OS after diagnosis was 30 months.[41] RT dose was the single most important prognostic factor, with a higher total dose correlating with improved local control (P = .03) and OS (P = .02). No significant treatment-related toxicities were reported. These results suggest that BED of 80.5 Gy or greater may be

ablative for large ICC tumors, with long-term OS rates comparing favorably to surgical resection. This requires careful treatment planning with attention to organ motion control, protection of surrounding organs, daily image guidance, and incorporation of conformal RT techniques such as IMRT and proton therapy.

A prospective study of hypofractionated proton RT for patients with either HCC or ICC further validated the findings of MDACC's retrospective analysis. In a study of 44 patients with HCC, 37 patients with ICC, and two patients with mixed HCC and ICC, patients received 15 fractions of radiation to a maximum of 67.5 Gy in 15 fractions.[53] The 2-year local control for ICC was 94.1%, and the 2-year OS for ICC was 46.5%. Encouraging results were also noted for HCC. Toxicities in both ICC and HCC were very low. This study led to two phase 3 randomized trials, NRG GI001 for ICC (hypofractionated radiation vs observation after initial chemotherapy; NCT02200042) and NRG GI003 for HCC (protons vs photons; NCT03186898). The NRG GI001 was terminated because of lack of patient accrual, and the NRG GI003 study is ongoing.

The results of escalated-dose RT in unresectable ECC have not been as clearly favorable as those for ICC. In 1990, a multicenter, retrospective study of patients with ECC reported an improved median survival in patients receiving more than 40.0 Gy compared with those receiving 40.0 Gy or less.[54] A retrospective analysis of 52 patients with unresectable ECC treated between 1957 and 2000 at MDACC shed light on the limitations of conventional dosing in preventing local progression.[55] Although the study was limited in its statistical power by its small patient number, it did suggest a possible association between increasing radiation dose and improved local control.

However, in a modern retrospective cohort of patients with unresectable ECC (2001–2015), there was no dose-response relationship.[42] In this study, RT was given at a median dose of 50.4 Gy with a range of BED between 36–98 Gy (median 59.5). The cohort was split into an escalated-dose RT (EDRT) group (>50.4 Gy in 28 fractions, BED >59.5) and a conventional-dose group (BED ≤59.5). The EDRT group did not demonstrate improved OS or freedom from local progression, and showed worse freedom from distant progression. In addition, EDRT was associated with the onset of grade 3 or higher lymphopenia, which has been shown to portend poor prognosis in other disease sites.[56] Toxicity rates were comparable between radiation dose groups. Thus, although dose escalation has shown promising results in unresectable ICC, the results with ECC suggest that higher RT doses do not provide the same local control and OS benefits. The proximity of ECC tumors to the bowel limit the ability to completely cover the tumor with higher doses of radiation and may explain the differences in outcomes.

In contrast to the locally advanced setting, consolidative chemoradiation has shown promise in the earlier-stage resectable setting. SWOG's S0809 study investigated the use of gemcitabine and capecitabine followed by consolidative chemoradiation.[57] This study is discussed below and showed that survival rates were similar between R0 and R1 resection groups after radiotherapy.

In summary, there is benefit in the use of adjuvant and definitive RT to achieve local control and prolonged survival for patients with ICC and ECC. The assessment of response in these settings can be challenging, and rigorous standards remain to be defined. There is also a strong rationale to combine RT with systemic therapy to achieve both local and distant control. In recent years, various molecular targets have been identified for cholangiocarcinoma. Preclinical data combining RT with targeted agents in these different molecular settings of cholangiocarcinoma may be fruitful; clinical trials in these areas are needed.

SYSTEMIC THERAPY

Neoadjuvant Therapy

The rationale for neoadjuvant therapy includes tumor downstaging, treatment of micrometastatic disease, and assessment of tumor biology before resection.[58–60] Neoadjuvant therapy enhances the R0 margins rate and prevents distant metastases, both of which are associated with improved clinical outcomes.[61–66] For example, a study of patients who had neoadjuvant chemoradiation showed 100% of the margin-negative surgical resection (R0) versus 54% in those who did not have neoadjuvant therapy. Survival benefit was manifested in a study comparing patients who received neoadjuvant concurrent chemoradiation with those who did not, and the 5-year survival rate was superior (53 vs 23%).[67] Intrahepatic, combined intrahepatic and extrahepatic, and extrahepatic recurrence rates were 60.9%, 18.6%, and 21.0% in resected ICC.[68] The sites of recurrence in 41% to 60% of resected hilar cholangiocarcinoma were distant metastases[69,70] and in 85% of patients with recurrent gallbladder carcinoma.[70] In a study of 401 patients,[71] the cumulative recurrence rate was higher in R1 than in R0 resections (86 vs 57% at 5 years; $P < .001$). Other studies show that patients with a R0 resection had longer median OS and recurrence-free survival, and lower recurrence probability than those with a R1 resection.[72–75]

The ideal systemic chemotherapy regimen in the neoadjuvant setting is unclear. The combination of gemcitabine and cisplatin has been the most frequently used chemotherapy regimen for resectable cholangiocarcinoma since the validation of clinical efficacy by

the ABC-02 trial.[76] FOLFIRINOX (5-fluorouracil, irinotecan, and oxaliplatin) resulted in favorable antitumor activity in locally advanced or metastatic biliary tract cancer.[77] More recently, the combination of gemcitabine, cisplatin, and nab-paclitaxel was tested in advanced biliary tract cancers, and it showed promising OS and PFS superior to historical controls treated with gemcitabine-cisplatin alone.[34] Objective response rates (ORR) in patients who received the doublet and triplet chemotherapy were 26.1%[76] and 45%,[37] respectively. This superior efficacy has led to the frequent use of the triple chemotherapy in the neoadjuvant setting at MDACC. The National Comprehensive Cancer Network (NCCN) officially listed the triple combination as one of the neoadjuvant chemotherapy options (NCCN Guidelines, v. 2.2020). As of this writing, a neoadjuvant clinical trial of gemcitabine, cisplatin, and nab-paclitaxel is underway at MDACC along with seven other institutions (NCT03579771).

Adjuvant Therapy

Cholangiocarcinoma has a high recurrence rate at distant sites after a curative surgical resection, and this suggests the importance of adjuvant therapy in addition to neoadjuvant therapy (perioperative therapy). Two large studies compared survival in patients who underwent curative-intent resection alone, chemotherapy alone, chemotherapy with RT, and RT alone.[78,79] Overall, adjuvant therapy did not provide statistically significant survival benefit with a trend toward better survival—the median recurrence-free survival (odds ratio [OR] 0.74, 0.55–1.01). Chemotherapy (OR 0.39, 0.23–0.66) and chemoradiation therapy (OR 0.61, 0.38–0.99) showed statistically significant survival benefit, but RT alone did not, with an OR of 0.98 (0.67–1.43). This study clearly demonstrated that any form of adjuvant therapies had survival advantage in patients with R1 resection or a lymph node–positive disease: margin-positive and node-positive patients had the ORs of 0.36 (0.19–0.68) and 0.49 (0.30–0.80), respectively. Radiation therapy alone showed benefit in patients with R1 resection (OR 0.33, 0.14–0.81). A meta-analysis including 15 studies and 5060 patients revealed that adjuvant chemotherapy was associated with improved OS with a HR of 0.66 (0.55–0.79).[80] Survival benefit was larger in high-risk patients with positive margins and lymph nodes.[81] Based on these strong clinical data, adjuvant therapy has been generally recommended in all the patients who undergo surgical resection for ICC, ECC, and gallbladder carcinoma. However, phase 3 evidence was lacking until recently.

A randomized, phase 3 study (PRODIGE 12-ACCORD 18-UNICANCER GI) compared the efficacy of adjuvant gemcitabine and oxaliplatin, and it did not show statistically significant clinical benefit with a trend toward better survival, with the median recurrence-free survival of 30.4 versus 18.5 months with a HR of 0.88 (0.62–1.25).[82] The median OS was 75.8 versus 50.8 months with a HR of 1.08 (0.70–1.66). Most patients included in this study had a R0 resection (86%). However, this trial was underpowered and may have missed a positive outcome because of low patient numbers and heterogeneity of biliary cancers that were included. Another study from Japan in patients with intravenous (IV) mitomycin C with 5-fluorouracil, followed by oral fluorouracil compared survival with those who had surgical resection alone.[79] It revealed that patients who had resected gallbladder carcinoma had a statistically significant 5-year survival rate and disease-free survival, whereas patients with pancreatic cancer, cholangiocarcinoma, and ampullary cancer did not have survival benefit.

Adjuvant 5-fluorouracil or gemcitabine was compared after surgical resection with observation in an open-label, phase 3, randomized, controlled clinical trial in patients with resected periampullary cancers (ESPAC-3 trial).[83] This study included patients with cholangiocarcinoma (ampullary 297 and bile duct 96), both node-positive and -negative diseases, and R0 and R1 resections. 5-fluorouracil 425 mg/m^2 IV was administered 1 to 5 days every 28 days, and gemcitabine 1000 mg/m^2 IV once a week for 3 weeks of every 4 weeks for 6 months. The median OS in the chemotherapy and observation groups was 43.1 and 35.2 months (HR 0.86, 95% CI 0.66–1.11), respectively. After adjusting for independent prognostic variables, a HR was 0.75 (P = .03). When compared with the observational group, the gemcitabine group (HR 0.77, 95% CI 0.57–1.05) had better survival than the 5-fluorouracil group (HR 0.95, 95% CI 0.71–1.28). Of note, a R1 resection was a poor prognostic indicator, with a HR of 1.98.

Capecitabine monotherapy was investigated in a randomized, controlled, phase 3 study for patients with cholangiocarcinoma or gallbladder carcinoma who had undergone a surgical resection (BILCAP trial).[84] Patients assigned to capecitabine 1250 mg/m^2 twice daily on days 1 to 14 of a 21-day cycle for eight cycles, and clinical outcomes were compared with patients who did not receive adjuvant chemotherapy under observation. The study included patients with R0 and R1 resections; positive and negative lymph nodes; tumor grades I, II, and III; and ICC and ECC and gallbladder carcinoma. This trial did not meet its primary end point. The median OS by intention-to-treat was 51.1 months (95% CI 34.6–59.1) in the capecitabine arm compared with 36.4 months (95% CI 29.7–44.5) in the observation arm (HR 0.81, 95% CI 0.63–1.04; P = .097). However, the survival benefit was significant after adjusting for nodal status, disease grade, and sex (HR 0.71, 95% CI 0.55–0.92; P = .010). The most common adverse events from capecitabine

were hand-foot syndrome (20%), diarrhea (8%), and fatigue (8%). In an unplanned subset analysis, no statistical benefit was noted with capecitabine for patients with hilar cholangiocarcinoma or muscle-invasive gallbladder carcinoma.

Although there are no prospective randomized clinical trials that are available to compare the efficacy of monotherapy with combination chemotherapy, most clinicians use combination chemotherapy (eg, gemcitabine + cisplatin or gemcitabine + capecitabine), particularly in patients with a node-positive disease or R1 resection because combination therapy is better established in the advanced or metastatic setting.[76] The NCCN guidelines recommend capecitabine as a preferred medication in the adjuvant setting. Combination regimens including 5-fluorouracil (or capecitabine) plus oxaliplatin (or cisplatin), gemcitabine plus capecitabine (or cisplatin) are potential alternatives, as is gemcitabine or 5-fluorouracil (or capecitabine) monotherapy.

Concurrent Chemoradiation

Adjuvant chemotherapy alone discussed above demonstrated improved survival in the BILCAP trial. Traditionally, in the US, a combination of concurrent chemoradiation and chemotherapy has been used in patients with high-risk features (positive node, R1 resection, or lymphovascular and perineural invasion).[85–87] Adjuvant concurrent chemoradiation, sequential chemotherapy followed by RT, and chemotherapy alone were compared in resected ICC.[88] This study demonstrated that patients had better clinical outcomes when RT was added in the adjuvant setting. A HR for overall mortality at advanced pathologic stages III and IV were 0.55 (0.41–0.74) and 0.92 (0.70–1.33), respectively, in patients who received concurrent chemoradiation and chemotherapy followed by radiation, compared with those who only received chemotherapy.

Capecitabine (1650 mg/m^2/day) and 5-fluorouracil (225 mg/m^2/day) are widely used as a radiosensitizer in gastrointestinal malignancies including pancreatic adenocarcinoma, rectal cancer, and cholangiocarcinoma.[89,90] These agents are known to cause direct and abscopal effects when combined with RT.[89,91] Capecitabine is more frequently used than 5-fluorouracil because of the convenience of oral administration and elimination of catheter-related complications.[92]

In ECC and gallbladder carcinoma, a phase 2 clinical trial investigated adjuvant capecitabine and gemcitabine followed by concurrent chemoradiation therapy (SWOG S0809).[57] The study included patients with stages pT2–4, lymph node–positive and –negative diseases, and R0 and R1 margins. Treatment consisted of four cycles of gemcitabine (1000 mg/m^2 IV on days 1 and 8) and capecitabine (1500 mg/m^2/d on days 1–14, in divided doses twice daily) every 21 days. After reimaging, patients not experiencing disease progression then received capecitabine (1330 mg/m^2/d, in divided doses twice daily, 7 days per week) concurrent with radiotherapy (45 Gy to regional lymph nodes including retro-pancreaticoduodenal, celiac, and portal vein nodes and 54–59.4 Gy to a preoperative tumor bed). The median OS was 35 months, and that of patients with R0 and R1 resections was 34 and 35 months (not statistically different); the 2-year survival rate was 67% and 60% in R0 and R1 resections (not statistically different). The median disease-free survival was 26 and 23 months in R0 and R1 resections, respectively. This study demonstrates that patients who received concurrent chemoradiation after combination chemotherapy have similar OS and disease-free survival in R0 and R1 resections.

In summary, adjuvant capecitabine is regarded as the standard of care after surgical resection of biliary tract cancer based on the BILCAP trial. The role of adjuvant capecitabine for hilar cholangiocarcinoma remains controversial, and chemoradiation should be considered, particularly for R1 resection. Adjuvant gemcitabine and cisplatin remains a potential option, because the phase 3 trial with this combination was underpowered. The ongoing phase 3 ACTICCA-1 trial (NCT02170090) investigating gemcitabine and cisplatin versus capecitabine will be instructive in regard to future options.

Incidental Gallbladder Carcinoma

Better imaging techniques and assessment of risk factors have led to a higher rate of preoperative diagnosis of gallbladder carcinoma.[93] However, this cancer is often discovered incidentally during cholecystectomy for benign diseases such as polyps or cholecystitis[94–99]; the incidence of gallbladder carcinoma in all cholecystectomies is 0.2% to 3%.[100] In a retrospective analysis, 68% of patients underwent re-resection, with the most common surgical procedures being gallbladder BED resection, liver 4B/5 segmentectomy, and hepatoduodenal ligament lymphadenectomy. Resection with T2/T3 diseases significantly increased survival, whereas the resection of the common bile duct did not increase the R0 resection rate but increased postoperative complications, unless the cystic duct was involved by cancer.[95] The incidence of port-site metastases is about 10%, and routine resection of port sites has no effect on survival.[101] If gallbladder carcinoma is deemed unresectable perioperatively, systemic therapy is recommended. After surgical resection is completed for a resectable disease, adjuvant chemotherapy is recommended, with radiation reserved for margin-positive disease.

SYSTEMIC THERAPY FOR METASTATIC DISEASE

First-Line Chemotherapy

The standard-of-care frontline therapy for metastatic biliary tract cancer was established by the ABC-02 trial in 2010 which showed superiority of gemcitabine plus cisplatin compared with gemcitabine alone for advanced biliary cancers (Table 29–4).[76] In this phase 3 study, 410 patients with cholangiocarcinoma, gallbladder, or ampullary carcinoma were randomized in a 1:1 fashion to receive gemcitabine alone (1000 mg/m^2 on days 1, 8, and 15 of a 4-week cycle) or cisplatin (25 mg/m^2) followed by gemcitabine at above dose on day 1 and 8 of a 3-week cycle. At a follow-up of median 8.2 months, medial OS was 11.7 months in the gemcitabine plus cisplatin arm compared with 8.1 months with gemcitabine alone (HR 0.64, 95% CI 0.52–0.80; $P < .001$). Median PFS was 8.0 months in the doublet arm compared with 5.0 months with gemcitabine alone ($P < .001$). Rates of neutropenia were higher in the doublet arm (25.3% vs 16.6% grade 3/4); however, rates of infection were similar. Increased liver enzymes occurred with gemcitabine alone (27.1% vs 16.7%; $P = .01$), which the authors concluded may have been secondary to inferior control of the disease compared with the doublet.[76] Other toxicities were comparable. Gemcitabine and cisplatin compared with gemcitabine alone was also tested in a Japanese population with similar findings.[102]

A treatment regimen with better efficacy than gemcitabine and cisplatin has yet to be approved for clinical use, although several promising therapies are emerging. In a phase 2, open-label, single-arm study of gemcitabine, cisplatin, and nanoparticle albumin-bound (nab)-paclitaxel (NCT0239263), patients were treated with gemcitabine 1000 mg/m,^{2} cisplatin 25 mg/m,^{2} and nab-paclitaxel 125 mg/m^2 on days 1 and 8 of a three-week cycle.[34] Because of grade 3/4 hematologic toxicities, doses were reduced to 800 mg/m^2 of gemcitabine, 25 mg/m^2 of cisplatin, and 100 mg/m^2 of nab-paclitaxel ($n = 28$ in reduced-dose group). Of 60 patients, the majority had ICC (63%), followed by gallbladder carcinoma (22%), and ECC (15%). Patients who had prior chemotherapy were excluded (except in the adjuvant setting >6 months prior). A median PFS of 11.8 months (95% CI 6–15.6) and disease control rate of 84% was noted at 12.2 months follow-up. Twelve patients who had unresectable disease were converted to resectable and underwent surgery. Median OS of 19.2 months (95% CI 13.2–unable to estimate) was reported, which is an improvement compared with historical controls of gemcitabine and cisplatin.[34] Grade 3 or greater toxicity was seen in 58% (61% high-dose, 54% low-dose group). The most common grade 3 or higher toxicity was neutropenia (33%), followed by anemia (16%). Nonhematologic toxicities ranged from 2% to 6% for diarrhea, elevated alkaline phosphatase, vomiting, constipation, and transaminitis. A phase 3, randomized clinical trial to compare gemcitabine, cisplatin, and nab-paclitaxel with standard-of-care gemcitabine and cisplatin is currently underway (SWOG 1815 study; NCT03768414).

Other frontline studies have assessed the addition of agents such as S-1, an oral fluoropyrimidine derivative designed to enhance clinical use and reduce gastrointestinal toxicity (NCT02182778),[103,104] or derivatives such as NUC-1031 (a phosphoramidate transformation of gemcitabine) designed to overcome resistance mechanisms to gemcitabine (ABC-08 study, NCT02351765).[105,106] As described further below, there has been a paradigm shift toward targeted therapy in biliary tract cancers, and targeted agents alone or in combination with chemotherapy are also being evaluated in the frontline setting.

Second-Line Cytotoxic Chemotherapy

After progression on gemcitabine and cisplatin, standard-of-care second-line chemotherapy options are limited. In the ABC-06 study (NCT01926236), patients were randomly assigned 1:1 to modified (m) FOLFOX (folinic acid, fluorouracil, and oxaliplatin) with active symptom control (ASC) versus ASC alone after prior gemcitabine-cisplatin therapy.[107] Of 162 patients, the median OS was 6.2 versus 5.3 months for ASC with mFOLFOX compared with ASC alone; the 6- and 12-month OS rate was 50.6% and 25.9%, compared with 35.5% and 11.4%, respectively. Approximately 59% of patients experienced grade 3 or 4 toxicity in the chemo-ASC arm compared with 39% in the ASC-alone arm. Although survival was greater than expected with ASC alone, the findings indicate clinical benefit of mFOLFOX with ASC in the second-line setting.[107] Modified FOLFIRI (folinic acid, fluorouracil, and irinotecan) has been compared with mFOLFOX in the second-line setting via a 1:1 randomization after progression on gemcitabine/cisplatin, and mFOLFIRI was noted to be tolerable but not superior to mFOLFOX in the second line (NCT03464968).[108] Retrospective and meta-analyses of chemotherapy in the second or later line setting have shown a modest PFS of 2.4 to 3.2 months across studies, with an average median OS average of 7 months.[109–111]

Targeted Therapy: Molecular Profiling of Biliary Tract Cancers

The development of molecular profiling technologies has led to increased genomic-profiling studies of all cancers, including those of the biliary tract.[112–119] At

Table 29–4 Summary of pertinent systemic therapy trials in unresectable and metastatic biliary tract carcinoma

Trial Name (Clinical Trials Identifier)	Phase	Molecular Target	Treatment Regimen	Patients	Outcome	Adverse Events	Status[a] [reference]
ABC-02 (NCT00262769)	Randomized, phase 2 – first line	None – cytotoxic	Cisplatin (25 mg/m^2) + gemcitabine (1000 mg/m^2) D1, D8 (every 3 weeks) vs gemcitabine 1000 mg/m^2 D1, D8, D15 (every 4 weeks)	N = 410 randomized N = 204 assessed (gem/cis) N = 206 assessed (gem)	**mPFS:** 8.0 vs 5.0 mo ($P < .001$) **mOS:** 11.7 vs 8.1 mo (for gem/cis) **HR:** 0.64% (95% CI 0.52–0.80; $P < .001$)	**Gr 3/4: (gem/cis vs gem)** neutropenia (25.3 vs 16.6%), any hematologic (32.3 vs 23.6%); LFT abnormal (16.7 vs 27.1%); any infection (18.2 vs 19.1%)	Completed; standard of care first line[76]
Gemcitabine, cisplatin, and nab-paclitaxel for treatment of advanced biliary tract cancers (NCT02392637)	Open-label, single-arm, phase 2 – 1st line	None – cytotoxic	Gemcitabine 1000 mg/m,^{2} cisplatin 25 mg/m^2, and nab-paclitaxel 125 mg/m^2 D1, D8 (21-day cycle) After– N = 32, doses reduced: 800 mg/m,^{2} 25 mg/m,^{2} 100 mg/m,^{2} respectively	N = 60	**mPFS:** 11.8 mo (95% CI, 6.0–15.6) **mOS:** 19.2 mo (95% CI 13.2–not reached) **PRR:** 45% **DCR:** 84%	**Gr ≥3:** 58% total (61% in high dose; 54% dose reduced) **Gr3, Gr4:** neutropenia (30, 11%); diarrhea/ elevated ALP/ vomiting (4%)	Active, not recruiting[34]

the chromosome level, initial studies of comparative genomic hybridization (CGH) shed light on chromosomal losses and gains and insight into the heterogeneity of biliary tract cancer.[113] A meta-analysis of five CGH studies encompassing a total of 98 ICCs showed frequent gains in chromosomes 1q, 5p, 7p, 8q, 17q, and 20q in three or more studies (>20% overall change).[113] Losses of copy number on chromosome 1q, 4p, 8p, 9p, 17p, and 18p were also reported. The aggregate data noted possible ethnic diversity between three Asian studies compared with a German study. Similarities were also noted to a previous CGH meta-analysis of HCC.

Comprehensive molecular profiling technologies and high-throughput genomic-profiling studies have shed light on commonly occurring alterations in biliary tract cancers.[114–119] Next-generation sequencing of 75 patients with cholangiocarcinoma that examined 236 cancer-related genes had shown tumor protein p53 (*TP53*) (35 and 45%) and *KRAS* (24 and 40%) as commonly occurring alterations in both ICC and ECC, respectively.[114] Other frequently altered genes in the intrahepatic subgroup include AT-rich interaction domain 1A (*ARID1A*), isocitrate dehydrogenase 1 (*IDH1*), myeloid cell leukemia 1 (*MCL1*), Erb-B2 receptor tyrosine kinase 2 (*ERBB2*), *SMAD4*, F0box, WD repeat domain containing 7 (*FBXW7*), and cyclin-dependent kinase inhibitor 2A (*CDKN2A*). In a larger study of patients (412 ICC, 57 ECC, and 85 gallbladder carcinoma), a similar profile was noted with commonly altered genes in *TP53*, *CDKN2A/B, KRAS, ARID1A, IDH1, SMAD4, ERBB2,* and fibroblast growth factor receptor (*FGFR*).[115] Of these, *FGFR* (11%) and *IDH* (20%) alterations were predominantly found in ICC and noted to be mutually exclusive. *KRAS* and *TP53* mutations were associated with poor prognosis, and *FGFR2* alterations were associated with better prognosis and OS (HR 0.478; $P = 0.03$), female gender, and younger age (<40 years). *IDH1/2* alterations were not found to be prognostic. *ERBB2* (16%) alterations were found predominantly in gallbladder carcinoma. Broadly, the functionally validated genes can be categorized into cell cycle–related (*TP53*, *CDKN2A* mutation/deletion, and *CCND1* amplification), receptor tyrosine kinases (*FGFR*), *MAPK* pathway (*KRAS, NRAS,* and *BRAF*), chromatin modifying (*ARID1A/B, BAP1, PBRM1*), and *IDH1/2* alterations.[116–121] *BAP1* alterations also appear to confer a more aggressive phenotype, associated with bone metastases, although case numbers have been limited.[114] A summary of commonly altered genes and their frequencies are found in Table 29–5.

Table 29–5 Frequency of Genetic Alterations in Biliary Tract Carcinomas

Genetic Alteration	Prevalence of Genetic Alterations		
	Intrahepatic Cholangiocarcinoma[a]	Extrahepatic Cholangiocarcinoma[a]	Gallbladder Carcinoma[a]
Total Genomic Alteration/Patient	**3.6**	**4.4**	**4.0**
TP53	25%–30%	40%	60%
RAS (KRAS/NRAS)	20%–25%	40%–45%	10%–15%
CDKN2A/B Loss	25%–30%	15%–20%	20%
ARID1A	15%–20%	10%–15%	10%–15%
BAP1	10%–15%	10%	6%
FGFR1-3	10%–15%	<5%	3%–5%
ERBB2 (HER2/neu) Amplification	3%–5%	15%	15%–20%
PBRM1	10%	5%	n/a[b]
IDH1/2	20%	0%	0%
SMAD4	4%–7%	20%–25%	30%
PTEN	5%	n/a[b]	Up to 4%
BRAF Substitution	5%	3%	1%
PIK3CA Substitution	5%–6%	7%	10%–15%
BRCA1	0.4%	2%	0.3%
BRCA2	2.7%	2%–3%	4%

[a]Rates of genetic alterations greater than 10 are rounded to the nearest 5 and provided in ranges.[114,115]
[b]Consensus on prevalence unclear.

The results of these and other molecular profiling studies have led to a paradigm shift in the treatment of advanced and metastatic biliary tract cancers with development and use of targetable agents. An estimated 35% to 40% of biliary tract cancers contain targetable genetic alterations.[122]

Targeted Therapies

FGFR Alterations

The *FGFR* signaling pathway is a family of proteins consisting of four receptors (FGFR1–4) and 22 ligands, which, when activated, results in downstream signaling via the mitogen-activated protein kinase, phosphoinositide 3-kinase (PI3K)/AKT, Janus kinase/signal transducers, and activators of transcription (JAK-STAT) pathways. This in turn leads to cell proliferation, growth, migration, and angiogenesis.[123,124]

FGFR alterations are found in approximately 15% of ICCs and tend to be driver mutations. *FGFR2* fusions or translocations are the most common type of alteration, and two common fusion partners identified have been the genes *AHCYL1* and *BICC1*.[125] These two fusions have been shown as mutually exclusive with *KRAS* and *BRAF* mutations and result in constitutive phosphorylation of mitogen-activated protein kinase in both in vitro and in vivo studies.[126,127]

Several FGFR inhibitors are currently under investigation. BGJ398, also known as infigratinib is an orally bioavailable FGFR1–3 inhibitor and was studied in a multicenter, open-label, phase 2 trial in the second-line setting for advanced or metastatic cholangiocarcinoma with *FGFR* alterations (NCT02150967).[128] Infigratinib was dosed at 125 mg once daily for 21 days of a 28-day cycle. Of the 61 patients reported at data cutoff, the majority (n = 48) had FGFR2 fusions, but mutations were found in eight patients and amplification in three patients. An ORR of 14.8% (18.8% for *FGFR2* fusion subset) and a median PFS of 5.8 months (95% CI 4.3–7.6), and a disease control rate (DCR) of 75.4% (83.3% in the FGFR2 fusion subset) was reported.[128] An update with 71 patients with *FGFR2* fusions showed an ORR of only 31.0% (95% CI 20.5–43.1) and disease control rate of 83.6% (95% CI 72.5–91.5). Median PFS was 6.8 months (95% CI 5.3–7.6) and median OS of 12.5 months (95% CI 9.9–16.6) was noted.[129] Overall the therapy was well tolerated, with hyperphosphatemia (73.2%), fatigue (49.3%), and stomatitis (45.1%) noted as the most common adverse events. Hyperphosphatemia is a common class effect of FGFR inhibitors secondary to the role of the FGFR pathway in renal phosphate metabolism and is considered an on-target effect.[130,131] As of this writing, hyperphosphatemia is managed with phosphate binders, low-phosphate diets, and diuretics.[131] Ocular toxicity is also a potential unique side effect of FGFR inhibitors.

Pemigatinib is another FGFR1–3 oral inhibitor investigated in a phase 2, multicenter, open-label study (FLIGHT-202; NCT02924376) for previously treated advanced or metastatic cholangiocarcinoma (89% ICC) patients with *FGFR* alterations.[132] The study included three cohorts: (1) those with FGFR2 fusions/rearrangements, (2) those with other FGF pathway alterations, and (3) patients without FGFR alterations. Patients were treated with 13.5 mg pemigatinib orally once daily for 14 consecutive days on a 21-day cycle until progression or toxicity. Of 146 patients enrolled in the study, the majority (n = 107) had FGFR2 fusions/rearrangements. At median follow-up of 17.8 months, an ORR of 38% (95% CI 26.5–45.4) was noted in the *FGFR2* fusion/rearrangement–containing subset. No responses were noted in the patients with other *FGFR* alterations or in those without *FGFR* alterations. A DCR of 82% (range 74%–89%) for fusion-containing patients was noted, compared with 40% (range 19%–64%) and 22% (range 6%–48%) in other and no *FGFR* alteration groups, respectively. Median OS was 21.1 months (range 14.8–not reached) in patients with *FGFR2* fusions. A similar side effect profile to infigratinib was noted with hyper- and hypophosphatemia, arthralgias, and stomatitis.[132] Based on these results, pemigatinib was given a FDA-accelerated approval for advanced or metastatic cholangiocarcinoma patients with *FGFR2* gene fusions or rearrangements after progression on at least one prior line of therapy pending verification in a confirmatory trial.

TAS120 or futibatinib is a highly selective FGFR1–4 irreversible inhibitor that has completed phase 1/2 trials in cholangiocarcinoma. In an initial phase 1 study of TAS120 in advanced solid tumors, an ORR of 25% was noted in cholangiocarcinoma patients with FGFR2 fusions (n = 28).[133] These initial results led to the FOENIX-CCA2 (NCT02052778) phase 2, single-arm, multicenter study in second-line or greater advanced or metastatic cholangiocarcinoma patients with *FGFR2* gene fusions/rearrangements.[134] Of 103 patients, an interim analysis of 67 patients with more than 6 months of follow-up showed an ORR of 34.3% and DCR of 76.1%. Median duration of response of was 6.2 months (range 2.1–14.2) with a 1.6-month (range 1.0–4.9) median time to response. Side effect profile was similar to the other FGFR inhibitors above.

Multiple other nonselective tyrosine kinase inhibitors with anti-FGFR activity are also under investigation in the second-line setting in patients with FGFR-altered cholangiocarcinoma.[124,135–139] All three of the agents above (infigratinib, pemigatinib, and futibatinib) are also under investigation in the first-line setting in phase 3, randomized clinical trials compared with standard-of-care gemcitabine-based chemotherapy in

this patient population (NCT03773302, NCT03656536, and NCT04093362).[140] The results of these studies can potentially lead to a chemotherapy-free option for patients with advanced or metastatic cholangiocarcinoma harboring *FGFR2* fusions/rearrangements.

IDH Inhibitors

Approximately 20% of cholangiocarcinomas (predominantly intrahepatic) contain *IDH1/2* mutations.[114,115,119] IDH1 and 2 are essential for production of metabolic enzymes that prevent cellular oxidative damage via conversion of isocitrate to alpha-ketoglutarate.[141] Mutations in these genes increase the production of D-2-hydroxyglutarate, an oncometabolite, and decreased α-ketoglutarate production, which in turn increases oncogenesis. The most common IDH1 mutation seen in cholangiocarcinoma is R132C.[141]

The phase 3, multicenter, randomized, double-blind study ClarIDHy (NCT02989857) investigated the efficacy of ivosidenib in *IDH1*-mutated cholangiocarcinoma after progression on prior therapy. Patients were randomly assigned 2:1 to receive ivosidenib 500 mg or placebo with the possibility for crossover on progression.[142] At 6.9 months, median PFS was 2.7 months for the ivosidenib group (95% CI 1.6–4.2) versus 1.4 months (95% CI 1.4–1.6) with a HR of 0.37 (95% CI 0.25–0.54; $P < .0001$). A significant difference in OS was not noted between the treatment and placebo groups (10.8 months in intent-to-treat [95% CI 7.7–17.6] vs 9.7 months [range 4.8–12.1], HR 0.69 [95% CI 0.44–1.10; $P = .06$]). Correcting via rank-preserving structural failure time method had noted a median OS of 6.0 months (HR 0.46 [range 0.28–0.75]; $P = .0008$). Objective response rates were low ($n = 3/124$ patients [2%]) with 51% achieving stable disease compared with 28% in the placebo group.[142] The 12-month OS rate of this study (48%) when compared with historic controls of regorafenib and mFOLFOX in second line (27% and 25.9%, respectively) show comparable results.[108,143,144] The most common grade 1/2 adverse events in the treatment group included nausea (33%), diarrhea (31%), and fatigue (23%). Grade 1/2 ascites was noted in 13% of the treatment group and 8% in the placebo group. Ascites was the most common grade 3 or greater adverse event, although rates were the same between the treatment and placebo groups (7%).[142]

HER2 Blockade

Overexpression of human epidermal growth factor receptor 2 (HER2) encoded by *ERBB2* is a well-established driver of oncogenesis in multiple cancer types and approved for use in breast and gastric/gastroesophageal carcinoma. In biliary tract cancer, genetic alterations (amplifications or mutations) in *ERBB2* are predominantly seen in gallbladder carcinoma (16%), followed by ECC (11%), and ICC (3%).[115,145]

A multihistology trial of ado-trastuzumab emtansine (T-DM1) at a dose of 3.6 mg/kg IV given once every 3 weeks in HER2-amplified solid cancers included 6 ($n = 58$) patients with biliary tract cancer (NCT02675829).[146] ORR was 26%, and 1 of 6 (17%) in biliary cancer. No significant correlation was found between the degree of HER2 amplification and response. MyPathway is an ongoing open-label, multicenter, phase 2a basket study (NCT02091141) aimed at evaluating safety and efficacy of targeted therapies across tumor types.[147] In a subset of 11 patients with advanced biliary tract cancer, with eight HER2 amplifications/overexpression and three mutations, four partial responses were seen at 12 months, with three others achieving disease stability. The National Cancer Institute–Molecular Analysis for Therapy Choice is a national study using genomic testing for matching patients with refractory disease to potential targeted therapies.[148] In a subprotocol evaluating T-DM1 in 36 patients with HER2-amplified nonbreast and nongastroesophageal cancers, three biliary adenocarcinoma patients were included. In this study, a trend toward increased tumor shrinkage was seen with higher levels of gene copy number. Although the above studies had small sample sizes and a small number of responders, basket trials are particularly useful for identification of signals to targeted therapy in rare tumors to warrant further investigation.[148,149]

BRAF Blockade

BRAF alterations are found in approximately 1% to 5% of biliary tract cancer. In the histology-independent, phase 2 basket study (NCT01524978) with *BRAF V600*–containing nonmelanomatous cancers, a total of 122 patients were enrolled.[150] Of these, eight patients with advanced cholangiocarcinoma were included. No CRs were noted; a partial response lasting more than 12 months was noted in one (12%) patient, and stable disease was achieved in four (50%) patients.[150] Combination BRAF + MEK inhibition (dabrafenib and trametinib) in *BRAFV600*-mutated rare tumors was studied in the phase 2, open-label "ROAR" basket trial, where 33 patients with biliary tract cancer were included (NCT02034110).[151] Of 32 evaluable patients, investigator-assessed ORR was 41% (95% CI 24–59). Median PFS of 7.2 months (95% CI 4.6–10.1 months) and median OS of 11.3 months (95% CI 7.3–17.6 months) was seen, warranting further clinical investigation in this patient population.

Other Targetable Pathways

Neurotrophic tropomyosin-related kinase gene fusions are present in approximately 3% to 5% of

cholangiocarcinomas, and larotrectinib tissue agnostic approval for all solid tumors in the refractory setting without known acquired mutation is also applicable to biliary tract cancers.[152] Anti–angiogenesis-directed therapies have also been highly studied in advanced biliary tract cancers, including vascular endothelial growth factor inhibitors and multi-tyrosine kinase inhibitors. Overall, results have not shown significant added benefit to the chemotherapy backbone in unselected patients with cholangiocarcinoma.[153–160]

Taken together, the identification of targeted genetic alterations in biliary tract cancer and the development of targeted agents have revolutionized therapy in the advanced and metastatic setting. Pertinent trial data have been summarized in Table 29–5. Sequencing of these agents and further studies into resistance mechanisms in terms of gatekeeper mutations and development of other secondary genetic alterations is an area of active research. In addition, with multiple FGFR inhibitors now being studied in the first-line setting compared with standard of care, a chemotherapy-free frontline option may soon become available in the metastatic setting for the FGFR-altered population (particularly those with *FGFR2* gene fusions).

Immunotherapy

Immune checkpoint inhibitors (ICIs) have revolutionized the treatment of multiple cancer types; however, their role in biliary tract cancer is not well established. Certain genetic factors have shown to predict response to ICIs such as tumor mutation burden (TMB), program death-ligand/program cell death protein 1 (PD-L1/PD-1) expression, and mismatch repair (MMR) gene deficiency. These factors are indicative of high microsatellite instability (MSI-H) and an increased likelihood of tumor-specific neoantigen that can be recognized by the immune system.[161] The majority of biliary tract cancers have a low-to-intermediate TMB. Comprehensive genomic profiling of 3634 cholangiocarcinomas showed an approximately 1% rate of MSI-H.[119] Global loss of heterozygosity (gLOH) higher than 16% was seen in 11% of studied cases. Approximately 3.5% and 1.4% of evaluated cases had TMB higher than 10 and more than 20 mutations/megabase, respectively. PD-L1 positivity was seen in 9% of tested cases, and *PD-L1* amplification was present at a rate of 0.27%.[119,161] Stages of chronic inflammation and infectious/viral etiologies are associated with cholangiocarcinoma. Although other virally-associated cancer types have shown encouraging response rates to ICI therapies, it is unclear whether this pattern is evident in biliary tract cancer. The highly heterogeneous nature of these cancers and desmoplastic stroma may also be barriers of response to ICIs.[161] Key immunotherapy trials with dosing schedules and outcomes are summarized in Table 29–6 and highlighted below.

In the KEYNOTE-028 phase 1b study (NCT02054806) of pembrolizumab in advanced or metastatic biliary tract cancers in the second line or greater with at least 1% PD-L1 expression, an ORR of 13% (all PR, 95% CI 2.8–33.6) was seen among 23 patients at a median follow-up of 5.7 months (range 0.6–55.4). This translated to a median OS and PFS of 5.7 months (95% CI 3.8–9.8) and 1.8 months (95% CI 1.4–3.1), respectively. No grade 4 or 5 adverse events were noted, although 16.7% had grade 3 toxicities.[162,163] PD-L1 positivity was not a requirement for inclusion in KEYNOTE-158 (NCT02628067), a phase 2 study of 200 mg pembrolizumab given once every 3 weeks after progression on prior standard-of-care therapy. Of 104 patients included in this study, 61 were positive for PD-L1 expression. ORR was 5.8% (all PR, including 1 PD-L1–negative patient; 95% CI 2.1–12.1) in all patients (6.6% among PD-L1 expressors vs 2.9% among nonexpressors). Median duration of response had not been reached; however, an estimated 50% had duration of response at 24 months or longer. Median OS and PFS were 7.4 months (95% CI 5.5–9.6) and 2.0 months (95% CI 1.9–2.1), respectively. One patient had grade 5 renal failure, and grade 3 or higher adverse events were reported in 13.5%. Taken together, these data suggest modest activity of pembrolizumab monotherapy without new safety signals noted[162,163]

A multicenter, phase 2 study of nivolumab in 54 patients with biliary tract cancer who had received between one and three prior lines (NCT02829918) showed a 22% investigator-assessed ORR had been noted with a DCR of 59% (central independent review; ORR 11%, DCR 50%). All responses were in patients with proficient MMR. Median PFS was 3.68 months (95% CI 2.3–5.69) and median OS was 14.24 (95% CI 5.98–not reached). PD-L1 expression was significantly associated with prolonged PFS ($P < .001$). Grade 3/4 toxicities included hyponatremia (6%) and elevated alkaline phosphatase (4%).[164]

Preliminary data from a randomized, phase 2, multicenter study (BilT-01; NCT03101566) of nivolumab with gemcitabine-cisplatin (Arm A) or nivolumab with anticytotoxic T-lymphocyte–associated protein 4 (CTLA-4) agent ipilimumab (Arm B) in untreated advanced or metastatic biliary tract cancer was reported.[165] Of 71 eligible patients (n = 35 Arm A; n = 36 Arm B), the 6-month PFS rate was 70% in arm A and 18.6% in Arm B. This translated to a median PFS of 8.8 months (95% CI 6.1–11.3) and median PFS of 4.1 months (95% CI 2.4–5.2)), respectively.[165] Although the combination immunotherapy arm appears to be inferior to the nivolumab with chemotherapy arm, the preliminary data are comparable with historical

Table 29–6 Summary of Pertinent Immunotherapy Therapy Trials in Unresectable and Metastatic Biliary Tract Carcinoma

Trial Name (Clinical Trials Identifier)	Phase	Molecular Target	Treatment Regimen	Patients	Outcome	Adverse Events	Statusa [reference]
KEYNOTE-028 (NCT02054806)	Phase 1b, basket study	PD-L1 positive	Pembrolizumab 10 mg/kg IV every 2 weeks	N = 24	**ORR:** 13.0% (95% CI 2.8–33.6) **mDOR:** not reached **mOS:** 5.7 mo (3.1–9.8) **mPFS:** 1.8 mo (1.4–3.1)	**Gr 3–5:** 16.7% **Any Gr:** pyrexia (16.7%), nausea/pruritis (12.5%), hypothyroid (8.3%), severe skin reaction/colitis (4.2%)	Active, not recruiting[162]
KEYNOTE-158 (NCT02628067)	Phase 2, multicohort	Unselected for PD-L1	Pembrolizumab 200 mg IV every 3 weeks	N = 104 (PD-L1 expressor, n = 61; PD-L1 nonexpressor, n = 24)	**ORR:** 5.8% (95% CI 2.1–12.1); (6.6% PD-L1 pos; 2.9% (PD-L1 neg) **mDOR:** not reached **mOS:** 7.4 mo (95% CI 5.5–9.6) **mPFS:** 2.0 mo (95% CI 1.9–2.1)	**Gr 3–5:** 13.5% **Any Gr:** fatigue (14.4%), rash (11.5%), hypothyroidism (7.7%), pneumonitis (5.8%)	Recruiting[163]
Nivolumab for patients with advanced/refractory biliary tract cancer (NCT02829918)	Multicenter, phase 2	PD-L1 positivity not required	Nivolumab 240 mg IV every 2 weeks (16 weeks), then 480 mg IV every 4 weeks	N = 54 (n = 46 assessed) • PD-L1+: n = 18	**ORR:** 22% (investigator-assessed); 11% (central review) • PD-L1 + investigator assessed: 50% **DCR:** 59% **mPFS:** 3.68 mo (95% CI 2.3–5.69) **mOS:** 14.24 mo (95% CI 5.98–not reached)	**Any Gr:** increased ALP (24.1%), lymphopenia (22.2%), AST increase/fatigue (20.4%), anemia (18.5%) **Gr 3:** hypoNa (5.6%), HTN/ALP increase (3.7%)	Active, not recruiting[164]

[a]Clinicaltrials.gov status as of 6/27/2020.

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; D, durvalumab; DCR, disease control rate; HTN, hypertension; HypoNa, hyponatremia; mDOR, median duration of response; mOS, median overall survival; mPFS, median progression-free survival; ORR, objective response rate; PD-L1, program death-ligand 1; PR, partial response; T, tremelimumab.

controls of PFS for gemcitabine-cisplatin alone, suggesting unclear survival benefit of nivolumab to standard-of-care chemotherapy at this time. Response rates, safety profiles, and survival data are pending maturity, which will shed further light on the clinical benefit and utility of the above combinations.

Durvalumab with or without tremelimumab has also been studied in the phase 1 setting (NCT01938612) in an Asian population.[166] A DCR and median OS of 16.7% and 8.1 months, and 32.2% and 10.1 months in the durvalumab (n = 42) arm compared with the durvalumab and tremelimumab (n = 65) arm, respectively, was reported at 12 weeks. Both the monotherapy and combination therapy arms were noted to show encouraging clinical benefit warranting further investigation.

Preliminary data from a phase 2 study of durvalumab and gemcitabine-cisplatin with or without tremelimumab in patients naïve to prior chemotherapy (NCT03046862)[167] has also been reported. Patients were enrolled in three cohorts as detailed in Table 29–6. Initial biomarker analyses noted frequent mutations in ataxia telangiectasia–mutated (*ATM*), *BRCA2*, DNA polymerase epsilon, mutS homolog 2 (*MSH2*), and *CDKN2A* genes with distinct somatic variants in responders compared with nonresponders. TMB had not correlated with survival outcomes (PFS or OS); however, interestingly, early reductions in cell-free circulating tumor (ct) DNA allele frequencies on cycle 3 on day 1 were significantly associated with ORR ($P < .015$). Response rates (73.4% and 73.3%) were similar in the three- and four-combination cohorts, and the triple combination (gemcitabine-cisplatin and durvalumab) has moved forward to phase 3 testing compared with gemcitabine-cisplatin alone in the first line (TOPAZ-1; NCT03875235).

In summary, the treatment of biliary tract cancer has evolved rapidly in the last decade. An understanding of the diversity of these cancers and their molecular underpinnings, and access to novel therapies have led to transformative changes for patients with this cancer.

MD ANDERSON APPROACH TO BILIARY TRACT CARCINOMA

Our approach to biliary tract cancer is guided by its clinical and molecular diversity and focuses on multidisciplinary management. Given the guarded prognosis of these cancers, clinical trials are encouraged in all clinical settings. The majority of cases of biliary tract cancer treated at our center are ICC, a trend that is commonly seen in all cancer centers in the United States. The diagnosis of ICC is established by a core-needle biopsy and includes an immunohistochemical analysis to exclude other sites of primary invasion. Routine endoscopies to rule out other primary sites are not performed in the absence of symptoms. High-quality liver protocol imaging is mandated for all patients, and PET/CT is used to examine ambiguous findings. Surgical resection with nodal dissection, followed by adjuvant capecitabine or gemcitabine and cisplatin is offered for patients with early-stage disease. Neoadjuvant chemotherapy with gemcitabine and cisplatin or gemcitabine, cisplatin, and nab-paclitaxel is considered for high-risk cases such as multifocal and radiologic node-positive diseases. Postoperative radiotherapy is usually reserved for margin-positive ICC.

Extrahepatic biliary tract cancers, particularly hilar cholangiocarcinoma (Klatskin tumor) requires a complex, multispecialty approach that includes endoscopy; interventional radiology; and medical, surgical, and radiation oncology teams. Complications from this cancer include biliary obstructions and cholangitis with sepsis, and therefore, establishment and maintenance of biliary drainage is critical. Specialized imaging to detect a hilar mass, vascular approximation, and nodal spread is required, and specific CT/MRI protocols have been established. A tissue diagnosis for these cancers is established with brush cytology or biopsy using endoscopic ultrasound. Core biopsy of the hilar stricture carries a risk of peritoneal dissemination and is therefore discouraged. A minority of patients are candidates for surgery and adjuvant therapy. Given the relatively limited benefit with adjuvant capecitabine for hilar cholangiocarcinoma, chemotherapy with gemcitabine and capecitabine, followed by chemoradiation with capecitabine as per prior phase 2 data (SWOG 0809) are encouraged. Select patients with hilar tumors larger than 3 cm and fitting the Mayo Clinic criteria are offered orthotopic liver transplantation. Gallbladder cancer in the early stages is often detected incidentally during cholecystectomy. For these cases and for surgically resectable tumors, radical cholecystectomy is performed, followed by adjuvant chemotherapy. Perioperative chemotherapy is often considered for a high-risk disease, such as with nodal disease, T3 tumors, and regional spread.

All patients with biliary tract cancer, regardless of stage or histology, are offered molecular profiling using next-generation sequencing. Furthermore, patients receiving targeted therapies are also offered serial liquid biopsies. Given the timeline for these analyses, targeted therapy is typically offered in the second or subsequent lines of treatment. Typical first-line regimens for biliary tract cancers include gemcitabine-cisplatin and gemcitabine-cisplatin-nab-paclitaxel, or clinical trials such as currently with a first-line FGFR inhibitor versus chemotherapy. Sequencing of therapies based on clinical outcomes, such as systemic chemotherapy followed by consolidative IMRT or SBRT, is commonly used in cholangiocarcinoma at MDACC.

Continuous chemotherapy until progression is not encouraged because this affects quality of life.

The choice of systemic therapy in the second-line setting is guided largely by molecular profiling results. ICC, in particular, is enriched with *FGFR, IDH1*, *BRAF*, and other actionable targets and has many options available as clinical trials; pemigatinib was recently FDA approved in this setting for ICC with *FGFR2* fusions. Biliary tract cancers without actionable mutations are usually treated with FOLFOX as per the ABC-06 clinical trial. The role of immunotherapy with checkpoint inhibitors is considered as experimental for biliary tract cancers, other than those tumors with MSI-H. However, several clinical trials are currently investigating the role of checkpoint inhibitors combined with systemic chemotherapy or radiotherapy.

MD ANDERSON PRACTICE TIPS

- Treatment is guided by clinical and molecular diversity and uses a multidisciplinary approach.
- In early-stage ICC, surgical resection with nodal dissection is followed by adjuvant capecitabine or gemcitabine-cisplatin; radiation therapy is given postoperatively for positive margins.
- Neoadjuvant chemotherapy is considered for disease with high-risk features, including presence of a multifocal disease or radiographic node positivity.
- Select patients meeting the Mayo Clinic criteria with hilar tumors smaller than 3 cm are candidates for orthotopic liver transplantation.
- All patients with biliary tract cancer are offered molecular profiling using next-generation sequencing.
- The choice of systemic therapy in the second-line metastatic setting is guided largely by molecular profiling results and actionable targets. *FGFR, IDH1, HER2*, and *BRAF* alterations are among the most enriched and numerous clinical trial options available for these patients.

KEY CONCEPTS

- Risk factors for liver cirrhosis and hepatocellular carcinoma (HCC) include chronic hepatitis B and C infections, metabolic syndrome, and alcohol abuse. Hepatology management of risk factors reduces the risk of cancer recurrence.
- Treatment for HCC is multidisciplinary and involves hepatology; interventional radiology; and medical, surgical, and radiation oncology.
- Surgical resection is considered for patients who have small-volume disease without portal hypertension. Those with portal hypertension receive locoregional and/or radiation therapy, and liver transplantation is considered.
- Systemic therapy is recommended for patients with advanced or metastatic HCC, and locoregional and radiation therapy are combined in eligible patients.
- Targeted therapy (anti-vascular endothelial growth factor and tyrosine kinase inhibitors) and immune checkpoint inhibitors are two main backbones of systemic therapy. These include sorafenib, lenvatinib, atezolizumab with bevacizumab, nivolumab with and without ipilimumab, pembrolizumab, cabozantinib, regorafenib, and ramucirumab.
- There are no established guidelines for fibrolamellar HCC (FLHCC) and combined HCC-cholangiocarcinoma (cHCC-CC). Systemic therapy such as 5-fluorouracil plus interferon-α2b for FLHCC and platinum-based chemotherapy for cHCC-CC is combined with surgical resection and locoregional and radiation therapy.

Hepatocellular carcinoma (HCC) is a malignancy of worldwide significance and has become increasingly important in the United States (US). It is the most common primary liver malignancy, the sixth most common cancer, and the third most common cause of cancer-related deaths worldwide.[1] Eighty percent of new cases occur in developing countries, but the incidence is rising in economically developed regions, including Japan, Western Europe, and the US.[2–5] Liver cirrhosis is the seventh leading cause of death in the world, the tenth most common cause of death in the US, and is acknowledged as a premalignant condition for developing HCC.[6,7]

In the US, hepatitis C virus (HCV), alcohol use, and nonalcoholic fatty liver disease (NAFLD) are the most common causes of cirrhosis.[8] The incidence of HCC doubled between the years 1975 to 1995 and continued to rise through 1998.[9,10] This trend was previously expected to continue because of the estimated 4 million US individuals who are HCV-seropositive and the known latency of HCC development from the initial HCV infection, which may take two to three decades.[10] However, given the improved treatment regimens now available for patients with chronic HCV, HCV-related HCC incidence may decrease in the next few years.[11] It is also known that NAFLD-associated cirrhosis is on the rise in the US.[12–14] A majority of patients diagnosed with HCC present with advanced disease that is not amenable to curative procedures.

EPIDEMIOLOGY

Hepatocellular carcinoma represents approximately 85% of all primary liver cancers.[15] The distribution of HCC varies significantly by geography; it is endemic in parts of the world where hepatitis B virus (HBV) is also endemic. In Western countries, HCV infection

and alcoholic cirrhosis are the principal risk factors for HCC. Because of the rising incidence of HCV infection in American subpopulations, the incidence has increased.[10] Moreover, HCC incidence increases with age, with the age of peak incidence varying somewhat with the population. The median age group for development of HCC is between the fifth and sixth decades of life. The disease is also seen in children and young adults in areas where HBV is endemic, and most of these infections occur perinatally. In all populations worldwide, there is a strong male predominance in HCC incidence. In the US, the male-to-female ratio is 2.7:1, and HCC incidence rates are higher among Blacks than Whites (6.1 vs 2.8 per 100,000 in men). Hispanics, Asians, Pacific Islanders, and Native Americans have a higher HCC frequency. Independent of HBV status, a family history of HCC in first-degree relatives carries a relative risk of 2.4 and overall risk (OR) of 2.9.[16] Hepatoblastoma is the most common type of childhood liver cancer, and Beckwith-Wiedemann syndrome is known to be associated with this.[17] Familial aggregation and germline mutations of the *APC* (adenomatous polyposis coli) gene have also been reported in hepatoblastoma.[18] Hereditary tyrosinemia, type 1 glycogen storage disease, Alagille syndrome, Fanconi anemia, and ataxia-telangiectasia increase the risk of HCC.[19–25]

ETIOLOGY AND RISK FACTORS

HCC develops commonly, but not exclusively, in a setting of liver cell injury, which leads to inflammation, hepatocyte regeneration, liver matrix remodeling, fibrosis, and ultimately cirrhosis. The major etiologies of liver cirrhosis are diverse and include chronic hepatitis B and chronic hepatitis C infections, chronic alcohol consumption, certain medications or toxic exposures, and genetic metabolic diseases. Nonalcoholic fatty liver disease, especially in association with obesity and diabetes, is emerging as a recognized risk factor for HCC, even in patients without cirrhosis. The mechanisms by which these varied etiologies lead to HCC are not fully elucidated. The principal risk factors that have been associated with cirrhosis and HCC are listed in Table 30–1. As such, the populations deemed to bear a significant risk for HCC generally reflect the same population for which routine screening is targeted (Table 30–2). The recommendations for the target population are also deemed to be cost-effective.[26] The ability of the clinician to identify at-risk patients eligible for HCC screening should be emphasized because utilization of HCC screening is revealed to be suboptimal, even among patients with a gastroenterology subspecialist.[27,28] This has significant implications for early detection of HCC and treatment options.

Chronic Hepatitis B Infection

Chronic infection HBV remains common and well recognized as a strong risk factor for HCC. An important mechanism in HBV is the integration of HBV DNA into the cellular DNA of hepatocytes.[29,30] Effects on transcription factors, JAK/STAT pathways, and DNA repair, even in the absence of fibrosis, may be a culprit in the pathogenesis.[29,31] In vitro studies suggest that the X protein encoded by HBV plays a role in the pathogenesis of HCC through the mechanism of HBV binding to and inhibiting p53-mediated transcriptional activity and downregulating DNA repair ability.[32] It is hypothesized that this mechanism is related to potential carcinogenesis, augmented by HBV replication in the case of active chronic HBV.

The estimated 5-year cumulative frequency of progression to cirrhosis ranges from 8% to 20% without treatment for HBV, at higher frequencies in HBV e-antigen (HBeAg)-negative patients relative to HBeAg-positive patients.[29] The incidence of HCC in patients with chronic HBV without cirrhosis is estimated to be 0.1 to 0.8 per 100 person-years, in contrast to 2.2 to 4.3 per 100 person-years in the context of cirrhosis.[33] Based on the examination of ethnicity, geographic origin, and medical history, certain high-risk groups have been identified in the recommendations to implement HCC screening.[26,29,33]

Hepatitis B virus replication also correlates with HCC risk.[34] Patients with active chronic HBV with ongoing viremia should also be screened, although chronic HBV treatment is available and considered safe. However, achieving viral suppression may not reduce the risk of HCC to nil, and this population continues to be screened. Inactive carriers who are HBeAg-negative also bear a higher risk for HCC compared with controls who are HBsAg-negative.[34,35] Although not tested for routinely, genotype C in Asians, genotype F in Alaskans, and mutations in precore or basal core promoter regions have been implicated in increased HCC risk.[31,34]

The at-risk population in chronic HBV with or without cirrhosis should undergo routine HCC screening.[29,30,33] Screening also applies to patients who have achieved viral suppression (ie, undetectable HBV DNA levels, normal serum alanine aminotransferase level) who are HBsAg-positive because ongoing treatment does not entirely eliminate the risk for HCC. The REACH-B scoring system allows the clinician to readily input data including gender, age, serum alanine aminotransferase level, HBeAg status, and HBV DNA levels to generate a 3-, 5-, and 10-year estimates for the risk of development of HCC.[36,37]

Chronic Hepatitis C Infection

Hepatocellular carcinoma in the context of chronic HCV is diagnosed more frequently in the cirrhotic liver

Table 30–1 Etiologic Factors Associated with an Increased Risk of Cirrhosis and Hepatocellular Carcinoma

Category	Specific Etiology	Comment
Infectious (77% of cases of HCC worldwide attributed to viral hepatitis)	Chronic hepatitis B virus infection	Underlying etiology in a significant majority of HCC cases worldwide, primarily in Asia, sub-Saharan Africa; patients without cirrhosis are at increased risk of HCC
	Chronic hepatitis C virus infection	Principal underlying etiology in Japan, the United States, Western Europe, Mediterranean basin countries; may account for 20%–25% HCC cases worldwide
Metabolic disorders deficiency	Hereditary hemochromatosis	Phlebotomy in patients whose disease has progressed to cirrhosis does not alter or improve the HCC risk
	Wilson disease	
	α-1 antitrypsin deficiency	
	Porphyria cutanea tarda	
	Glycogen storage disease (GSD)	HCC risk is best described in GSD type I via adenoma transformation
	Citrullinemia	
	Familial intrahepatic cholestasis	
Other	Alcohol	Significant cause of cirrhosis; synergistic cofactor with HCV
	Aflatoxin B_1	Cofactor with HBV that increases risk of developing HCC; relative risk varies from 2- to 4-fold in nonendemic regions
	Androgenic steroids	Some association reported, primarily case reports and small series
	Oral contraceptives	
	Autoimmune hepatitis	
	Primary biliary cholangitis (PBC)	Elevated HCC risk is pertinent when disease progresses to cirrhosis or in male patients with PBC
	Nonalcoholic fatty liver disease (NAFLD)/ nonalcoholic steatohepatitis (NASH)	Increasing evidence for association with HCC with or without cirrhosis; incidence of NAFLD is rising in the United States
	Tobacco	Weak association suggested that it is independent of HBV infection, alcohol

than in the non-cirrhotic liver.[38] Unlike HBV, HCV does not integrate into the host DNA. The exact mechanism of carcinogenesis is not well understood. The risk of developing HCC further increases with concomitant alcohol use, which may act in synergy.[39]

Pertinent risk factors for acquiring HCV include but are not limited to intravenous drug use, sexual exposure, chronic hemodialysis, blood transfusions before year the 1992, perinatal transmission, and acquiring tattoos/piercings at unregulated establishments.[40,41] In the US, the birth cohort of patients born between 1945 and 1965 directed prior screening recommendations.[41,42] In 2020, the US Services Preventative Task Force updated the screening recommendation to include general screening of patients ages 18 to 79 years for HCV infection.[43] Expanding the screening cohort allows for identification of the undiagnosed population. As such, eligible patients can be promptly treated to achieve sustained viral remission (SVR), preferably before cirrhosis develops, thereby curtailing the progression to cirrhosis and, subsequently, the risk for developing HCC.

With interferon (IFN)-based therapies, the annual incidence of HCC could be reduced from 1% to 8% to 0.07% to 1.2%.[31,44] The motivation for treatment is further driven by the advent and efficacy of direct-acting antivirals (DAAs) used to treat chronic HCV.[33] DAAs have become the standard for chronic HCV treatment since 2014, supplanting IFN-based treatment, which was fraught with limitations including genotype coverage and adverse effects. DAAs have better tolerance and improved adverse effect profiles

Table 30–2 Patients at Highest Risk for HCC with Recommendations for Screening

Population Group	Threshold Incidence for Efficacy of Surveillance (>0.25 LYG; % per year)	Incidence of HCC (% range per year)
Surveillance Benefit		
Asian male hepatitis B carriers over age 40 y	0.2	0.4–0.6
Asian female hepatitis B carriers over age 50 y	0.2	0.3–0.6
Hepatitis B carrier with family history of HCC	0.2	Incidence higher than without family history
African and/or North American Blacks with hepatitis B	0.2	HCC occurs at a younger age
Hepatitis B carriers with cirrhosis	0.2–1.5	3–8
Hepatitis C cirrhosis	1.5	3–5
Stage 4 PBC	1.5	3–5
Genetic hemochromatosis and cirrhosis	1.5	Unknown, but probably >1.5
Alpha-1 antitrypsin deficiency and cirrhosis	1.5	Unknown, but probably >1.5
Other cirrhosis	1.5	Unknown
Surveillance Benefit		
Hepatitis B carriers younger than 40 y (males) or 50 y (females)	0.2	<0.2
Hepatitis C and stage 3 fibrosis	1.5	<1.5
NAFLD without cirrhosis	1.5	<1.5%

LYG, life-years gained; PBC, primary biliary cholangitis.
Reproduced with permission from Marrero JA, Kulik LM, Sirlin CB, et al: Diagnosis, Staging, and Management of Hepatocellular Carcinoma: 2018 Practice Guidance by the American Association for the Study of Liver Diseases, Hepatology 2018 Aug;68(2):723-750.

to allow for achieving SVR after 8 to 12 weeks of treatment. Effective pan-genotypic coverage by glecaprevir/pibrentasvir and sofosbuvir/velpatasvir has overcome the challenges of treating some patients with HCV, such as those with genotype 3. Several DAAs, including these two medications, have also been approved for treatment in patients with compensated cirrhosis. In non-cirrhotic patients, SVR may curtail the risk of progression to cirrhosis and even potentially reduce the extent of fibrosis. In cirrhotic patients, SVR reduces but does not eliminate the risk of HCC.[44]

Once SVR is achieved, the risk of HCC persists. In a Veterans Affairs study, SVR led to a reduced risk of HCC to an annual incidence of 0.90%, in contrast to a higher annual incidence of 3.45% in those who did not achieve SVR.[45] In comparison, in patients who achieved SVR after receiving IFN-based therapies, the annual incidence was estimated to be 0.33%.[45,46] Direct-acting antiviral treatment was not without controversy in the field of HCC. One study was concerned that SVR with DAA still led to a 3.16% rate of developing de novo HCC; for the patients already treated for HCC, the study reported recurrence in 28.81% of patients.[47] Another study reported recurrence of HCC in 27.6% of the examined cohort.[48] Additional studies, however, did not support the aforementioned concern.[49,50] Nonetheless, after achieving SVR, these patients continue to undergo HCC screening or surveillance.[30,33]

Although some data have suggested that HCC can potentially arise in the non-cirrhotic liver, a formal recommendation about routine screening in this population is not established.[51,52] Specifically, there is risk observed in patients with bridging fibrosis without frank cirrhosis.[52] The American Association for the Study of Liver Diseases (AASLD) recognizes chronic HCV with advanced fibrosis (stage 3) without cirrhosis as being at an increased risk.[33] The decision of whether to screen this population is also predicated on the clinician's ability to reliably ascertain the fibrosis stage. Several noninvasive methods (such as the NAFLD fibrosis score, serologic fibrosis tests, and elastography) are available.

Some of the principal differences between hepatitis B- and hepatitis C-associated HCC are listed in Table 30–3.

Table 30–3 Comparison Between Hepatitis B Viral Infection and Hepatitis C Infection and Hepatocellular Carcinoma

Factor	HBV	HCV
Mean age (y) of HCC presentation (range)	55 (31–76)	66 (38–83)
Highest incidence	400 million carriers in Asia and Africa	170 million infected worldwide; accounts for 50% of HCC cases in Japan, the United States, and Western Europe
Cirrhosis	Cirrhosis presents in 88% of HBV infection	Cirrhosis presents in 93% of HCV infection
Morphology	Solitary lesions	Multifocal lesions, more severe inflammation
Rate of progression to HCC (y)	10–30	>30
Percentage likely to develop HCC	4% per year	1–7% per year

Metabolic Factors

Diabetes

The association of diabetes with the increased risk of HCC has been previously described, although with limitations inherent in the published studies, including confounding factors such as viral hepatitis C.[31,53] A study of VA patients comparing diabetic and nondiabetic patients, the majority comprised of men, demonstrated a doubling of the risk (HR 2.16), independent of alcoholic history, viral hepatitis, or demographics features.[53] Despite achieving SVR in HCV, diabetes is still a risk factor for HCC.[46]

Obesity

The high prevalence of obesity in the US has real clinical implications on liver health. Body mass index (BMI) alone, however, does not adequately account for the increased risk in developing HCC. One systematic review showed a positive association in 7 of 10 cohort studies, no associations in two studies, and even one study suggesting an inverse relationship.[54] The association between BMI and HCC may instead be clarified by identification of intermediary factors known as "proximal" associations, including abdominal fat (instead of BMI, which is considered a "distal" association), humoral mechanisms, and steatohepatitis.[55] Abdominal visceral fat, for instance, correlates with the waist-to-hip ratio. An elevated waist-to-hip ratio may confer up to about a 3.5-fold higher risk for development of HCC, implying that abdominal visceral fat plays a major role.[56,57] Because patients with obesity and/or metabolic syndrome are also at risk for NAFLD, careful evaluation for NAFLD should be made in conjunction.

Nonalcoholic Fatty Liver Disease

The widespread prevalence of NAFLD has prompted concern for its implications in patients whose disease evolves into a state of steatohepatitis and transforms to cirrhosis. These considerations have garnered particular interest in defining the degree of HCC risk in this population.

Certain genetic factors have been implicated in the pathophysiology of NAFLD/nonalcoholic steatohepatitis (NASH). Genetic variants of the *PNPLA3* (patatin-like phospholipase domain–containing 3) gene are hypothesized to play a role in the progression of NAFLD.[58–60] For instance, the *PNPLA3* polymorphism rs738409[G] (genotype GG), encoding I148M, is linked to increased hepatic fat levels and hepatic inflammation.[59] The prevalence of *PNPLA3* genotype CC (wild-type) is decreased in cases of NAFLD-related HCC.[61] In patients with NAFLD or alcoholic liver disease, wherein 11.5% of patients with NAFLD had HCC, the *KCNQ1* genotype TT was found to be significant in patients with HCC.[61]

NAFLD is increasingly recognized as a common etiology of cirrhosis. Some patients diagnosed with "cryptogenic" cirrhosis are also felt to have potentially undiagnosed NASH as an underlying etiology.[62] In these cases, HCC tended to present as a single nodule and with lower rates of portal vein thrombosis, compared with the other three underlying conditions.[62] Consequently, delineating the potential risks in the NAFLD population without cirrhosis is important. Broadly, the absolute risk in this population is not known; small studies indicate an estimated annual incidence less than 1% versus 2.6% in cirrhosis related to NASH.[33,63–65] The AASLD recognizes NAFLD without cirrhosis as bearing increased risk.[33]

The observation that HCC could arise in non-cirrhotic NAFLD has generated newfound vigilance.[64–66] The prevalence of HCC in patients with non-cirrhotic NASH was 38% (odds ratio [OR] of 2.61 vs the non-cirrhotic control).[67] From the national Veterans Affairs database, for those diagnosed with HCC in the absence of cirrhosis, both NAFLD and metabolic syndrome conferred increased risk with odds ratios of 5.4 and 5.0, respectively, when compared with HCV-related HCC.[68] Male gender, alcohol consumption, and the FIB-4 index (fibrosis score) are recognized risk factors.[69] One study suggested cumulative HCC mortality of potentially 0% to 3% over 20 years in patients without cirrhosis, and that NASH-related cirrhosis bore a cumulative risk of 2.4% over 7 years to 12.8% over 3 years; yet, the risk remained lower than that of cirrhosis related to hepatitis C.[70]

Even if the risk is perceived to be relatively lower than some other risk factors for HCC, the population-attributable fraction may argue for NAFLD being a more salient risk factor, especially when viewed in conjunction with metabolic syndrome.[33,55] The observation of an apparently increased HCC risk in patients with non-cirrhotic NAFLD emphasizes the importance of estimating fibrosis, identification of other concurrent HCC risk factors, and ongoing follow-up to continuously reassess risk and candidacy for undergoing an HCC screening program. These patients would benefit from engaging in related conversations with a hepatologist. Liver fibrosis estimation tools allow for a noninvasive way of risk-stratifying these patients in those clinical discussions.[71] Weight loss efforts remain the first-line recommendation for patients to potentially reduce steatosis, improve steatohepatitis, and in some cases reverse fibrosis, to secondarily reduce the risk of developing cirrhosis and HCC.

Glycogen Storage Diseases

Glycogen storage diseases (GSDs) represent disorders of inborn errors related to glucose or glycogen metabolism. Cases of HCC have been described in GSD type I, a rare autosomal recessive genetic disease. The association between GSD subtype Ia (related to deficiency in the glucose-6-phosphatase enzyme) and HCC is most commonly recognized. Hepatic malignancy in the context of GSD type I is hypothesized to arise from an adenoma-to-HCC transformation sequence.[72–74] The prevalence of hepatic adenomas is estimated to be up to 75% of adults with GSD type I and further increases with age.[72,75,76] The pathogenesis of these hepatic adenomas are thought to be related to inadequate metabolic control; improved metabolic control could lead to some degree of regression of the adenomas.[72,75] With hepatic adenomas, the risk is estimated to be about 10% for malignant transformation.[75] However, tumor markers such as serum α-fetoprotein (AFP) may be normal despite the presence of HCC, and ultrasonography may not always be sensitive enough to detect small hepatic adenomas, which presents a challenge in screening or surveillance.[72] Recommendations for screening in patients with GSDs is initially abdominal ultrasonography every 12 to 24 months in the pediatric population, with transition to interval surveillance with contrast-enhanced magnetic resonance imaging (MRI) or computed tomography (CT) of the abdomen in older patients (starting at age 18 years).[72,76,77]

Alcoholic Liver Disease

Excessive alcohol consumption can lead to cirrhosis and thus is a risk factor for development of HCC. The autopsies of patients with alcoholic cirrhosis have reported up to 10% undiagnosed HCC. In the US, alcoholic cirrhosis is associated with about 15% of HCC and cholangiocarcinoma.[78,79] One meta-analysis suggested that there was a dose-dependent effect of alcohol on the risk of HCC, where drinkers of three or more alcoholic beverages per day bore a 16% increased risk compared with nondrinkers.[80] A recent review compares the epidemiology and reported incidences of HCC in alcoholic and nonalcoholic liver disease.[81] As in studies of NAFLD, genetic factors have also been studied in alcoholic liver disease. Like NAFLD-associated HCC, the *KCNQ1* genotype TT was also observed to be significant.[61]

As previously introduced, alcohol use appears to have an adverse synergistic effect in patients with concurrent chronic HCV, such that alcohol increases circulating HCV viral titer and HCC risk.[39] Similar effects could be said in the context of metabolic syndrome. Other types of cirrhosis and parenchymal liver diseases—such as primary biliary cholangitis (PBC), hemochromatosis, Wilson disease, α-1 antitrypsin deficiency, and GSD—significantly increase HCC risk when alcohol is a cofactor.

Cirrhosis

The status of cirrhosis alone, regardless of etiology, is recognized as an inherent predisposition for increased risk of developing HCC. However, as previously suggested, differences in the magnitude of that risk depend on the etiology. For instance, chronic HBV or chronic HCV appears to pose a higher risk than NAFLD/NASH. In general, societies recommend routine screening for HCC every 6 months if the patient has a diagnosis of cirrhosis.[30,33,82]

The clinician should be attentive to specific conditions affecting the liver that may progress to severe fibrosis and cirrhosis, including PBC, hereditary hemochromatosis, Wilson disease, and α-1 antitrypsin

deficiency. In Wilson disease, copper accumulation in the liver is thought to induce oxidative stress, which is likely complicit in malignant transformation, as suggested in animal studies.[29,83] In patients with PBC, the increased risk of HCC is felt to be pertinent when cirrhosis develops, at which point routine HCC screening is recommended.[33] The AASLD also recommends HCC screening in men with PBC even outside the context of cirrhosis.[84]

Aflatoxin B_1

Food contaminated with aflatoxin, a mycotoxin found in grains, can induce HCC in animals. Peanuts, corn, and soybeans stored in damp environments increase the risk of exposure to aflatoxin. Exposure to *Aspergillus flavus* and *Aspergillus parasiticus* are important risk factors, especially in Asia and Africa.[29] Moreover, a strong synergistic association exists between aflatoxin exposure and HBV carrier status.[29] Relative risks of HCC are three-fold for aflatoxin, nine-fold for chronic HBV infection, and 59-fold for concurrent aflatoxin and chronic HBV infection. The underlying mechanism is polymorphism variants of glutathione *S*-transferase M1 and epoxide hydrolase genes and G-to-T point mutation of the *p53* gene.[85–87]

Other Environmental Factors

The use of oral contraceptive pills significantly increases the incidence of benign hepatic adenomas. There is some evidence that they also increase HCC risk. Multiple studies of tobacco smoking and HCC risk have yielded mixed conclusions. Occupational exposure to arsenic or vinyl chloride significantly increases the risk of liver angiosarcoma. Exposure to the radiograph contrast medium thorium dioxide from the years 1930 to 1955 is associated with a very high risk of hemangiosarcoma, cholangiocarcinoma, and HCC.[88]

CLINICAL PRESENTATION

Most cases of HCC are identified incidentally or through screening programs of high-risk individuals. It is common for patients to be asymptomatic until their disease is very far advanced. The only potentially curative modalities for HCC include liver resection (partial hepatectomy) and transplantation. Unfortunately, the actual number of patients who qualify for these modalities is small (~10%–30%) because most patients present with locally advanced and metastatic disease or have significant liver dysfunction that precludes curative options. Many patients present with symptoms of advanced liver dysfunction from both cirrhosis and HCC. The most common initial symptom is right upper quadrant abdominal pain. Anorexia or early satiety with weight loss is the second most common symptom. HCC may present with various paraneoplastic symptoms through the secretion of numerous hormones. Late-stage symptoms include jaundice, tumor fever, bone pain caused by metastatic lesions, and complications from portal venous hypertension, such as esophageal varices, hypoalbuminemia, ascites, thrombocytopenia, and coagulopathy.

On physical examination, hepatomegaly is present in more than 90% of patients. A hepatic arterial bruit or a friction rub, ascites, splenomegaly, and jaundice are found in up to 50% of patients. Muscle wasting, fever, and dilated abdominal veins are also common. The Budd-Chiari syndrome is caused by malignant invasion and occlusion of the hepatic veins. AFP is often elevated to above 400 ng/mL.

PATHOLOGY

Based on the growth pattern, HCC is classified into four major gross anatomic types: spreading, multifocal, encapsulated, and combined patterns.[89] Normal liver parenchyma is shown in Fig. 30–1. The spreading type of HCC grows in nodular, pseudolobular, or invasive patterns with poorly defined margins, occurs in the setting of hepatic cirrhosis, and accounts for nearly 50% of cases in the US. The multifocal type has numerous tumors of similar size that make it difficult to determine whether the lesions are intrahepatic metastases or second primary tumors (Fig. 30–2A, B). The encapsulated type of tumor grows by expanding, compressing, and distorting the surrounding liver tissue. Satellite or metastatic lesions are seen in late-stage disease. This type is most common in Asia and Africa but seen in only 13% of cases in the US. The combined patterns of the three are seen in up to 25% of cases. Figure 30–3 shows an HCC histopathology specimen.

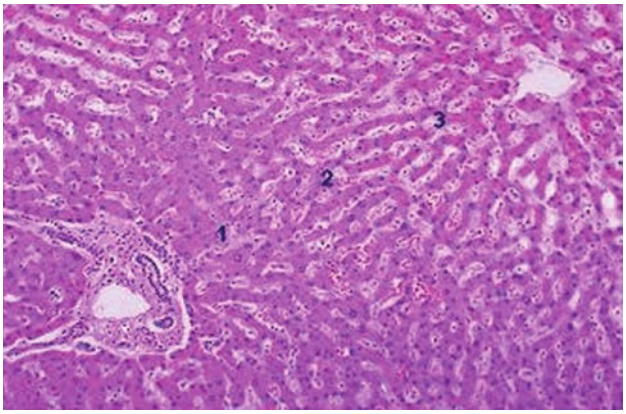

FIGURE 30–1 Photomicrograph of normal parenchyma.

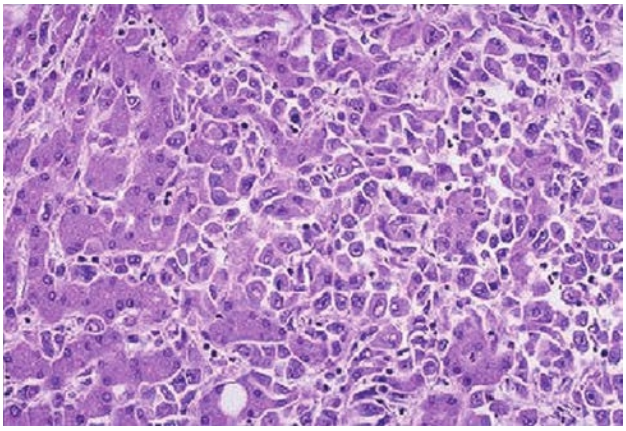

FIGURE 30–3 **Photomicrograph with standard hematoxylin and eosin stain of hepatocellular carcinoma cells in hepatic parenchyma.**

Approximately 60% to 70% and 80% to 90% of HCC in Whites and Asians, respectively, show elevated AFP, which is the most useful marker for HCC. Originally, AFP is produced by the fetal liver and yolk sac but falls to below 10 ng/mL in adult serum. A transient elevation of AFP to 20 to 400 ng/mL may occur when there is hepatocyte regeneration, as in cirrhosis, active hepatitis, or partial hepatectomy. The HCC positive predictive value of an AFP level of 400 ng/mL is over 95%, and normal AFP levels may exist in patients with low tumor burden. The lectin-reactive isoenzyme of AFP (AFP-L3) has shown increased sensitivity. As of this writing, serum AFP level and ultrasonography are the "gold standard" for HCC screening in high-risk populations.[90]

Variants of Hepatocellular Carcinoma

Hepatocellular carcinoma variants with differential molecular and prognostic significance include combined HCC and cholangiocarcinoma (cHCC-CC) and fibrolamellar HCC (FLHCC). cHCC-CC is a rare combination of cholangiocarcinoma and HCC and staged as intrahepatic cholangiocarcinoma, not HCC. This was believed to behave in a fashion similar to cholangiocarcinoma, but growing evidence suggests that cHCC-CC has intermediate clinical features and prognosis between HCC and CC.[91,92] A comprehensive molecular characterization of cHCC-CC demonstrates three main subclasses[93]: (1) a subtype sharing the molecular characteristics of both HCC and intrahepatic cholangiocarcinoma arising from a common clonal origin; (2) cholangiolocellular carcinoma representing a distinct biliary-derived entity, with significant upregulation of transforming growth factor-β signaling and enrichment of inflammation-related and immune response signatures; and (3) stem cell–like features with enrichment of progenitor-like signatures, leading to more aggressive tumor behavior and poor clinical outcome.

FLHCC is predominantly seen in the right hepatic lobe, accounts for 2% to 4% of HCC and occurs equally in men and women. It typically occurs in adolescents and young adults; the etiology is unknown. Histologically, it is characterized by fibrosis arranged in lamellar fashion around HCC cells, consisting of large polygonal tumor cells with eosinophilic granular cytoplasm, large vesicular nuclei, and prominent nucleoli. Immunohistochemistry profiles are similar to that of HCC and shows positive staining for hepatocyte paraffin 1 (HepPar1), glypican-3 (GPC3), arginase-1, polyclonal

carcinoembryonic antigen (pCEA), and CD10 positivity. CD68 and epithelial membrane antigen are specific for FLHCC.[94–96] It is associated with *DNAJB1-PRKACA* fusion, mainly seen in younger patients, and BAP1 mutation is commonly seen in older patient groups.[97,98]

Rare primary liver neoplasms include hepatoblastoma, sarcoma, angiosarcoma, rhabdomyosarcoma, and epithelioid hemangioendothelioma. Patients may present with fatigue, anorexia, weight loss, and abdominal pain. Hemorrhagic ascites is common, and AFP level is usually normal. Angiography and contrast-enhanced CT of the liver are the best diagnostic tools. Open or percutaneous liver biopsy is needed for diagnosis. Surgical resection is still the principal means of therapy if tumors are diagnosed at relatively early stages. They are often resistant to chemotherapy and radiotherapy (RT), and the overall prognosis is poor.

Benign Liver Tumors

Hemangiomas are the most common benign tumors of the liver. Their size ranges from a few millimeters to 25 cm. They appear as calcified solitary lesions in up to 7% of the general population. Magnetic resonance imaging is better than CT at distinguishing HCC from hemangioma on heavily T2-weighted images. Surgical resection is used for symptomatic lesions or when malignancy cannot be excluded. Hepatic artery ligation is an alternative for large, cavernous hemangiomas.[99] Hepatic adenoma is another common benign solitary tumor seen in women who have used estrogen-containing medications such as oral contraceptive pills for more than 10 years. It is composed of sinusoids, central veins, and arteries without well-defined portal tracts or bile ducts. Hepatic angiography is the most valuable diagnostic tool. Small adenomas usually regress when contraceptive pills are discontinued. Symptomatic lesions are treated with resection.[100,101] Focal nodular hyperplasia (FNH) occurs predominantly in young women. Liver function studies and the serum AFP level are normal. A technetium sulfur colloid radioisotope scan of the liver shows increased radioisotope uptake in FNH compared with hepatic adenomas or carcinomas. The prognosis is excellent. Female sex hormones such as oral contraceptive pills are not associated with FNH.[102,103]

DIAGNOSTIC EVALUATION, STAGING, AND PROGNOSIS

In addition to performing a complete medical history and physical examination, the diagnostic workup for a patient suspected of having HCC should include serum for complete blood cell count, electrolytes, liver function tests, albumin level, prothrombin time, hepatitis B and C serologies, and tumor markers (AFP and CA 19-9). The medical history should include a thorough review of potential HCC risk factors: transfusions, tattoos, intravenous drug abuse, high-risk sexual practices, familial syndromes, oral contraceptive pills or hormone replacement use, androgenic steroid use, and chemical exposures.

Several radiographic imaging modalities are useful in evaluating a patient with HCC. Ultrasonography often serves as the initial screening modality, followed by triple-phase CT scan or MRI. Randomized studies have shown that hepatic ultrasonography has 78% sensitivity and 93% specificity to detect HCC in high-risk populations, especially for patients with normal AFP levels.[104] Color-flow Doppler can assist preoperative assessment and planning.

Abdominal CT has relatively higher sensitivity and specificity than ultrasonography. With special arterial- and venous-phase scans, CT also makes it possible to evaluate the blood supply of the normal liver parenchyma (portal vein) and neoplastic lesions (hepatic artery). MRI is useful in distinguishing benign lesions from malignant tumors by the combination of T2-weighted phase-contrast and spin-echo sequences. MRI can also demonstrate fatty degeneration of tumor and vascular invasion.[105]

Hepatic radionuclide imaging has low spatial resolution and is only about 70% sensitive in demonstrating neoplasms. Using the glucose metabolic difference between neoplastic and normal cells, positron emission tomography differentiates benign lesions from malignant tumors, detects extrahepatic metastasis, and evaluates response to therapy.

In summary, ultrasonography is the most cost-effective HCC screening test in high-risk populations. Abdominal CT with liver protocol (with and without contrast) is the most helpful in accurately staging patients before surgery. No single diagnostic modality has greater than 50% to 60% sensitivity in detecting lesions less than 1 cm in size. The combination of AFP level, ultrasonography, and CT provides the best hope of early diagnosis.

A variety of staging and prognostic systems has been developed to evaluate patients with HCC. Four staging systems (Okuda; CLIP, Cancer of the Liver Italian Program; CUPI, Chinese University Prognostic Index; BCLC, Barcelona Clinic Liver Cancer Stage; and AJCC, American Joint Committee on Cancer TNM) have evolved since the 1980s. Currently, we use the AJCC-TNM and BCLC at MDACC (Table 30–4).[106] The Child-Pugh Classification System provides an estimate of a patient's functional liver reserve and is used principally to assist in evaluating a patient's suitability for hepatic resection.

Table 30–4 TNM Staging System for Hepatocellular Carcinoma

Stage Group	TNM	Scheme
Stage IA	T1aN0M0	Single tumor ≤2 cm
Stage IB	T1bN0M0	Single tumor >2 cm without vascular invasion
Stage II	T2N0M0	Single tumor >2 cm with vascular invasion, or multiple tumors, none >5 cm
Stage IIIA	T3N0M0	Multiple tumors, at least one of which is >5 cm
Stage IIIB	T4N0M0	Single tumor or multiple tumors of any size involving a major branch of the portal vein or hepatic vein or tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of visceral peritoneum
Stage IVA	T1–4NN1M0	Regional lymph node metastasis
Stage IVB	T1–T4N0–N1M1	Distant metastasis
Fibrosis score		0–4, none to moderate; 5–6, severe fibrosis/cirrhosis

TNM, tumor, node, metastasis; UICC, Union for International Cancer Control.
Data from Edge SB, Byrd DR, Byrd DR, et al: AJCC Cancer Staging Manual, 8th ed. New York, NY: Springer; 2017

TREATMENT

HCC is treated in the multidisciplinary fashion. There are five options: surgical resection, liver transplant, locoregional therapy, radiation, and systemic therapy. They are summarized in Table 30–5.

Surgical Resection

After liver transplantation, surgical resection offers the next best chance at long-term survival, with 5-year survival exceeding 50% in well-selected patients.[107] However, recurrence is common, with more than 70% of patients experiencing tumor recurrence at 5 years.[26] In considering surgery for patients with HCC, several factors must be balanced, including patient performance status, the condition of the underlying liver parenchyma, tumor characteristics, and the future liver remnant (FLR). When properly selected, surgery for HCC is safe, with modern series demonstrating perioperative mortality below 5% compared with rates of 20% in the 1980s.[108]

Patients with poor performance status, especially in the setting of severe uncontrolled comorbidities, and those with advanced, uncompensated cirrhosis (Child-Pugh class C) are not suitable candidates for hepatectomy and are best served with nonsurgical options. Instead, surgery is reserved for patients with preserved liver function. As a general rule, patients with Child-Pugh class A cirrhosis may be candidates for major hepatectomy, whereas those with class B cirrhosis should only be considered for more limited resections. Yet, because the Child-Pugh score does not fully account for portal hypertension, it is important to carefully review the patient's chart for evidence thereof, including the presence of varices, splenomegaly, ascites, recanalization of the umbilical vein, enlarged portal vein diameter, and thrombocytopenia. Additional investigational tools may include upper endoscopy to rule out esophageal varices and measurement of portal venous pressure. This heightened focus on portal hypertension is based on the fact that this condition is associated with increased risk of both long- and short-term mortality and postoperative decompensation and liver failure.[109] As such, patients with Child-Pugh class A cirrhosis with portal hypertension are often treated in the same fashion as those with class B disease.

In addition to the condition of the underlying liver disease, tumor characteristics must also be considered. Under the BCLC system, surgical resection is only recommended for single tumors without evidence of vascular invasion in the setting of normal liver function.[110] Additional factors associated with greater risk of disease recurrence and worse outcomes include tumor size larger than 5 cm and elevated AFP levels.[108] Thus, in our group's experience, no firm limits on either tumor size or AFP exist to contraindicate resection, because survival for these patients is improved compared with alternative approaches. Instead, these high-risk factors are taken into account during treatment planning, which may then consider preoperative adjunctive treatments for disease control and assessment of tumor biology. Likewise, multifocality and limited vascular invasion, although strongly associated with risk of disease recurrence, do not represent strict contraindications to hepatectomy, which must be considered with extreme care and should only be offered selectively in this patient population.

A final, but critical, element to consider when planning any liver resection is liver volumetry. In particular, the standardized FLR is predictive of the risk of postoperative liver failure. In the case of HCC, because of the presence of cirrhosis of the background liver, a standardized FLR of at least 40% is required for safe resection.[111]

Table 30–5 Treatment Options for Management of Hepatocellular Carcinoma

Treatment Option	Comments
Liver transplantation	Historically low survival rates (20%–36%)
	Recent improvement (75%–80% 5-year survival), likely related to adoption of Milan criteria at US transplant centers
	Currently HCC represents 25% or more of liver transplants performed annually in the United States.
Surgical resection	Historic 5-year survival rates 30%-40%
	Recent series indicated 5-year progression-free survival as high as 48%. A majority of patients develop recurrence or second primary tumors.
	Resection in cirrhotic patients carries high morbidity and mortality and is reserved for those with compensated disease: major hepatectomy is an option for Child-Pugh class A without portal hypertension; only minor hepatectomy for Child-Pugh class B or Child-Pugh class A with portal hypertension.
Transarterial chemoembolization (TACE)	Modest survival benefit demonstrated for repeated TACE (82% 1-year survival) vs supportive care (63%) in patients with preserved liver function, PS 0, small tumor burden
	Improvement in 1-year survival from 32% in control (supportive care) to 57% for TACE shown in randomized study of 279 primarily HBV patients with tumors <7 cm
Locoregional therapy and radiation therapy	Improvement in time-to-progression (26 months) with Y-90 compared with conventional TACE (6.8 months). Phase 3 clinical trials have shown mixed data on survival benefit from Y-90 combined with sorafenib. Ongoing trials will provide more information about a role of Y-90.
Percutaneous treatments (RFA, MWA, ethanol injection)	RFA similar recurrence rates to resection for small tumors. Higher recurrence rate than resection in tumors > 3cm. Ethanol injection has high rate of recurrence.
External beam radiation therapy	It can be delivered with stereotactic radiation therapy (3–5 fractions) to achieve 80%–90% local control at 1 year or with hypofractionated radiation therapy (10–15 fractions) to achieve 95% local control at 2 years. Ongoing phase 3 trials (RTOG1112 and NRG GI003) will help define a role of radiation therapy.
Molecular targeted therapy	Sorafenib, lenvatinib, cabozantinib, regorafenib, bevacizumab (combined with atezolizumab), and ramucirumab (for patients with AFP ≥ 400)
Immune checkpoint inhibitors	Nivolumab, nivolumab with ipilimumab, pembrolizumab, and atezolizumab (combined with bevacizumab)

MWA, microwave ablation; RFA, radiofrequency ablation; TACE, transarterial chemoembolization; Y-90, Yttrium-90.

Portal vein embolization (PVE) can be used to induce hypertrophy of the FLR if it falls below this threshold and improve postoperative outcomes.[112] The procedure has been shown to be safe and well tolerated, and response to PVE, especially in cirrhosis, is reflective of the regenerative potential and physiologic reserve of the liver. Indeed, degree of hypertrophy below 5% after PVE is associated with increased mortality and poor outcomes.[113] In the event of inadequate liver growth, although attempts at further augmenting the FLR may be considered with the addition of hepatic vein embolization and/or Yttrium-90 (Y-90) radioembolization, these patients may be better served with nonoperative treatment.

Liver Transplantation

With the increase in number of cases of HCC, the number of patients listed for liver transplantation (LT) is also increasing.[114,115] A large retrospective study using the United Network of Organ Sharing showed that among 109,018 registrants between January 2004 and December 2015, 18.5% were registered for LT because of HCC. In 2015, HCC was the leading diagnosis among registrants (23.9% of registrations) and recipients (27.2% of recipients).[114] LT is the treatment of choice for patients with advanced cirrhosis and clinically significant portal hypertension and decompensated liver disease where surgical resection is not possible, if the tumors are within Milan criteria (one tumor up to 5 cm, or two to three tumors with the largest being <3 cm).[116,117] Before universal acceptance of the Milan criteria for listing, the lack of good selection criteria led to poor outcomes, high recurrence rates (32%–54%), and low survival at 5 years.[118] Patients with small, unresectable HCC within the Milan criteria have excellent long-term survival, and hence LT is an effective

and efficient therapy.[33,116] Patients who are listed with tumors within Milan Criteria (T2HCC) have exception points, and patients with larger tumors (T3HCC) can be successfully downstaged and are eligible for exception (see https://optn.transplant.hrsa.gov/media/1200/optn_policies.pdf).

In the last two decades, multiple studies have shown good survival with larger tumors, based on the University of California–San Francisco criteria (a solid tumor <6.5 cm in size or up to three tumors with <4.5 cm as the largest diameter and a total tumor burden of 8 cm) with similar survival results.[119,120] Tumor markers including AFP, AFP-L3, and des-gamma-carboxy prothrombin have shown a predictive value along with an AFP cutoff value of 300 ng/mL for delisting patients to improve outcomes and reduce risk of recurrence post-LT.[121–124] A recent large series of LT for patients beyond University of California–San Francisco criteria showed overall survival (OS) and recurrence-free survival (RFS) to be comparable with that of patients transplanted within the Milan criteria.[125] A waitlist time of more than 9 months with aggressive locoregional therapies while waiting for transplant was used as a bridge for these patients.[125] Recurrence rates of 11% to 18% have been reported post-LT in patients with HCC, and recurrence rates are higher in patients with bigger tumors that were downstaged.[125–128] Based on explant liver pathology, the risk of recurrence is higher with vascular invasion, poorly differentiated tumors, history of hepatectomy, AFP at the time of transplant, and viable tumors.[125,127,129] A multicenter risk stratification scoring system (RETREAT) has been validated and takes into account AFP at the time of transplant, microvascular invasion, and largest viable tumor size with a score of 0–5, where a score of 0 had 3% and a score of 5 had a more than 75% risk of recurrence. This has been used to determine surveillance protocols for patients post-LT,[129] like frequent CT scans of the chest and abdomen every 6 months for the first 3 years post-LT.[33] Given the highest rates of recurrence in the first 2 to 3 years of transplant, avoiding calcineurin inhibitors that are known to be tumorigenic and instead selecting mammalian target of rapamycin (mTOR) inhibitors having antiproliferative properties against HCC is recommended.[130–132] Sirolimus is a mTOR inhibitor, has an anti-angiogenic activity that decreases the production of vascular endothelial growth factor (VEGF), and inhibits a response of vascular endothelial cells to stimulation by VEGF.[133,134] Sirolimus has been shown to reduce the risk of HCC recurrence after LT: in a large prospective, randomized, open-labeled, international trial, there was an improvement in RFS in the first 3 to 5 years.[135] In the case of recurrence post-LT, surgical resection, ablation, liver-directed therapy, stereotactic radiation, or therapy tailored to the site of recurrence can be considered.[128,136]

In the era of DAAs, two important factors that need to be considered in deciding timing of treatment for HCV include anticipated waitlist time and whether the patient has compensated or decompensated cirrhosis. Initiation of DAA may be withheld until after LT if LT is imminent (ie, <3–6 months), whereas treatment pre-LT may be considered for patients who may be on the waitlist longer than 6 months. Patients with decompensated cirrhosis should be treated and monitored at a transplant center. Recommendations guiding HCV treatment decisions in different scenarios are outlined in a review by Terrault et al.[137]

In summary, LT can be considered as the first-line treatment option for unresectable HCC with acceptable perioperative mortality and one-year mortality of 3% and less than 10%, respectively.[33,117] Locoregional therapies can be used for treating tumors within the Milan criteria and for downstaging larger tumors for listing. Aggressive post-LT surveillance scans and immunosuppression with mTOR inhibitors is recommended for patients who are at a higher risk of recurrence based on explant pathology.

Locoregional Therapy

Hepatocellular carcinoma derives its blood supply almost exclusively from the hepatic artery. This important anatomic feature offers unique advantages for catheter-based therapies, because arterial embolization interrupts blood flow to the tumor while preserving the portal vein and normal liver parenchyma. Transarterial therapies for HCC include transarterial chemoembolization (TACE), bland hepatic artery embolization (HAE) and selective internal radiation therapy (SIRT) using Y-90.

The combination of tissue ischemia with highly concentrated chemotherapy delivered into the hepatic artery enhances tumor necrosis. TACE was first described by Yamada et al and incorporates these concepts.[138] It has since become one of the most commonly used procedures in interventional radiology practice. Landmark, prospective, randomized clinical trials published in 2002 validated the use of chemoembolization for unresectable advanced HCC. In the multicenter study including 112 patients, when compared with bland embolization or best supportive therapy, patients who underwent TACE with a combination of doxorubicin and iodized oil followed by gelatin sponge demonstrated a clear survival advantage, leading to premature stoppage of the trial.[139] Survival in the chemoembolization group at 1 and 2 years was 82% and 63%, respectively. Survival in the bland embolization group was 75% and 50%, respectively; in the best supportive care group, survival was 63% and 27%, respectively, and reached statistical significance.

A single-center study compared 80 patients with unresectable HCC randomly assigned to undergo TACE with cisplatin and iodized oil followed by gelatin sponge or best supportive care.[140] Survival in the chemoembolization group at 1 and 2 years was 57% and 31%, respectively. Survival for the patients randomly assigned to the supportive care group was 32% and 11%, respectively, also reaching statistical significance. The difference in survival rates between the Llovet and Lo studies can be attributed to the inclusion of a larger proportion of patients with more advanced stages of underlying chronic liver disease in the latter study. Besides iodized oil used in those seminal studies, TACE using drug-eluting beads that enable controlled and sustained release of chemotherapeutic agents into the surrounding tumor was made available.[141] This device enables delivery of a higher concentration of drugs with low systemic toxicity.[142–144]

Bland HAE is similar to TACE in its embolic effect but is done without mixed or suspended chemotherapeutic. A small, randomized clinical trial comparing embolization with microspheres alone versus drug-eluting beads loaded with doxorubicin 150 mg in 101 patients with HCC did not show significant differences in progression-free survival (PFS) or OS between the groups.[145]

Selective interval radiation therapy with Y-90 has been in clinical use since 1999 when Y-90–impregnated glass microspheres (Therasphere, BTG) were given a humanitarian device exception from the FDA owing to studies showing safety and efficacy of glass microspheres in patients with HCC.[146] Y-90 had first been used in patients with portal vein thrombosis because of the nonembolic nature of glass microspheres compared with TACE and HAE. A long-term outcomes study of 291 patients with HCC who were treated with Y-90 showed the objective response rate of 57%, time-to-progression (TTP) of 7.9 months, and median OS of 17.2 months (Child-Pugh class A) and 7.7 months (Child-Pugh class B).[147] Y-90 has also been used in patients with more advanced disease who were not eligible for TACE or other local therapies. Hilgard et al demonstrated safety and efficacy of Y-90 in patients with advanced HCC, with TTP of 10 months and median OS of 16.4 months without lung or visceral toxicity.[148] Multiple comparison trials have been performed between Y-90 and TACE[149,150] and sorafenib.[151,152] Cohort OS with Y-90 therapy has not been significantly different from TACE or sorafenib in these trials, but has offered the advantages of improved response rates, lower rates of adverse events, and improved quality-of-life measurements. In addition, Y-90 has shown survival benefits in some subgroups (age <65 years, nonalcoholic cirrhosis, and noncirrhotic liver disease).[153] Y-90 has been shown to be an effective tool to downstage to transplant. Mohamed at el reviewed 60 patients treated with radiofrequency ablation (RFA), TACE, Y-90, and stereotactic body radiation therapy (SBRT), showing pathologic CR rates of 28.5% in SBRT, 41% in TACE, 60% in RFA, and 75% in Y-90.[154] A recent study published long-term results of 207 patients with HCC who had effective bridging or downstaging therapy with Y-90 before liver transplant.[155] Notably, most studies on Y-90 have not measured the dose delivered to the tumor, but only the administered dose. The dose delivered to the tumor has been shown to predict treatment response, and further advances in Y-90 dosimetry have the potential to further increase the efficacy and safety profile of Y-90.

Percutaneous therapy for patients with HCC includes heat-based thermal ablation (microwave ablation [MWA], radiofrequency ablation [RFA], cryoablation, ethanol injection, and irreversible electroporation [IRE]). Heat-based thermal ablation with RFA and MWA is the contemporary, preferred approach, owing to improved efficacy and safety. RFA and MWA both cause tissue necrosis by the controlled deposition of thermal energy and are traditionally used for nonresectable disease for lesions smaller than 5 cm, or three lesions smaller than 3 cm. These techniques are highly effective in the treatment of small and early HCC, with outcomes similar to surgical resection.[156] Recurrences after RFA are usually attributable to a microsatellite disease and the limitation of ablation size that can be obtained with RFA. MWA is an alternative hyperthermic ablative technique that has recently become the favored ablative modality for HCC. The main reason for this is that MWA does not rely on heat conduction through the tissue and similarly is not limited by the "heat sink" effect that surrounding vessels may impart,[157] allowing for the creation of larger ablation zones. Furthermore, combination therapy consisting of hyperthermic ablation with arterial HAE/TACE can improve cell death because an occlusion of blood flow leads to larger ablation zones.[158,159] Both RFA and MWA are limited by lesion proximity to adjacent critical structures, such as lung, gallbladder, colon, and central bile ducts. However, with the exception of lesions adjacent to a central bile duct, utilization of advanced organ displacement techniques allows most lesions to be treated with MWA or RFA.

At MDACC, for nonsurgical patients, ablation is the preferred strategy for lesions less than 3 cm. TACE is routinely used for patients with HCC with more than three lesions measuring up to 3 cm each, or a single lesion greater than 5 cm. In patients with portal vein thrombosis, infiltrative diseases, or more than four lesions, Y-90 SIRT is preferred. SIRT is also used to treat patients with single lesions up to 7 cm who do not have significant extrahepatic arterial supply.

Radiation Therapy

Technological advances in RT delivery have enabled the safe escalation of radiation doses to focal parts of the liver. Specifically, these technologies include image guidance, respiratory motion management, and highly conformal radiation delivery techniques. Retrospective and prospective data demonstrate that the combination of these technologies results in high rates of local control and promising rates of survival in several different settings of HCC management. Collectively, these promising clinical data from multiple studies demonstrate that HCCs are radiosensitive. Sustained local control rates ranging from 71% to 100% have been reported after 30 to 90 Gy delivered over 1 to 8 weeks.[160,161]

Historically, investigators from Michigan used conformal RT (1.5 Gy twice daily over 6–8 weeks) with concurrent hepatic arterial 5-fluorodeoxyuridine to treat HCC safely to doses as high as 90 Gy and achieved a median survival duration of 15.2 months.[162] Analysis of these data suggested that doses greater than 75 Gy resulted in more durable in-field local control than lower doses.

A prospective French phase 2 trial administered 66 Gy in 33 fractions to HCC in patients ineligible for curative therapies and noted 92% tumor responses and 78% one-year local control rates.[163] Using higher doses and fewer fractions (hypofractionated RT), Canadian researchers have noted excellent local control rates ranging from 70% to 90% when the radiation beam can be directed from multiple planes (stereotactic body RT, SBRT) converging on the tumor. Often with SBRT, the majority of the liver can be spared from irradiation using image guidance and respiratory motion management.[160,164,165] The ongoing RTOG 1112 randomized study of sorafenib versus sorafenib with SBRT for patients with HCC is ongoing and has OS as the primary end point.

In contrast to photon irradiation, for which the dose delivered to the tumor is limited by the entrance and exit doses that can potentially harm normal tissues, accelerated proton beams deposit a dose within the tumor without exiting through normal tissues beyond the tumor.[166] Japanese investigators have reported mature results of the treatment of 162 patients with 192 unresectable HCCs with 72 Gy in 16 fractions of proton beam therapy.[167] The 5-year local control rate of 87% and OS rate of 23.5% in the absence of significant toxicity are clinically noteworthy. Furthermore, an impressive 5-year survival rate of 53.5% was achieved in a subset of 50 patients with solitary tumors and Child-Pugh class A cirrhosis. A prospective multicenter phase 2 trial of hypofractionated radiation therapy (58.05–67.5 Gy in 15 fractions) for HCC and intrahepatic cholangiocarcinoma demonstrated similar results.[168] In this study, the median maximum dimension for patients with HCC was 5.0 cm, and 27.3% of patients had multiple tumors; 29.5% of patients had portal vein tumor thrombus, and the majority of the patients were treatment naïve (30/44). For the HCC group (n = 44), the 2-year local control rate was 94.8%, and the 2-year OS rate was 63.2%.

Our own MDACC experience reflects these observations that higher doses are associated with better overall, in-field progression-free and biochemical PFS.[169,170] Across all partial liver radiation paradigms, the most common site of first recurrence is intrahepatic but outside the high-dose irradiated volume, and toxicities are more common in Child-Pugh class B patients.

Given the excellent local control rate as noted with RT alone, RT has been combined with TACE to overcome treatment resistance. Korean researchers initially noted more than 60% response rates and a significant drop in tumor marker levels using this combination treatment strategy.[171,172] It was reported that TACE followed by RT improved OS over TACE alone in a retrospective analysis of this experience. Similar results have been reported by other groups as well.[173–175]

For the treatment of unfavorable tumors, multiple groups have reported favorable outcomes in patients with portal venous tumor thrombus (PVTT) treated with RT.[176–185] Response rates from these older studies ranged from 37.5% to 100%, and median survival durations ranged from 3.8 months to 10.7 months. Our retrospective data from MDACC indicate that patients with PVTT who received higher doses of RT had better rates of local control and longer survival compared with those who received lower doses.[186] Most recently, neoadjuvant 3D conformal RT before hepatectomy for patients with limited PVTT and resectable HCC demonstrated an OS advantage with strong effect compared with hepatectomy alone in a multicenter, randomized controlled trial in Japan.[187] On multivariable Cox regression analyses, the hazard ratio was 0.35 (range 0.23–0.54), favoring the preoperative RT regimen.

Future directions for RT with photons and protons will include use of functional imaging or biomarkers to personalize therapy for patients. Proof of concept has been demonstrated in a phase 2 study of SBRT for patients with advanced cirrhosis or impaired liver function.[188] The investigators used indocyanine green as a readout of liver function during SBRT to decide whether it was safe to deliver the full five-fraction course of SBRT or stop after three fractions. Sixty-two of 90 enrolled patients completed all five fractions using this personalized strategy. Six of the patients (7%) experienced a 2-point decline in Child-Pugh score within 6 months, which was lower than historical data that used a nonadaptive approach. The 2-year local control rate was 95%.

Taken together, these advances have permitted the escalation of radiation dose to unresectable HCCs without causing undue toxicity in multiple clinical scenarios from resectable to unresectable disease, as well as in the context of patients with limited hepatic reserve. Strategies that combine RT with other therapies merit continued evaluation to maximize the relative benefits of each approach.

Systemic Therapy

A majority (>80%) of patients diagnosed with HCC have advanced disease at presentation and—based on the number, size, location of lesions, and the severity of the underlying cirrhosis—are not candidates for transplantation, surgical resection, or locoregional therapies. Systemic therapy is recommended for patients with adequate liver function as demonstrated by Child-Pugh class A or B cirrhosis. Those with Child-Pugh class C cirrhosis have insufficient liver function to tolerate medication treatment, locoregional therapy, radiation therapy, or surgical intervention.[189,190] Therefore, best supportive care is recommended for this patient population.

Since the approval of sorafenib in 2007, several medications have been investigated, approved by the FDA, or recommended by the National Comprehensive Cancer Network guideline. Sorafenib, lenvatinib, atezolizumab plus bevacizumab, and nivolumab monotherapy (for patients considered ineligible or intolerant to other frontline medications) are recommended in the first-line setting; nivolumab monotherapy, nivolumab plus ipilimumab, pembrolizumab, cabozantinib, regorafenib, and ramucirumab (patients with AFP >400) are recommended in the subsequent-line therapy. Systemic therapy is recommended for patients with Child-Pugh class A except for nivolumab (Child-Pugh class A/B) and sorafenib (Child-Pugh class A/B7) by the National Comprehensive Cancer Network.

Hepatocellular carcinoma is inherently chemotherapy resistant[191] and known to express the multidrug-resistance gene *MDR-1*.[192,193] 5-fluorouracil plus oxaliplatin versus doxorubicin as palliative chemotherapy was navigated, and it showed the median OS and PFS of 6.4 versus 5.0 months and 2.9 versus 1.8 months, respectively.[194] Other chemotherapeutic medications showed similar results, and chemotherapy is rarely considered outside a setting of a clinical trial.

Sorafenib

Sorafenib is a tyrosine kinase inhibitor of VEGFR 1, 2, and 3 and platelet-derived growth factor receptor–β (PDGFR-β). It was approved by the FDA for patients with renal cell carcinoma.[195,196] Sorafenib was later tested in patients with advanced HCC in a phase 3, double-blind, placebo-controlled trial.[197] The median OS was 10.7 months in the sorafenib group (vs 7.9 months in the placebo group) with a HR of 0.69 (range 0.55–0.87). The median time-to-radiologic progression was 5.5 months (vs 2.8 months). The ORR was 2%, and the disease control rate (DCR) was 43%. The most common grade 3–4 adverse events were diarrhea, palmar-plantar erythrodysesthesia, and fatigue. Based on this study, sorafenib was approved in November 2007 for patients with unresectable HCC. Sorafenib was the only option for advanced HCC until April 2017, when regorafenib was approved for the second-line therapy and the only frontline medication, until lenvatinib was approved in August 2018.

Lenvatinib

Lenvatinib is a tyrosine kinase inhibitor of VEGFR 1, 2, 3; fibroblast growth factor receptor (FGFR) 1, 2, 3, and 4; and PDGFRα, KIT, and RET. It has been approved for patients with endometrial cancer, renal cell carcinoma, and thyroid cancer.[198–200] It was initially investigated in a phase 2 clinical trial for patients with advanced HCC, and safety and efficacy were validated.[201] This study demonstrated that lenvatinib had an ORR and DCR of 37% and 78%, respectively. Median OS and TTP were 18.7 and 7.8 months, respectively. The efficacy of lenvatinib was further investigated in a phase 3, randomized, noninferiority study to compare the efficacy versus sorafenib as a frontline treatment.[202] Patients were Child-Pugh class A only and BCLC stage B/C. Patients with portal vein tumor thrombosis and 50% or higher liver occupation were excluded from the study. Lenvatinib dose was 12 mg for patients with a body weight of 60 kg or more and 8 mg for those weighing less than 60 kg. The primary end point, the medial OS, was 13.6 months (range 12.1–14.9), and it was noninferior to sorafenib (12.3 months, range 10.4–13.9). The median PFS was 7.4 months (range 6.9–8.8), and ORR and DCR were 24% (1% complete response) and 75%. Based on this promising result, the FDA approved lenvatinib 12 mg daily in patients with 60 kg or greater body weight or 8 mg in those less than 60 kg in August 2018. Lenvatinib was the first frontline systemic therapy approved by the FDA after sorafenib in 2007.

Atezolizumab and Bevacizumab Combination

Atezolizumab is a fully humanized, monoclonal antibody of IgG1 isotype against the programmed cell death-ligand 1 (PD-L1). Atezolizumab has a proven efficacy in patients with triple-negative breast cancer, non–small cell lung cancer, small cell lung cancer, and urothelial carcinoma.[203–210] Bevacizumab is a humanized antibody binding to VEGF and prevents

angiogenesis. It has shown antitumor efficacy in multiple tumors including cervical cancer, colorectal cancer, glioblastoma, non–small cell lung cancer, ovarian cancer, renal cell carcinoma, and endometrial cancer.[209,211–215] A phase 1b study of atezolizumab and bevacizumab in patients with unresectable HCC showed an ORR of 36% and a median PFS of 7 months.[216] This combination was recently validated in a global, phase 3 clinical trial, and patients were randomized to this combination or sorafenib in patients with unresectable HCC.[217] Patients were Child-Pugh class A5 or A6, and 82% of patients were BCLC stage C. Primary end points were OS and PFS. The median OS of patients in the combination arm could not be evaluated at the time of data collection (over 17 months), and that of those who received sorafenib was 13.2 months (range 10.4–NE). HR for death was 0.58 (range 0.42–0.79). The median PFS was 6.8 months (range 5.7–8.3) versus 4.3 months (range 4.0–5.6) in the respective groups, with a HR of 0.59 (range 0.47–0.76). The ORR was 33.3% (10.2% and 23.1%, complete and partial response rates, respectively) versus 13.3% (range 1.9% and 11.4%), and the DCR was 72.3% and 55.1%, respectively. The most common grade 3–4 adverse events included hypertension (15.2%), increased aspartate aminotransferase (7%), thrombocytopenia (3.3%), and proteinuria (3%) in the combination arm. Of note, atezolizumab monotherapy and bevacizumab monotherapy also showed antitumor activity for advanced HCC, with an ORR of 17% and 13% to 14%, respectively.[216,218–220] This combination is the first regimen in HCC showing better survival than sorafenib as all other FDA-approved medications showed similar outcomes when compared with sorafenib.

Nivolumab

Nivolumab is a fully human IgG4 antibody inhibiting programmed cell death-1 (PD-1) from binding to the ligands PD-L1 and PD-L2. It is an immune checkpoint inhibitor with known activities in multiple cancer types including microsatellite unstable colorectal cancer, head and neck squamous cell carcinoma, Hodgkin lymphoma, melanoma, non–small cell lung cancer, small cell carcinoma, renal cell carcinoma, and urothelial carcinoma.[221–231] It was tested in a phase 1/2, open-label trial (CheckMate 040).[232] Forty-eight patients and 214 patients were treated in the dose-escalation phase and the dose-expansion phase for patients with Child-Pugh class A cirrhosis. Nivolumab 3 mg/kg was chosen for dose expansion. The ORR was 20% (range 15%–26%) in the dose-expansion phase and 15% (range 6%–28%) in the dose-escalation phase. A total of 154 patients received sorafenib and progressed on or were intolerant to it. The confirmed ORR in this patient group was 14.3% (range 9.2%–20.8%) with 3 complete responses and 19 partial responses. The DCR was 64%. The median OS and PFS were 15.0 and 4.0 months, respectively. The duration of response ranged from 3.2 to 38.2+ months; 91% of responders had responses lasting 6 months or longer, and 55% had responses lasting 12 months or longer. The most common grade 3–4 adverse events were increased lipase, aspartate aminotransferase, and alanine aminotransferase, as well as fatigue. The FDA approved nivolumab 240 mg every 2 weeks in the second-line setting in September 2017. It is also recommended in the frontline setting if patients are considered ineligible or intolerant to other frontline medications.

Pembrolizumab

Pembrolizumab is a humanized monoclonal antibody binding to PD-1 and inhibiting the binding of PD-1 to its ligand PD-L1 and PD-L2. Its clinical activities have been proven in several different cancers that include triple-negative breast cancer, cervical cancer, endometrial cancer, esophageal and gastric cancers, head and neck squamous cell carcinoma, Hodgkin lymphoma, melanoma, Merkel cell carcinoma, mycosis fungoides and Sézary syndrome, non–small cell lung cancer, primary mediastinal large B-cell lymphoma, renal cell carcinoma, small-cell lung cancer, urothelial carcinoma, and microsatellite unstable cancers.[198,233–250] Pembrolizumab was investigated in Keynote 224, a single-arm trial for patients with Child-Pugh class A and disease progression on or intolerance to sorafenib.[251] The median PFS and OS were 4.9 (range 3.4–7.2) and 12.9 months (range 9.7–15.5), respectively. The ORR and DCR were 17% (range 11%–26%) and 67%. The duration of response ranged from 3.1 to 16.7 months. Fatigue (4%) and increased aspartate aminotransferase (7%) and alanine aminotransferase (4%) were the most common grade 3–4 adverse events. Pembrolizumab 200 mg every 3 weeks was approved for advanced HCC in the second-line setting by the FDA in November 2018.

Nivolumab and Ipilimumab Combination

Nivolumab was tested in combination with ipilimumab, a recombinant human IgG1 antibody binding to the cytotoxic T lymphocyte–associated antigen 4 (CTLA-4) for advanced HCC. Ipilimumab showed clinical efficacy in microsatellite unstable colorectal adenocarcinoma, melanoma, renal cell carcinoma, and small-cell lung cancer.[117,222,227,252,253] This combination was investigated in cohort 4 of CheckMate 040.[254] A total of 50 and 49 patients received nivolumab 1 mg/kg plus ipilimumab 3 mg/kg and nivolumab 3 mg/kg plus ipilimumab 1 mg/kg every 3 weeks followed by nivolumab 240 mg

every 2 weeks. Most patients had advanced HCC at baseline: 88% of patients had vascular invasion or extrahepatic spread, and 91% had BCLC stage C. This combination showed the ORR of 32% and 31%, and DCR of 54% and 43% in respective arms. The median OS was 23 months and 12 months, respectively. Response duration ranged from 4.6 to 30.5+ months, with 31% of responses lasting at least 24 months. As discussed above, the ORR and median OS of nivolumab monotherapy demonstrated in CheckMate 040 were 14% and 16 months, and the combination of nivolumab and ipilimumab clearly showed clinical benefit. The combination showed that 37% of patients had grade 3–4 adverse events, with the most common being pruritus and rash, as well as other known immune-related adverse events reported in clinical studies for other cancers. Based on this result, nivolumab 1 mg/kg in combination with ipilimumab 3 mg/kg every 3 weeks for four doses, followed by single-agent nivolumab 240 mg every 2 weeks or 480 mg every 4 weeks was approved by the FDA in March 2020 in the second-line setting.

Cabozantinib

Cabozantinib is an inhibitor of VEGFR 1, 2, and 3; MET; and AXL. It has shown its clinical efficacy in renal cell carcinoma and thyroid cancer.[255–257] It was initially tested in a phase 2 trial for patients with advanced HCC, regardless of previous treatment with sorafenib.[258] Patients with Child-Pugh class B/C were excluded. This showed a median OS of 11.5 months and a median PFS of 5.2 months. This was validated in a randomized phase 3 trial, and a total of 707 patients were assigned in a 2:1 ratio to receive cabozantinib 60 mg daily or placebo.[259] The primary end point was OS, and the secondary end points were PFS and ORR. A median OS was 10.2 months versus 8.0 months in the cabozantinib and placebo arms, with a HR of 0.76 (range 0.63–0.92). Median PFS and ORR were 5.2 months with a HR of 0.44 (range 0.36–0.52) and 4% (P = .009). The DCR was 64%. The most common grade 3–4 adverse events were palmar-plantar erythrodysesthesia (17%), hypertension (16%), and increased aspartate aminotransferase (12%). Based on this trial, cabozantinib was approved by the FDA in January 2019 in the second-line setting.

Regorafenib

Regorafenib is a multikinase inhibitor of multiple targets including VEGFR 1, 2, and 3; KIT; and PDGFRα and β. It had been approved for patients with metastatic colon cancer and gastrointestinal stromal tumor.[260–262] It was investigated in a randomized, double-blind, placebo-controlled trial for patients with advanced HCC.[263] Patients were Child-Pugh class A and BCLC stage B/C. Patients in the regorafenib arm had a median OS of 10.6 months (vs 7.8 months in the placebo arm; range 9.1–12.1) with a HR of 0.63 (range 0.5–0.79) and a PFS of 3.1 months (vs 1.5 months in the placebo arm) with a HR of 0.46 (range 0.37–0.56). The ORR and DCR were 11% and 65%, respectively. The most common grade 3–4 adverse events were hypertension (15%), palmar-plantar erythrodysesthesia (13%), fatigue (9%), and diarrhea (3%). The FDA approved regorafenib 160 mg once a day after a low-fat meal for 21 days on and 7 days off of each 28-day cycle for patients with advanced HCC in the second-line setting in April 2017.

Ramucirumab

Ramucirumab is a recombinant monoclonal antibody inhibiting VEGFR2 and blocking ligand-receptor interaction with VEGF-A, -C, and -D. It causes reduced cancer vascularity and growth.[264] It has been used in metastatic non–small cell lung cancer, esophageal and gastric cancers, and colorectal cancer.[264–267] Ramucirumab was investigated in a randomized, double-blind, placebo-controlled, phase 3 trial for HCC patients with Child-Pugh class A, BCLC stage B/C, and AFP >400 ng/mL.[268] The medication was used for patients who had received sorafenib. The median OS was 8.5 months (vs 7.3 months in the placebo arm; range 7.0–10.6) with a HR of 0.71 (range 0.53–0.95). The PFS was 2.8 months (range 2.8–4.1) versus 1.6 months with a HR of 0.45 (range 0.34–0.60). The ORR and DCR were 5% and 59.9%, respectively. Grade 3–4 adverse events included hypertension (13%), hyponatremia (6%), and increased aspartate aminotransferase (3%). Ramucirumab 8 mg/kg once every 2 weeks was approved by the FDA in May 2019 for patients with AFP of ≥400 ng/mL in the second-line setting.

Neoadjuvant Systemic Therapy

The only potentially curative modalities for HCC include liver resection and transplantation. However, the actual number of patients who qualify for these modalities is small (~10%–30%) because most patients present with locally advanced or metastatic disease or have significant liver dysfunction that precludes curative options. In addition, for those who undergo resection, tumor recurrence is common, with a 5-year recurrence rate of more than 70%,[26,269] and the 5-year survival rate for patients with resected HCC has been reported to be 30% to 70%.[270–272] The potential reasons for recurrence after surgical resection involve the presence of micrometastases not

seen on conventional imaging or the dissemination of tumor cells during surgery. Patients who initially are surgical candidates at diagnosis could have significant progression during the time between initial diagnosis and surgery and do not quality for surgery at a later time.

In this regard, preoperative therapy has been proposed and has theoretical benefits including tumor downsizing and reduction in micrometastases. Recently, sorafenib was tested in the neoadjuvant setting. In the open-label, phase 2 study reported at the Gastrointestinal American Society of Clinical Oncology (GI ASCO) in 2016, four weeks of sorafenib given before surgical resection resulted in 50% or higher tumor necrosis in 24% of surgical specimens.[273] In addition, this small study yielded a 32% ORR by mRECIST.

Immune checkpoint inhibitors can be safely administered in the preoperative setting as demonstrated by preoperative trials of an anti–CTLA-4 antibody before curative surgery in bladder cancer and other cancers.[274,275] In addition, immune checkpoint inhibitors investigated in the preoperative setting at MDACC indicated an impressive signal of activity in patients with resectable HCC.[276] In this pilot, randomized trial of perioperative immunotherapy with nivolumab with and without ipilimumab for resectable HCC, five of 21 resected cases (two treated with nivolumab and three with nivolumab and ipilimumab) demonstrated the complete pathologic response. However, there are no standard, systemic preoperative therapies for resectable HCC as of this writing. Ongoing trials with tyrosine kinase inhibitors or immune checkpoint inhibitors will provide more information in the neoadjuvant setting.

Adjuvant Systemic Therapy

Early studies of adjuvant chemotherapy published in the late 1990s to early 2000s demonstrated mixed results. For example, randomized studies of adjuvant capecitabine and 5-fluorouracil showed the improved time-to-recurrence and 5-year OS rate[277,278]; other studies of adjuvant epirubicin, tegafur, or carmofur did not show survival benefit or decrease in the recurrence rate.[279,280] More recently, sorafenib was tested as adjuvant treatment in a phase 3, randomized clinical trial.[281] This study included more than 500 patients in the sorafenib and placebo groups. The investigators did not find a difference in the median RFS (33.3 vs 33.7 months; HR 0.94, range 0.78–1.13), whereas patients in the sorafenib arm showed increased adverse events including palmar-plantar erythrodysesthesia and elevated liver enzymes. Adjuvant immunotherapy platforms including lymphocyte infusion, tumor-directed vaccines, cytokine-induced killer cells, and autologous cytokine-induced killer cells have been investigated with mixed results.[282–285] As of this writing, multiple clinical trials of tyrosine kinase inhibitors and immune checkpoint inhibitors are underway, but no systemic therapy is considered a standard of care in the adjuvant setting.[286]

Combined Hepatocellular Carcinoma and Cholangiocarcinoma (cHCC-CC)

Surgical resection is the only curative option in cHCC-CC, similar to intrahepatic cholangiocarcinoma and HCC. There are limited data on the role of LT. For example, two of three patients with cHCC-CC underwent LT, and two patients survived at 25 and 35 months[287,288]; another report shows that 8 of 14 patients had tumor recurrence at a median follow-up of 32 months, with a median DFS of 8 months status post-LT.[289] For unresectable tumors, systemic therapy is the main backbone of treatment. However, there is no consensus of opinions about chemotherapy or molecular targeted therapy. A retrospective analysis of patients with unresectable cHCC-CC who received systemic treatment including gemcitabine monotherapy, gemcitabine with platinum with or without bevacizumab, and sorafenib showed poor responses, with 71% having disease progression on the first radiographic scan.[290] The median OS and the tumor control rate were 8.3 months and 21%. Another retrospective analysis revealed the median OS for gemcitabine plus cisplatin, 5-fluorouracil plus cisplatin, and sorafenib of 11.9, 10.2, and 3.5 months, respectively,[291] whereas another case report of sorafenib monotherapy showed patients achieved remission after progression on chemotherapy.[292] Overall, gemcitabine plus platinum (cisplatin or oxaliplatin) with and without bevacizumab or molecular targeted therapy including sorafenib is considered the main backbone of systemic therapy.[293] Locoregional therapy or external beam radiation can also be considered in a similar fashion to the treatment in HCC or intrahepatic cholangiocarcinoma.

Fibrolamellar Hepatocellular Carcinoma (FLHCC)

In our recent publications[294,295] with the largest single-institution sample of 94 patients, the patients who received neoadjuvant (n = 34) or adjuvant therapy (n = 10) had the longest median OS—60 and 110.5 months, respectively—in the entire cohort.

The median age was 23 years (range 14–75), the median OS was 57.2 months (range 36.4–77.9), and the median RFS was 13.9 months (range 8.8–18.9). White race, female gender, early tumor stage, and tumor resection (including metastasectomy) were positively associated with a longer OS, whereas female gender was the only significant positive predictor of longer RFS. The 5-fluorouracil plus IFN-α2b combination was the most frequently used systemic therapy.[294]

Surgical resection remains the standard of care in patients with resectable and locally advanced FLHCC. In a systematic review that evaluated data from 575 patients with FLHCC, the authors noted that patients who underwent surgical resection had a 5-year survival rate of 70% compared with 0% among patients who did not undergo resection.[296] However, recurrence could be as high as 100% after surgical resection; moreover, chemotherapy options in neoadjuvant and adjuvant settings are not well defined.[295,297] None of the presently used chemotherapy regimens are based on randomized clinical data because of the limited number of patients with FLHCC. For patients with an unresectable disease, LT can be considered, and 3-year survival approaches 75% to 80% after transplantation,[298] whereas transplantation is much more commonly indicated for patients with HCC than for those with FLHCC. This is likely because HCC is more common than FLHCC, and a regional lymph node metastasis, a relative contraindication to transplant, is more common in FLHCC (42.2%) compared with patients with HCC (22.2%).[299]

Although not well studied, radiation therapy has been used to treat recurrent FLHCC in case reports and small case series[300,301]: in one case report, Peacock et al demonstrated an 85% decrease in tumor volume of FLHCC metastases after treatment with 40 Gy in 10 fractions over a 13-day period. In a retrospective study of 10 patients with metastatic FLHCC treated with external beam radiation in addition to chemotherapy, three patients had partial responses, six patients had stable disease, and one patient had early progression. The use of liver-directed therapies (eg, chemoembolization, Y-90, and ablation) in FLHCC remains poorly defined. Recently, Mafeld et al reported a patient with successful downstaging of an initially unresectable FLHCC with TACE followed by Y-90. The tumor decreased in volume from 350 to 20 cm^3, allowing curative or microscopically margin-negative (R0) resection with an extended left hepatectomy and reconstruction of the inferior vena cava.[302]

FLHCC is not typically responsive to chemotherapy.[294,303] Although there is no consensus regarding the ideal chemotherapeutic regimen for FLHCC, platinum-based chemotherapy regimens, as well as combination regimens including IFN-α2b have been used with some success.[304–306] A phase 2 trial reported complete or partial responses in 5 of 8 patients treated with 5-fluorouracil and IFN-α2b.[306] In this trial, patients received 5-fluorouracil at a dose of 200 mg/m^2 infused continuously over 21 days with IFN-α2b at a dose of 4 million U/m^2 three times weekly during 5-fluorouracil infusion on a 28-day cycle. The median OS was 23.1 months (range 10.3–35.9). Approximately 9% of patients had grade 3–4 neutropenia, thrombocytopenia, or anemia. Nonhematologic toxicities were mostly grade 1–2 mucositis (39.5%), diarrhea (13.9%), nausea and vomiting (13.9%), fatigue (34.9%), and skin reaction (23.3%). Since that publication, the 5-fluorouracil plus IFN-α2b combination has been established as the most frequently used systemic therapy.[294] There is limited and conflicting evidence demonstrating the efficacy of immune checkpoint inhibitors.[307,308] However, the addition of an immune checkpoint inhibitor to 5-fluorouracil plus IFN-α2b, which is known to augment immune cell infiltration, increases PD-L1 expression and restores the INF-γ–producing capacity of CD8+ T cells and may prolong survival.[309,310] As of this writing, there is a clinical trial for patients with FLHCC at MDACC: a phase 1/2 study of atezolizumab plus bevacizumab with 5-fluorouracil and IFN-α2b for unresectable FLHCC.

MD ANDERSON APPROACH TO HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma and other primary liver tumors require multidisciplinary input, and patients benefit from clinical care that integrates the expertise of surgical oncology, LT, diagnostic and interventional radiology, gastroenterology and hepatology, radiation oncology, and medical oncology. New cases of HCC are reviewed at a weekly multidisciplinary liver tumor conference to develop a consensus approach to each patient's case. Careful attention is paid to precise tumor staging, histopathologic diagnosis, and each patient's performance status. Figure 30–4 depicts the general approach followed by the multidisciplinary hepatobiliary team in treating patients with HCC. MDACC has multiple clinical trials of combined approaches with systemic therapy, radiation therapy, and locoregional therapy, and clinical trials are offered at different levels of treatment.

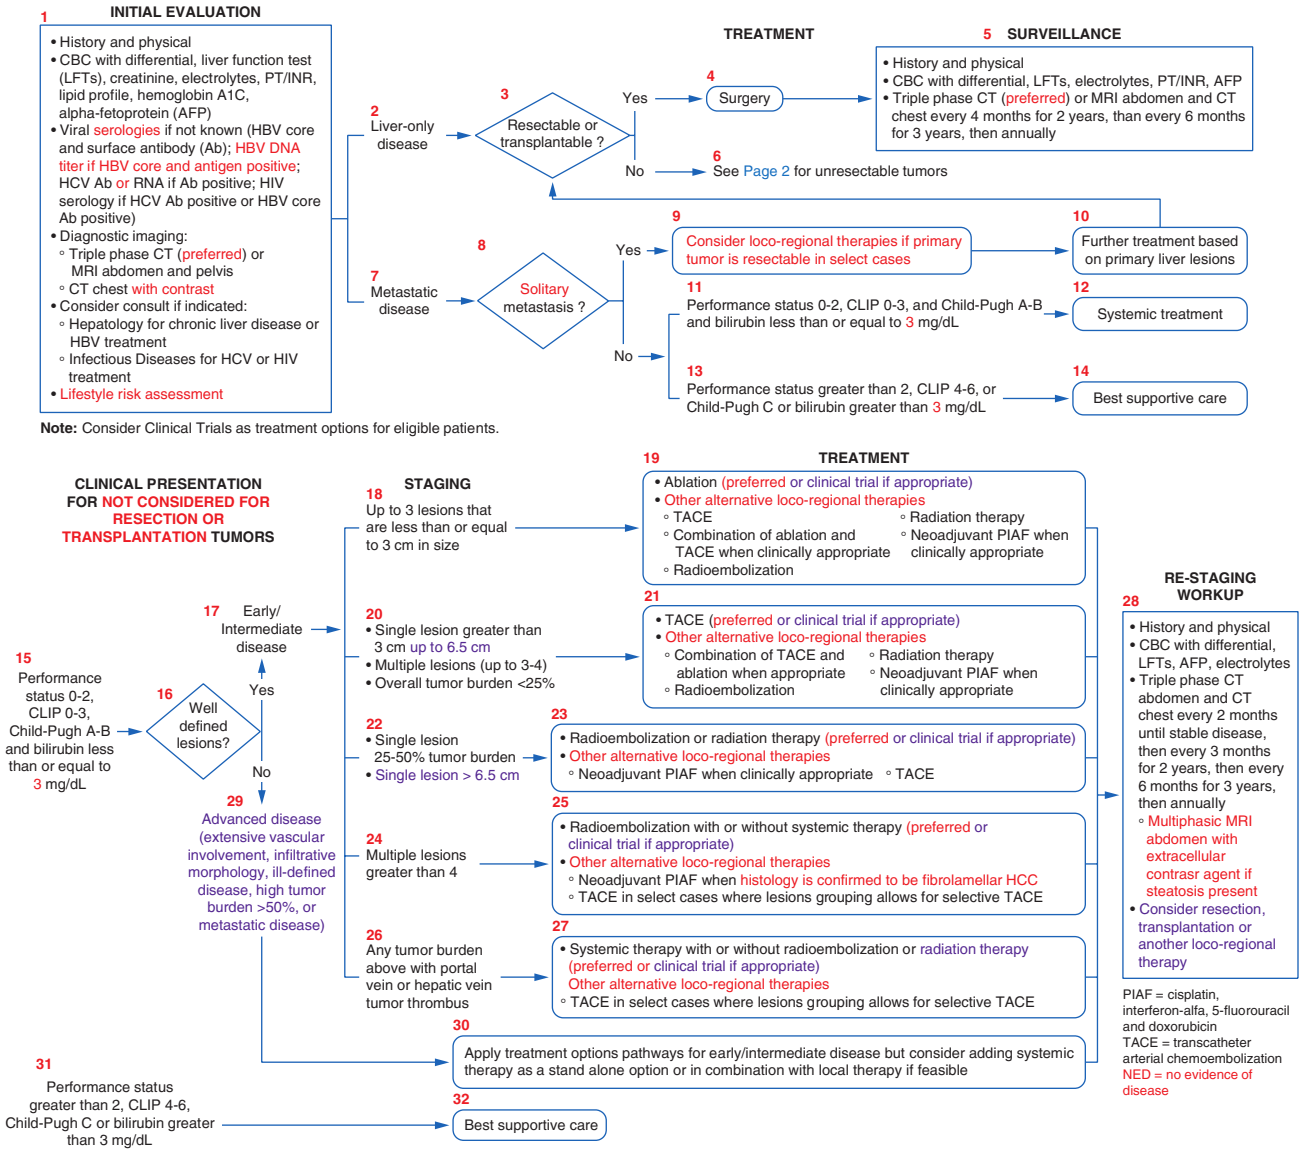

FIGURE 30–4 MDACC approach to HCC treatment. (Adapted with permission from the University of Texas MD Anderson Cancer Center.)

MD ANDERSON PRACTICE TIPS

- Patients with HCC are co-managed by a multidisciplinary approach with hepatology, medical oncology, surgical oncology, radiation oncology, and interventional radiology.
- MDACC collaborates with transplant hepatology at Houston Methodist and Baylor College of Medicine for transplant-eligible patients.
- Liver function (eg, Child-Pugh score for liver cirrhosis) and portal hypertension, as well as the stage of liver cancer, are assessed before a treatment decision is made.
- For patients with early-stage liver cancer, locoregional therapy, radiation therapy, surgical resection, and LT are considered. Clinical trials of neoadjuvant and adjuvant therapy are offered.
- Systemic therapy is the main backbone of cancer treatment for patients with advanced or metastatic HCC. Clinical trials are offered for eligible patients, and locoregional and radiation therapy are combined.
- All patients with HCC are offered pathologic and molecular profiling using next-generation sequencing.

31 Small Bowel Cancer and Appendiceal Tumors

Pat Gulhati
John Paul Shen
Kanwal P. Raghav
Michael J. Overman

KEY CONCEPTS

- Small bowel neoplasms are rare with roughly 12,000 new cases per year in the United States. The two most common histologies are adenocarcinoma (30%–40%) and carcinoid tumors (40%–45%).
- Inflammatory bowel disease, Peutz-Jeghers, familial adenomatous polyposis, celiac disease, and hereditary nonpolyposis colorectal cancer and all increase the risk of developing small bowel adenocarcinomas.
- Surgery is the mainstay of curative therapy; however, patients often present with more advanced disease, especially with adenocarcinomas.
- There is no firmly established adjuvant therapy for patients with either carcinoid tumors or adenocarcinoma.
- Systemic therapy for patients with advanced disease mirrors treatment for neuroendocrine tumors for carcinoids, whereas FOLFOX (modified 5-fluorouracil and oxaliplatin), CAPOX, and regimens with irinotecan are active for patients with adenocarcinoma.
- The molecular defects in adenocarcinomas are being elucidated. To date, however, no targeted therapy has an established role in advanced disease. Mismatch repair defects (even more frequent than in colorectal cancer) are predictive of response to immune checkpoint blockade.
- Appendiceal neoplasms are very rare consist of two major types: appendiceal carcinoid tumors and appendiceal epithelial tumors, each accounting for roughly half all cases.
- No clear risk factors for appendiceal neoplasms have been identified.
- Surgery is the mainstay of curative therapy for all patients with appendiceal neoplasms. Patients with adenocarcinomas are more likely to present with advanced disease in comparison with those with carcinoid tumors.
- The histologic subtypes of epithelial appendiceal neoplasms include low- and high-grade appendiceal mucinous neoplasms and invasive adenocarcinomas that may be mucinous (low or high grade), nonmucinous, or with signet ring cell features.
- Metastatic low-grade mucinous tumors have a more indolent disease course, respond poorly to systemic therapy, and are primarily managed with surgical cytoreduction and hyperthermic intraperitoneal chemotherapy (HIPEC).
- Metastatic high-grade adenocarcinomas, which include all tumors with signet ring cell features, are often treated with systemic chemotherapy. The benefit from cytoreductive surgery and HIPEC is uncertain.

SMALL BOWEL CANCER

Small bowel cancer is a rare malignancy representing approximately 3% of gastrointestinal (GI) neoplasms.[1] In 2020, it was estimated that 11,110 new cases of small bowel cancer and 1700 small bowel cancer–related deaths would occur.[1] The two most common histologies seen in cancers of the small intestine are carcinoids and adenocarcinomas.[2] Because of the nonspecific clinical presentation of small bowel adenocarcinoma (SBA) and the difficulty in imaging the small bowel, most patients with SBA present with lymph node involvement or distant metastases. Even in patients with localized disease who undergo resection with curative intent, the prognosis is poor, and no studies have yet demonstrated a clear benefit from adjuvant therapy. However, there have been some recent advances in molecular profiling as well as the use of chemotherapy, targeted therapy, and immunotherapy as palliative treatments. In this chapter, the

epidemiology, diagnosis, and treatment of small bowel cancers, in particular SBA, are reviewed.

Epidemiology

Based on an analysis of the Surveillance, Epidemiology, and End Results (SEER) database, the age-adjusted incidence rate for small bowel cancers slowly increased from 0.9 per 100,000 persons in the years 1973 to 1982 to 2.4 per 100,000 persons in the years 2013 to 2017.[3,4] The majority of this increase has been attributed to an increase in the incidence of carcinoid tumors. Carcinoids account for 39% to 45% of all cases, whereas SBA accounts for 31% to 40% of all small intestinal cancer diagnoses.[5] Most primary tumors arise in the duodenum (60%), with 25% to 29% arising in the jejunum and 10% to 13% in the ileum.[5] The incidence of histologic subtypes varies in the different sections of the small intestine, with adenocarcinomas representing 59% of duodenal cancers and carcinoids representing 57% of ileal cancers.[2,5] The median age at diagnosis is 60 years, and there is slightly increased incidence seen in men and Blacks.[5,6]

One of the more interesting aspects of SBA is its rarity in comparison with large intestine adenocarcinoma. Even though the small intestine represents approximately 70% to 80% of the length and more than 90% of the surface area of the alimentary tract, the incidence of SBA is 50- to 100-fold less than the incidence of colorectal carcinoma (CRC). Numerous theories have been proposed to explain the small intestine's relative protection from the development of malignancy. Proposed protective factors have centered on two concepts. First, the rapid turnover time of small intestinal cells results in epithelial cell shedding before the necessary acquisition of multiple genetic defects. Second, the small bowel's exposure to the carcinogenic components of our diet are limited because of rapid small bowel transit time; the lack of bacterial degradation activity that occurs in the small bowel; the relatively dilute, alkaline environment of the small bowel; and greater lymphoid infiltrate in small intestinal mucosa. In a population-based comparison of adenocarcinomas of the large (n = 261,521) and small (n = 4,18) intestine identified from the SEER registry, SBA demonstrated a distinctly worse stage-adjusted cancer-specific survival than CRC.[7]

Anatomy

The small intestine is divided into three sections. The duodenum represents the first 25 cm of the small intestine and is subdivided into four anatomic segments. The proximal portion of the first (ascending) segment of the duodenum is intraperitoneal, and then the distal portion, as well as the rest of the duodenum, becomes retroperitoneal. The second (descending) segment of the duodenum contains the ampulla of Vater, through which the pancreatic and biliary secretions exit. The third (horizontal) segment of the duodenum is the longest, and as it crosses the left border of the aorta, the fourth (ascending) segment of the duodenum begins. The duodenal–jejunal junction is characterized by the attachment of the suspensory ligament of Treitz. The next segment of the small bowel, the jejunum, is approximately 2.5 m long, and the final segment, the ileum, is approximately 3.5 m long.

Etiology

Little is known about the etiology of SBA. As seen in CRC, SBA undergoes a similar phenotypic adenoma–carcinoma transformation.[8–10] An increase in the size of small bowel adenomas and the presence of a villous histology are risk factors for the development of invasive adenocarcinoma.

Common underlying genetic or environmental factors of both large and small intestine adenocarcinomas have been suggested by studies that have demonstrated an increased risk of SBA in patients with colon adenocarcinoma and vice versa.[11] SBA has a higher likelihood of microsatellite instability (7.6%) and high tumor mutational burden (9.5%) compared with CRC (4.0% and 4.3%, respectively).[12]

The possible role of pancreaticobiliary secretions in the development of adenocarcinoma of the duodenum has been suggested by the anatomic clustering of duodenal carcinomas in the periampullary area. For example, in patients with familial adenomatous polyposis (FAP), 80% of SBAs occur in the second portion of the duodenum. One study evaluating 213 cases of duodenal carcinomas identified from the Los Angeles County tumor registry determined that 57% of the cases originated in the second part of the duodenum.[13]

Environment and Dietary Risk Factors

A number of case-control studies have analyzed associations between environmental and dietary factors and the development of SBA. Two studies have demonstrated that there is an association between the ingestion of smoked or salt-cured foods and the development of SBA.[14,15] An association between tobacco use and cancer risk has been inconsistently demonstrated. Case-control studies have demonstrated an association between an increased risk of SBA and high alcohol intake, high sugar intake, high red meat intake, low fiber intake, celiac disease, peptic ulcer disease, and prior cholecystectomy[14–18] Studies of the relationship with obesity have been conflicting, although a case-cohort study of 500,000 participants with 134 incident cases of small bowel cancer showed a statistically nonsignificant trend

toward increased risk in subjects with high body mass index (BMI) with a hazard ratio (HR) of 1.5 (95% confidence interval [CI], 0.76–2.96) for BMIs greater than 27.5 kg/m2 compared with BMIs of 22.6 to 25.0 kg/m^2.[19]

Genetic Cancer Syndromes

The genetic cancer syndromes hereditary nonpolyposis colorectal cancer (HNPCC), FAP, and Peutz-Jeghers syndrome (PJS) are all associated with SBA. The estimated lifetime risk for SBA is 1% to 4% in patients with HNPCC, 5% in those with FAP, and 13% in those with PJS[20–23] Patients with HNPCC develop SBA at a younger age, with a median age at diagnosis of 49 years. Patients with PJS, an autosomal dominant polyposis disorder characterized by multiple hamartomatous polyps throughout the intestinal tract, have a markedly increased risk for SBA, with one meta-analysis demonstrating a 520-fold increased relative risk.[24] Duodenal adenomas are seen in approximately 80% of patients with FAP, and regular endoscopic screening for the development of adenocarcinoma is required for these patients. The optimal frequency of endoscopic screening depends on a number of factors, such as the number of polyps, polyp size, polyp histology, and amount of dysplasia present.[20] With the early use of colectomy in patients with FAP, duodenal adenocarcinomas and desmoid tumors are now a more common cause of death in this population than CRC.

Inflammatory Bowel Disease and Celiac Disease

Inflammatory bowel disease (IBD), particularly Crohn disease, is associated with the development of SBA. The increase in risk varies depending on both the extent and duration of small bowel involvement. In one study, the cumulative risk of SBA in patients with Crohn disease was 0.2% at 10 years and 2.2% at 25 years.[25] Because Crohn disease frequently involves the ileum, 70% of the small bowel cancers in patients with Crohn disease occur in the ileum. Patients with Crohn disease who develop SBA appear to have a worse prognosis, with one study of 37 patients with SBA demonstrating significantly shorter overall survival (OS) in patients with Crohn disease.[26] Celiac disease is another proinflammatory condition that increases the risk of developing SBA 34-fold.[5] In general, these patients may be younger at disease onset and have better OS compared with those with SBA caused by other disorders.[5]

Molecular Profile

Accumulation of genetic defects such as loss of E-cadherin and SMAD4 and mutations in *KRAS*, *TP53*, and *SMAD4* have been implicated in the adenoma–dysplasia–carcinoma sequence of SBA.[2] In a pivotal study comparing chromosomal copy number aberrations in 85 gastric cancer, CRC, and SBAs, hierarchical clustering revealed a substantial overlap of SBA copy number profiles with matched CRCs but less overlap with profiles of gastric adenocarcinomas, indicating a genetic profile similar to CRC.[27] However, SBA is a unique molecular entity with distinct differences compared with other GI cancers, including CRC and gastric adenocarcinoma. The most commonly noted alterations were *TP53* (58.4%), *KRAS* (53.6%), *APC* (26.8%), *SMAD4* (17.4%), *PIK3CA* (16.1%), *CDKN2A* (14.5%), and *ARID1A* (12.3%).[12] The low rate of *APC* alterations in patients with SBA compared with those with CRC is a fundamental genomic difference between these malignancies. The most common potentially targetable alterations in SBA were identified in *PIK3CA* (16.1%), *ERBB2/HER2* (9.5%), *BRAF* (9.1%), *ATM* (7.6%), *FBXW7* (6.9%), *ERBB3* (6.3%), *NF1* (6.0%), *CTNNB1* (5.7%), *MDM2* (5.7%), and *PTEN* (5.7%). Although in CRC, most *BRAF* alterations are V600E, this codon is infrequently altered in patients with SBA. Similarly, despite equivalent rates of *ERBB2* alterations, only 23% alterations are amplifications in SBA, but 69% of alterations are amplifications in gastric adenocarcinoma. Interestingly, whereas tumor from patients with IBD associated SBA had higher frequencies of *CDKN2A/B*, *CASP8* and *ATRX* mutations, *APC* mutations were exclusively noted in non–IBD-associated SBA. Moreover, celiac disease–associated SBA has high rates of microsatellite instability, ranging from 50% to 73%.

Presentation and Diagnosis

Clinical Presentation

The symptoms associated with SBA are nonspecific and frequently do not occur until advanced disease is present. The most commonly reported symptoms are abdominal pain (45%–76% of patients), nausea and vomiting (31%–52%), weight loss (22%–29%), and GI bleeding (8%–34%). Delays in diagnosis are common, with one retrospective study reporting a mean delay of 7.8 months from the time of initial physician evaluation until a final diagnosis was made.[28] Unfortunately, SBA tends to be diagnosed at a later stage compared with CRC. Unlike CRC, SBA has no population-based screening given its rarity, which creates low value for screening among the general population. According to SEER–Medicare data, 33.7% of patients present with stage I/II disease compared with 52.3% of those with CRC, and 32.1% of patients with SBA are initially diagnosed with stage IV disease compared with 15.6% of those with CRC.[29]

Diagnosis

Given the nonspecific presenting symptoms, a high index of suspicion is a crucial first step in diagnosis. Because imaging of the small intestine is difficult, multiple tests may be needed. Unfortunately, there are few prospective, randomized trials comparing different visualization modalities. However, with the availability of wireless capsule endoscopy, the need for older small bowel imaging techniques has declined.

A barium small bowel follow-through study was previously the radiographic gold standard for small bowel evaluation. In patients with advanced-stage disease, this technique has a sensitivity of approximately 60% for diagnosing small bowel tumors. Enteroclysis, in which contrast material is infused directly into the small intestine through a nasogastric tube, provides a slightly higher sensitivity than small bowel follow-through. Endoscopic evaluation of the small intestine, or enteroscopy, requires expertise and is frequently unable to evaluate the entire small intestine.

The incorporation of wireless capsule endoscopy has allowed improved evaluation of the lumen of the small intestine. This technique has primarily been applied to the evaluation of obscure GI bleeding, for which it has shown superiority over other imaging and endoscopy techniques.[30] In one study evaluating capsule endoscopy in 60 patients with suspected small bowel pathology but without GI bleeding, the overall diagnostic yield of capsule endoscopy was 62%.[31] In that study, all patients had undergone upper and lower GI endoscopy, and many had undergone enteroclysis, small bowel follow-through, push enteroscopy, and abdominal computed tomography (CT). In a large, single-center, retrospective review of 562 patients who underwent capsule endoscopy, small bowel tumors were found in 8.9% of cases.[32] The major limitations of capsule endoscopy are inability to obtain biopsy and lack of therapeutic intervention capability (eg, in case of bleeding). Moreover, patients cannot have bowel obstruction, which could result in the capsule's becoming trapped in the bowel.

Three-dimensional imaging with either CT or magnetic resonance imaging is useful in identifying locoregional lymph node involvement and the presence of distant metastatic disease. For tumors of the duodenum, endoscopic ultrasonography can be useful in assessing both the tumor and nodal status. Although not directly studied for duodenal adenocarcinomas, endoscopic ultrasonography has been demonstrated to improve staging accuracy for both ampullary and pancreatic cancers.

Staging and Prognosis

The TNM (tumor, node, metastasis) staging system for SBA is shown in Table 31–1.[33] A multivariate analysis from a SEER–Medicare study identified advanced age, Black race, advanced stage, poor tumor differentiation, high comorbidity index, and distal location as poor prognostic factors. In other studies, the histopathologic factors reported to be correlated with poor survival were poorly differentiated histology, positive margins, lymphovascular invasion, lymph node involvement, and T4 tumor stage.[26,34–36]

Treatment

Surgical Management

For patients with localized disease, complete removal of the tumor with negative surgical margins and local lymph node removal are critical for a potentially curative resection. For jejunal and ileal lesions, an oncologically successful resection requires a wide local excision with lymphadenectomy. Lesions located in the duodenum generally require a pancreaticoduodenectomy; however, for small distal lesions in the third and fourth portions of the duodenum, a wide local excision may be an option. In a surgical series of 68 patients with duodenal adenocarcinoma, no differences in the 5-year OS rates, local recurrence rates, or margin-negative resection rates were seen between the 50 patients who underwent pancreatic resections and the 18 patients who underwent distal duodenal segmental resections.[37] The presence of locoregional lymph node involvement should not deter surgical intervention because well over one third of patients will survive long term.[29,38] This is in contrast to patients with lymph node–positive pancreatic cancer, of whom only 7% survive 5 years.[39] As is seen with CRC, the total lymph nodes (TLNs) assessed during surgery and the number of positive lymph nodes (PLNs) have prognostic implications in SBA. In a SEER registry retrospective review of 1991 patients, the 5-year disease specific survival rate for patients with stage II disease appeared to be associated with the TLNs assessed (44%, 69%, and 83% for 0 TLNs, 1 to 7 TLNs, and >7 TLNs, respectively).[40] Furthermore, the 5-year DSS with stage III disease was associated with the number of PLNs (58% and 37% for <3 PLNs and ≥3 PLNs, respectively).[40]

Patterns of Recurrence

Recurrence after potentially curative resection of SBA occurs most commonly at distant sites. In a series of 146 patients with SBA who underwent resection, 56 patients relapsed at a median of 25 months, with the sites of relapse reported as distant in 59%, peritoneum in 20%, abdominal wall in 7%, and local in 18%.[41] In a second study of 30 patients who underwent potentially curative resection for SBA, 21 patients experienced a relapse, with the sites of relapse being the liver

in 67% of the patients, lung in 38%, retroperitoneum in 29%, and peritoneum in 25%.[34]

Patients with duodenal adenocarcinoma have a higher rate of locoregional failure than patients with jejunal and ileal adenocarcinoma, with one study reporting a 39% rate of locoregional failure among 31 patients after curative resection of duodenal adenocarcinoma.[42] In that study, positive margin status was the strongest predictor of local recurrence, with four of the five patients who had a margin positive resection developing a local recurrence. However, distant recurrences are still predominant, with a retrospective review of recurrence patterns in 67 patients with resected duodenal adenocarcinoma revealing local recurrences in 33% of the patients and distant recurrences in 67%.[43]

Adjuvant Therapy

Currently, there is no evidence demonstrating a benefit from adjuvant therapy in patients with SBA who undergo potentially curative resection. However, owing to the rarity of SBA, only a limited number of primarily small retrospective studies have been conducted (Table 31–2). Selection bias is the major limitation of these retrospective studies because the patients selected to receive adjuvant therapy were those believed to be at highest risk for disease recurrence. One prospective phase III study conducted by the European Organization for Research and Treatment of Cancer randomized 93 eligible patients with periampullary carcinoma (defined as adenocarcinoma of the

distal common bile duct, ampulla of Vater, or duodenum) to receive either no adjuvant therapy or concurrent 5-fluorouracil (5-FU) and radiation therapy.[44] The 5-year OS rates were similar in the two groups, but 30% of the patients assigned to receive adjuvant therapy did not actually receive it, and no description of the results in the duodenal adenocarcinoma subgroup were reported. Another randomized phase III trial, European Study Group for Pancreatic Cancer (ESPAC-3), randomized 428 patients with periampullay carcinoma after resection to receive no adjuvant therapy or 5-FU or gemcitabine.[45] Although primary analysis did not identify significant survival benefit with either adjuvant chemotherapy compared with observation, multivariate analysis after adjusting for prognostic variables, including age, bile duct cancer, poor tumor differentiation, and PLNs, demonstrated a statistically significant survival benefit associated with adjuvant chemotherapy.

In a series by Kelsey et al,[42] no differences in the 5-year OS rates were seen between the patients who did or did not receive adjuvant therapy after resection of duodenal adenocarcinoma. However, in the subgroup of patients who had undergone a margin-negative resection, the 5-year OS rates were 53% in the patients who underwent resection only and 83% in the patients who had resection and adjuvant chemoradiation therapy (P =.07). A trend toward improvement of disease-free survival (DFS) and OS was seen in patients receiving adjuvant therapy in a retrospective series at MD Anderson Cancer Center (MDACC) (n = 54).[46] However, in the subgroup analyses in patients with high-risk disease, defined by a lymph node ratio of 10% or greater, adjuvant therapy was associated with significant improvement in OS.[46] In contrast, in a single-institution retrospective review at Mayo Clinic, no benefit of adjuvant chemotherapy or chemoradiotherapy was seen in patients with resected SBA.[47]

Limited data are available regarding a neoadjuvant (preoperative) treatment approach for patients with duodenal adenocarcinoma. In one report in which 11 patients underwent neoadjuvant chemoradiation therapy followed by resection for duodenal adenocarcinoma, a complete pathologic response was seen in two patients, and none of the 11 patients had histopathologic nodal involvement at the time of surgery.[42]

The MD Anderson Approach to Nonmetastatic Disease

At MDACC, patients with high-risk, resected SBA are typically offered postoperative adjuvant chemotherapy. In general, patients who are considered to be at high risk are those with lymph node involvement and positive resection margins. The lack of proven benefit from adjuvant chemotherapy for this tumor type must be discussed with the patient. However, the rationale for considering adjuvant chemotherapy is based on

1. The known poor prognosis of patients with high-risk disease
2. The predominantly systemic relapse pattern for small intestinal adenocarcinoma
3. The proven activity of chemotherapy in the treatment of metastatic small intestinal adenocarcinoma
4. The known benefit of adjuvant chemotherapy in large intestinal adenocarcinoma, which appears to have a number of similarities to small intestinal adenocarcinoma
5. The extremely limited amount of high-quality data to support or refute the role of adjuvant therapy for SBA

Based on the substantial activity of a 5-FU and platinum combination in the metastatic disease setting, we generally use the combination of capecitabine and oxaliplatin (CAPOX) as adjuvant therapy for nonmetastatic SBA. In addition to systemic chemotherapy, radiation therapy is considered for patients with duodenal adenocarcinoma who are at high risk for a local recurrence based on the presence of positive margins or T4 disease.

Metastatic Disease

In general, chemotherapy for metastatic SBA has been based on the principles used for treating patients with colon cancer. Several single-institution retrospective series have demonstrated a survival benefit in patients with metastatic or unresectable SBA who received chemotherapy compared with patients who did not receive chemotherapy.[41,48]

Most of the studies evaluating chemotherapy for SBA have been retrospective, with only seven prospective phase II studies reported (Table 31–3). One multicenter study conducted by the Eastern Cooperative Oncology Group reported on the combination of 5-FU, doxorubicin, and mitomycin C (FAM) in 39 patients with adenocarcinomas of the duodenum, jejunum, ileum, or ampulla of Vater. The overall response rate (ORR) was 18%, with a median OS of 8 months.[49] A single-institution study conducted at MDACC evaluated CAPOX in 30 patients with metastatic or locally advanced small bowel or ampullary adenocarcinomas. The ORR was 50%, with a median time to progression (TTP) of 9.8 months and OS of 20.3 months.[50] An example of a response to CAPOX chemotherapy in a patient treated in that study is shown in Figure 31–1. In 33 patients treated with continuous infusional 5-FU and leucovorin in combination with oxaliplatin (modified 5-FU and oxaliplatin [FOLFOX] regimen), the ORR was 48.5%, and the median OS was 15.2 months.[51] Another prospective, multicenter, first-line study (n = 23) using CAPOXIRI (capecitabine, oxaliplatin, and irinotecan) showed an ORR of 39% and a median OS of 12.7 months.[52]

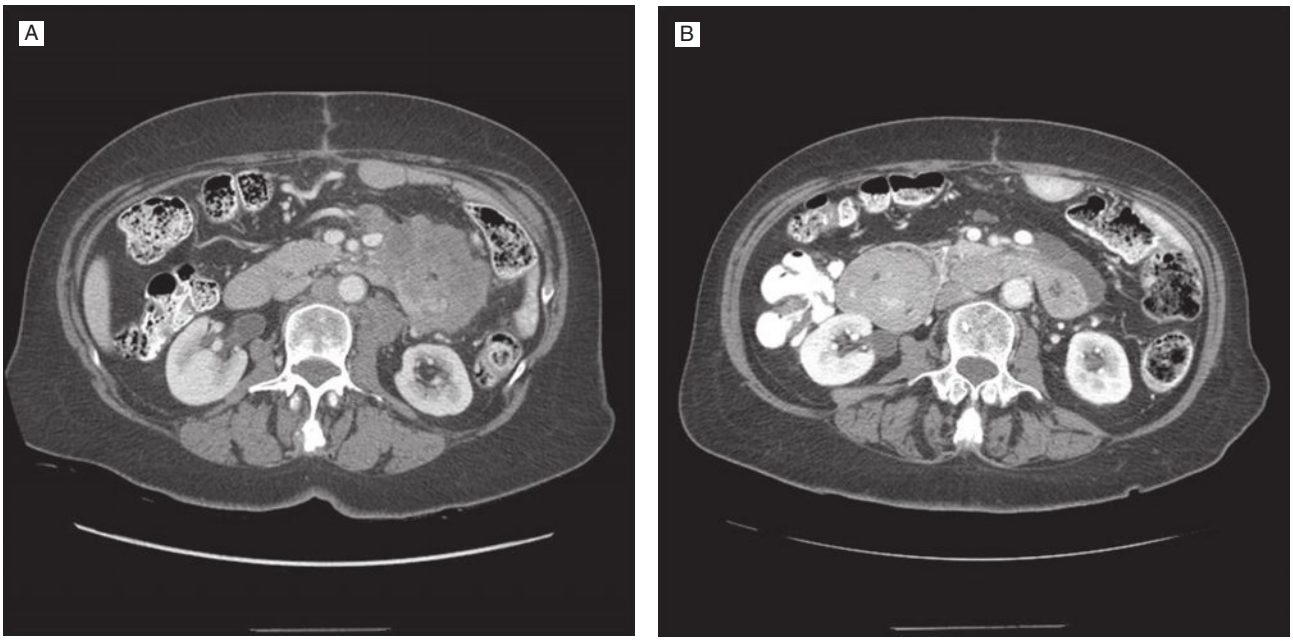

FIGURE 31–1 **Radiographic response to capecitabine and oxaliplatin (CAPOX) chemotherapy in a patient with locally advanced small bowel adenocarcinoma. Pretreatment (A) and posttreatment (B) computed tomography scans.**

Several retrospective studies have confirmed the substantial activity of 5-FU combined with a platinum agent for metastatic SBA, with response rates of 18% to 46%.[53–56] In one of the largest retrospective studies to date, a total of 80 patients with metastatic SBA were treated with various regimens: 29 received 5-FU with a platinum (19 received cisplatin, four received carboplatin, and six received oxaliplatin), 41 received 5-FU–based therapy without a platinum (32 received 5-FU alone, three received FAM, three received 5-FU and mitomycin, and three received other 5-FU combinations), and 10 received non–platinum-based and non–5-FU–based therapy.[56] Patients who received 5-FU combined with a platinum agent had a higher ORR (46% vs 16%; P <.01) and longer median progression-free survival (PFS) (8.7 vs 3.9 months; P <.01) than patients who received other chemotherapy regimens. Although not statistically significant, there was also a trend toward improved median OS times in patients who received 5-FU plus a platinum agent (14.8 vs 12.0 months; P =.1). A French multicenter study in SBA receiving frontline chemotherapy with 5-FU (n = 10), FOLFOX (n = 48), (5FU + irinotecan) (n = 19), and 5-FU-cisplatin (n = 16) demonstrated median PFSs of 7.7, 6.9, 6.0, and 4.8 months, respectively.[48] The corresponding median OSs were 13.5, 17.8, 10.6, and 9.3 months, respectively.[48] In the subgroup analysis, patients treated with 5-FU–cisplatin had decreased PFS (P <.01) and OS (P =.02) compared with those treated with oxaliplatin-based chemotherapy.[48]

Irinotecan-based chemotherapy is also active against metastatic SBA. One retrospective study reported that five of 12 patients responded to irinotecan-based therapy (three patients responded to 5-FU plus irinotecan, one responded to capecitabine plus irinotecan, and one responded to single-agent irinotecan).[54] A second study of salvage therapy with irinotecan in the second-line setting noted stable disease (SD) in four of eight treated patients.[55] Among the 19 patients in the Association des Gastro-Entérologues Oncologues (AGEO) study treated with 5-FU plus irinotecan, one had a partial response (PR), and SD was seen in seven patients.[48] Responses to gemcitabine-based therapy have also been noted, although the number of patients treated has been small. Although taxanes have not been classically used for treatment of patients with SBA, a recent single-center retrospective study evaluating the activity of taxanes in SBA demonstrated clinical activity with responses noted in 30% patients, SD in 35%, and PD in 35% patients.[57] Median TTP and OS were 3.8 and 10.7 months, respectively.

The remaining prospective phase II studies evaluated the role of targeted therapy and immunotherapy in patients with metastatic SBA. A single-institution study conducted at MDACC evaluated CAPOX with bevacizumab (anti–vascular endothelial growth factor [VEGF] antibody) in 30 patients with advanced small bowel or ampullary adenocarcinomas. The ORR was 48.3%, with a median PFS of 8.7 months and median OS of 12.9 months.[58] An exploratory analysis comparing this regimen to a prior phase II clinical trial of CAPOX alone

from the same institution did not demonstrate significant difference in ORR or PFS. Another phase II study conducted at MDACC evaluated the efficacy of panitumumab (anti–epidermal growth factor receptor [EGFR] antibody) in metastatic *RAS* wild-type SBA or ampullary adenocarcinoma given the known benefits of EGFR antibodies in metastatic CRC.[59] The study was stopped early because of futility with no responses in nine patients, SD in two patients, and PD in seven patients. Median PFS and OS were 2.4 and 5.7 months, respectively. No patients had extended RAS mutations (exons 2/3/4), but two patients had BRAF G469A, and one patient had PIK3CA H1074R mutations. The authors proposed that these findings may relate to the primarily midgut and foregut derivation of the small bowel and ampulla. Finally, the ZEBRA trial was a prospective, multicenter phase II study evaluating pembrolizumab (anti–programmed cell death protein 1 [PD-1] antibody) in SBA patients given the more frequent microsatellite instability, greater programmed cell death ligand 1 expression compared to CRC.[60] Median PFS and OS were 2.8 and 6.9 months, respectively. Both microsatellite instability–high (MSI-H) patients achieved PR and remained alive without progression. Of patients with microsatellite SD, disease control rate was 50% with a PR noted. The findings from these studies taken together with the differences in mutational profiles between SBA and CRC described previously suggest that approaches to SBA should not be extrapolated from CRC but should be based on data derived from SBA.

The MD Anderson Approach to Metastatic Disease

The substantial response rates and prolonged OS reported with modern-day chemotherapy combinations in SBA strongly argue for an aggressive approach in treating patients with metastatic SBA. Given the encouraging results with CAPOX and FOLFOX for metastatic SBA, we generally recommend these regimens at MDACC. After frontline CAPOX or FOLFOX chemotherapy, patients are then treated with an irinotecan-based regimen. In addition, patients with limited metastatic disease who respond to initial chemotherapy are considered for surgical resection if all disease sites can be successfully excised. Data for use of anti-VEGF and anti-EGFR targeted antibodies in SBA are limited, and further investigation into their clinical benefit is indicated. Although anti–PD-1 immunotherapy is approved for use in MSI-H SBA, further studies are needed to comprehensively evaluate the benefit from these agents in microsatellite-stable SBA. More effective treatments for patients with SBA remain needed, and participation in clinical trials for this rare tumor type is strongly encouraged. A proposed treatment algorithm for SBA is presented in Figure 31–2.

APPENDICEAL TUMORS

Appendiceal tumors encompass a rare and diverse group of neoplasms. Epidemiologic studies based on the SEER database have shown a steady increase in incidence from approximately 0.2 cases per 100,000 in the 1970s, to approximately 0.6 per 100,000 in 2000, to current estimates of between 1 and 4 per 100,000.[61–63] There are no definitive risk factors for developing appendiceal cancer.[64] In comparison, this is 10- to 40-fold less common than colon cancer, which in the United States has an incidence of approximately 40 per 100,000. Historically, appendiceal tumors have been grouped together with CRCs, and as of 2020, the National Comprehensive Cancer Network guidelines still suggest that patients with appendiceal tumors should be treated similar to those with colon tumors. However, there is a growing body of evidence that appendiceal tumors, in which outcomes are strongly determined by histologic subtype, are quite distinct from CRC at the molecular level.[65,66] Recognizing the clear differences in biology, natural history, and response to therapy between CRC and appendix cancer, there is now an effort underway to develop national guidelines specifically for appendiceal tumors. Appendiceal tumors comprise two major types: appendiceal carcinoid tumors and appendiceal epithelial tumors, each accounting for roughly half of all appendiceal neoplasms.[67] This section on appendiceal tumors discusses the management of these two tumor types (carcinoid and epithelial) as well as the unusual clinical syndrome of pseudomyxoma peritonei (PMP).

Incidence

Data derived from the SEER database of the National Cancer Institute between 1973 and 1998 revealed that the most common histologic subtypes of malignant tumors of the appendix were adenocarcinomas (67%) and carcinoids (33%).[68] However, this SEER analysis captured neither adenomatous tumors nor benign carcinoids. The SEER subtypes of adenocarcinoma were mucinous type (56%), nonmucinous intestinal type (38%), and signet ring cell type (6%). A more recent SEER-based analysis of 7170 tumors again found mucinous adenocarcinoma most common (39%) followed by nonmucinous adenocarcinoma (also called colonic type) (33%), goblet cell carcinoid (13%), malignant carcinoid (9%), and signet ring cell carcinoma (6.5%).[62] Alternatively, in a separate study of 7970 appendectomy specimens, tumors were identified in 1% of specimens, with carcinoids representing 57% of all tumors identified.[67] Adenomas and adenocarcinomas represented 18% and 11% of the identified tumors, respectively.

CHAPTER 31

Presentation and Prognosis

Appendiceal tumor presentation is bimodal; tumors are generally either identified incidentally at the time of pathological review of appendectomy specimens or only after the tumor has spread to the peritoneal space. Symptoms of appendicitis are most often the presenting symptom for early-stage tumors, especially with tumors located at the base of the appendix where obstruction is more likely to occur. Presenting symptoms of advanced appendiceal disease reflect the nonspecific abdominal symptoms associated with peritoneal involvement: abdominal pain and distention, altered bowel motility, and early satiety. Metastatic carcinoid tumors may also present with symptoms related to the carcinoid syndrome such as episodic flushing, wheezing, and diarrhea. Patient age at presentation differs depending on histologic subtype of the tumor, with carcinoid tumors occurring in younger patients (goblet cell carcinoid, 54 years; malignant carcinoid, 43 years) relative to adenocarcinomas (mucinous, 59 years; nonmucinous, 64 years; signet ring, 58 years).[62]

The prognosis for patients with appendiceal cancer is strongly dependent on the histopathologic subtype of the tumor, with patients who have carcinoids having a significantly better survival than do patients with adenocarcinomas (Fig. 31–3).[68] However, longitudinal data in appendiceal cancer can be difficult to interpret because of inconsistent terminology in describing the multiple subtypes of appendiceal tumors.[69] In 2016, a consensus classification and reporting system was adopted that has greatly helped to standardize the histopathologic categorization of appendix cancer.[70] Importantly, these guidelines distinguished mucinous neoplasms without infiltrative invasion as a separate entity from adenocarcinoma, which by definition had presence of infiltrative invasion. Mucinous neoplasms without infiltrative invasion were further subdivided into low grade (low-grade appendiceal mucinous neoplasm [LAMN]) and high grade (HAMN). Uniform criteria for PMP, a unique clinical syndrome with spread of tumor and ascites within the peritoneal cavity but not to distant organs, were also developed differentiating PMP from acellular mucin.[69]

As would be expected, patients with early-stage tumors identified incidentally at the time of appendectomy have a better prognosis than patients who are diagnosed after symptoms develop. For these early-stage patients, the distinction between LAMN and adenocarcinoma has important prognostic implications. In a study of 107 patients with localized LAMN of adenocarcinoma, no LAMNs confined to the appendix experienced recurrence at a median follow-up period of 6 years.[71] LAMNs that had extra-appendiceal spread did recur and had OS rates of 100%, 86%, and 45%, at 3, 5, and 10 years, respectively. In contrast, mucinous adenocarcinomas were more likely to have extra-appendiceal spread and had worse OS, of 90% and 44% at 3 and 5 years, respectively.

The importance of grade is captured in the eighth edition of the American Joint Committee on Cancer

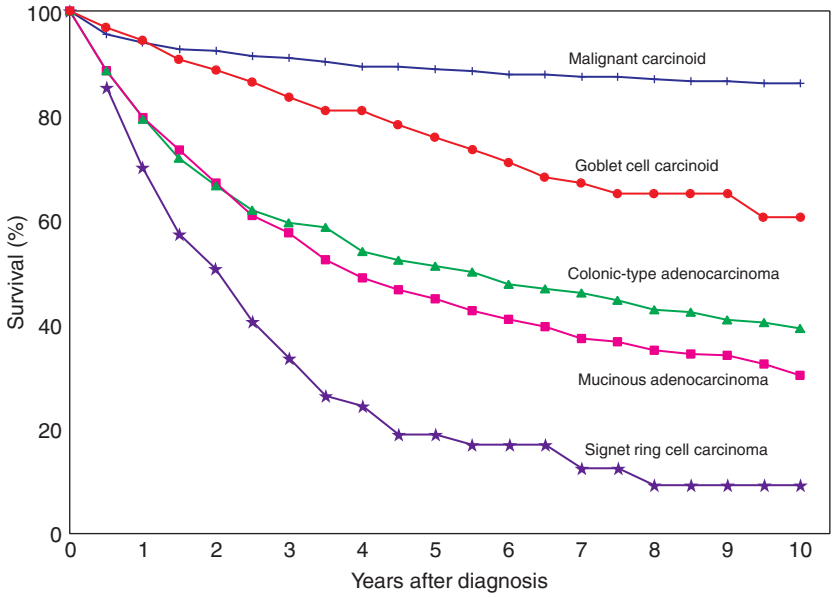

FIGURE 31–3 **Overall survival of malignant appendiceal cancers according to the Surveillance, Epidemiology and End Results registry (SEER), stratified by histological subtype. (AJCC) staging for appendix cancer, which differentiates between stages IVA and IVB (Table 31–4).[33,66] There have been conflicting reports regarding the prognosis of patients with mucinous adenocarcinoma relative to those with nonmucinous or colonic-type adenocarcinoma,[72] with recent report that mucinous moderately differentiated adenocarcinomas appear to have a prognosis more akin to mucinous well-differentiated carcinomas as opposed to mucinous poorly differentiated carcinomas.[73] Despite these nuances, grade trumps all clinico-molecular parameters with regards to the prognostic impact in appendiceal adenocarcinomas.[66] Among carcinoid tumors, pure malignant carcinoids have the best OS (median, 396 months) followed by goblet cell carcinoids (median, 162 months). Goblet cell carcinoids, also called goblet cell tumor (GCT), adenocarcinoma ex goblet cell carcinoid, or mixed adenoneuroendocrine carcinoma, have a mixed histologic appearance that includes neuroendocrine cells and goblet cells, as well as features of adenocarcinoma, increasing percentage of the adenocarcinoma proportion associated with worse outcomes.[74]

TABLE 31–4 Tumor, Node, Metastasis Staging for Appendiceal Carcinomas

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ (intramucosal carcinoma; invasion of the lamina propria or extension into but not through the muscularis mucosae)
Tis(LAMN)	LAMN confined by the muscularis propria; acellular mucin or mucinous epithelium may invade into the muscularis propria T1 and T2 are not applicable to LAMN; acellular mucin or mucinous epithelium that extends into the subserosa or serosa should be classified as T3 or T4a, respectively
T1	Tumor invades the submucosa (through the muscularis mucosa but not into the muscularis propria)
T2	Tumor invades the muscularis propria
T3	Tumor invades through the muscularis propria into the subserosa or the mesoappendix
T4	Tumor invades the visceral peritoneum, including the acellular mucin or mucinous epithelium involving the serosa of the appendix or mesoappendix, and/or directly invades adjacent organs or structures
T4a	Tumor invades through the visceral peritoneum, including the acellular mucin or mucinous epithelium involving the serosa of the appendix or serosa of the mesoappendix
T4b	Tumor directly invades or adheres to adjacent organs or structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One to three regional lymph nodes are positive (tumor in lymph node measuring ≥0.2 mm) or any number of tumor deposits is present, and all identifiable lymph nodes are negative
N1a	One regional lymph node is positive
N1b	Two or three regional lymph nodes are positive
N1c	No regional lymph nodes are positive, but there are tumor deposits in the subserosa or mesentery
N2	Four or more regional lymph nodes are positive
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a[a]	Intraperitoneal acellular mucin, without identifiable tumor cells in the disseminated peritoneal mucinous deposits
M1b	Intraperitoneal metastasis only, including peritoneal mucinous deposits containing tumor cells
M1c	Metastasis to sites other than peritoneum

[a]For specimens containing acellular mucin without identifiable tumor cells, efforts should be made to obtain additional tissue for thorough histologic examination to evaluate for cellularity.

Appendiceal Carcinoid Tumors

Similar to other intestinal carcinoid tumors, appendiceal carcinoid tumors arise from neuroendocrine cells within the lamina propria and submucosa. Appendiceal carcinoid tumors can secrete serotonin and vasoactive substances responsible for the carcinoid syndrome, although this is rarely seen in patients in the absence of extensive liver metastases. Appendiceal carcinoid tumors are usually seen in young patients and are seen slightly more often in women.[75,76] Goblet cell carcinoids or GCT, overall a rare histologic variant of carcinoid tumors, are actually more common in the appendix than pure carcinoid tumors. Characterized by malignant cells that demonstrate both exocrine and neuroendocrine characteristics, GCTs have outcomes in between that of a carcinoid and that of an adenocarcinoma (see Fig. 31–3).

Management of Appendiceal Carcinoids

Because most appendiceal carcinoid tumors are discovered incidentally from an appendectomy specimen, a critical and somewhat controversial oncologic question relates to the need for performing a more complete surgical staging procedure. For appendiceal cancers, a complete surgical staging procedure would entail a right hemicolectomy with complete removal of the base of the appendix, mesoappendix, and draining lymph nodes.

The most useful criteria for determining the need for a complete right hemicolectomy are tumor size (≥2 cm in diameter) and mesoappendix involvement.[77] In a retrospective study of appendiceal carcinoids, Moertel et al[78] reported no metastases in 127 patients with tumors smaller than 2 cm, whereas metastatic disease was seen in three of the 14 patients with tumors 2 to 3 cm in size and four of the nine patients with tumors 3 cm or larger. Patients with GCT are generally treated as having an appendiceal adenocarcinoma. Of note, a small study found no benefit in using 68Ga-DOTATATE positron emission tomography–computed tomography (PET-CT) for follow-up in these patients.[79]

For patients with metastatic malignant carcinoid tumors, the use of somatostatin analogues can alleviate the symptoms of the carcinoid syndrome but rarely causes objective tumor regression. Given the slow-growing nature of appendiceal carcinoid tumors, local modality therapies such as hepatic embolization or surgical resection may also be beneficial in selected patients with metastatic disease. For additional information on management of this type of tumor, please refer to Chapter 34 on neuroendocrine cancers.

Appendiceal Epithelial Tumors

Little is known about the risk factors or cause of epithelial tumors of the appendix. Historically viewed as a subset of CRC, epithelial tumors of the appendix have a markedly different biology and natural history relative to that of adenocarcinomas of the colorectum and do not align with any of the consensus molecular subtype (CMS) of CRC.[80] In particular, a subset of appendiceal epithelial tumors that have disseminated peritoneal mucinous deposits derived from a ruptured appendiceal mucinous adenoma can demonstrate excellent long-term survival with aggressive cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC).[81,82] This contrasts the result of the recent PRODIGE (Partenariat de Recherche en Oncologie Digestive) 7 trial in patients with CRC that showed no additional benefit to HIPEC in addition to CRS.[83] It is thought that most appendiceal epithelial tumors begin as a mucinous adenoma with appendiceal distention caused by excessive mucin production. On gross inspection or radiographic evaluation, this dilated mucin-filled appendix is frequently referred to as a mucocele. With progressive growth, the appendiceal lumen can become obstructed and result in increased intraluminal pressure within the appendix, which can cause the appendix to rupture. Appendiceal rupture represents the critical step in the dissemination of the mucinous appendiceal tumor to the peritoneal cavity. For this reason, it is critical that care is taken when surgically removing an appendiceal mucocele to prevent rupture and peritoneal seeding during a routine appendectomy.[71] When resecting an appendiceal mucocele, the peritoneum should be inspected closely to evaluate any evidence of dissemination to the peritoneal cavity. During pathological examination of the appendix, any fluid or mucus in the peritoneal spaces surrounding the appendix should undergo cytologic examination.[77] In patients with localized disease, the presence of carcinoma (as opposed to LAMN, which does not have invasive features) requires a completion right hemicolectomy for oncologic staging.

Histopathologic Subtypes of Epithelial Appendiceal Tumors

As noted previously, the often inconsistent and ambiguous terminology of appendiceal tumors was updated with consensus guidelines in 2016.[70] Here we will use the new consensus terminology but also list historical terminology for reference.

Pseudomyxoma Peritonei

PMP, literally translated from Latin as "false mucinous tumor of the peritoneum," is a term originally used by Werth in 1884 to describe the pathological findings in a patient with a ruptured ovarian cystadenoma who had copious gelatinous intraperitoneal ascites (Fig. 31–4).[84] This term has been applied broadly to include any mucinous tumor type involving the peritoneal cavity with any histologic grade of differentiation. PMP is a clinical syndrome of malignant mucinous peritoneal dissemination and can sometimes arise from tumors other than the appendix (colon, ovary, urachus, pancreas); notably, it does not reference the histopathologic characteristics of the tumor of origin.[69] To reduce confusion and better segregate patients by clinical outcome, PMP is now subdivided into three groups: low-grade mucinous PMP, high-grade mucinous PMP, and high-grade mucinous PMP with signet ring cells.

Low-Grade Mucinous Pseudomyxoma Peritonei

Low-grade mucinous PMP, previously referred to as disseminated peritoneal adenomucinosis (DPAM),[85] is characterized by peritoneal lesions composed of abundant extracellular, mucin-containing, scant, and simple to focally proliferative mucinous epithelium with little cytologic atypia or mitotic activity, with or without an associated appendiceal mucinous adenoma.[85] In essence, the underlying epithelium in low-grade mucinous PMP may have low-grade adenomatous changes but may not have any evidence of infiltrative invasion or carcinoma. However, there must be observed neoplastic cells; mucin without neoplastic cells is termed *acellular mucin*. Notably, in the setting of an appendiceal primary tumor, acellular mucin within the abdominal cavity is classified pM1a by the *AJCC Cancer Staging Manual*, eighth edition, whereas deposits with tumor cells are classified M1b.[33] Low-grade mucinous PMP

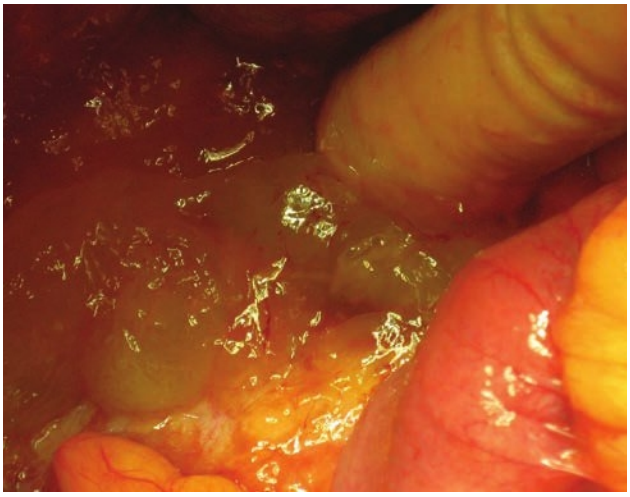

FIGURE 31–4 Peritoneal mucin in a patient undergoing surgical cytoreduction.

subgroup of tumors demonstrates the classic PMP clinical syndrome of massive amounts of benign-appearing mucinous ascites that over time slowly fill the entire peritoneal cavity (Fig. 31–5). Although spread to the peritoneal cavity is present, these tumors do not metastasize to regional lymph nodes or via hematogenous spread to the liver or other distant sites.

Patients with low-grade mucinous PMP typically present with gradually increasing abdominal girth. For women, DPAM may present as a new ovarian mass, and for men, it may present as a new-onset hernia. In women, secondary involvement of the ovaries is common, and because the histopathologic features of low-grade mucinous PMP from a primary ovarian tumor can be quite similar to those of appendiceal origin, a thorough pathological examination of the appendix should be conducted.[86] When molecular and immunohistochemical evaluations have been performed on patients with both appendix and ovarian involvement, these evaluations have generally demonstrated the primary site of disease as the appendix[87–89]

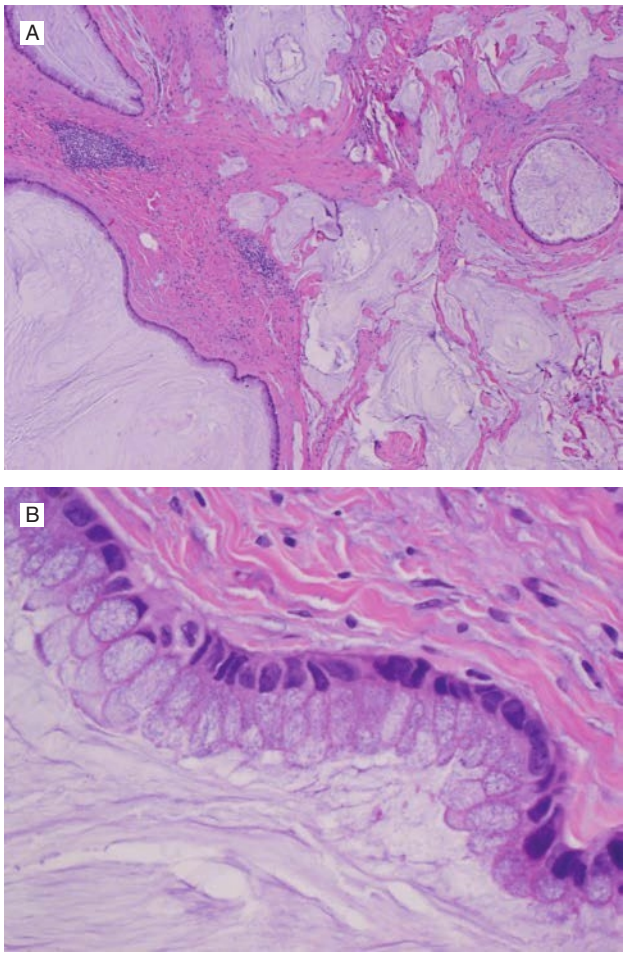

FIGURE 31–5 Histology from a patient with well differentiated mucinous appendiceal adenocarcinoma with the clinical syndrome of pseudomyxoma peritonei (PMP). A. Adenoma-like epithelium with acellular mucin pools dissecting through the fibrous stroma with chronic inflammation (×40). B. Adenoma-like epithelium with abundant acellular mucin (×400).

High-Grade Mucinous Pseudomyxoma Peritonei and Pseudomyxoma Peritonei-Grade Mucinous Pseudomyxoma Peritonei with Signet Ring Cells

If evidence of destructive, infiltrative invasion or high-grade cytologic atypia is present, then the pathological diagnosis of high-grade mucinous PMP should be used[69] Previously referred to as peritoneal mucinous carcinomatosis (PMCA),[85] these tumors are characterized by peritoneal lesions composed of more cellular mucinous epithelium with the architectural and cytologic features of carcinoma, with or without an associated primary mucinous adenocarcinoma. If high-grade features are found, even focally, the lesion should be classified as high grade, which makes adequate sampling and review of the complete resected specimen critical. High-grade mucinous PMP with signet ring cells, previously called peritoneal mucinous carcinomatosis with signet ring cells (PMCA-S), is included as a separate category given the worse prognosis associated with signet ring cells. In an analysis of 109 patients with clinical features of PMP, the 5- and 10-year survival rates for patients with low-grade disease were 75% and 68%, respectively. This was in stark contrast to those with high-grade disease, who had 5- and 10-year survival rates of 14% and 3%[90] (Fig. 31–6).

Mucinous Appendiceal Adenocarcinoma

The most common type of epithelial appendiceal tumor, like PMP, mucinous appendiceal adenocarcinoma really behaves like two distinct disease entities with low-grade tumors having a much more indolent clinical course relative to high-grade tumors. These tumors are differentiated from LAMN and HAMN by the presence of infiltrative invasion and by definition more than 50% of the cross-sectional area histologically comprises extracellular mucin.[69] The consensus guidelines recognize a trinary well-, moderately, or poorly differentiated grading scheme with poorly differentiated carcinomas showing little or no gland formation. A study of 201 mucinous appendiceal carcinomas has shown the trinary grading systems is strongly predictive of survival with 94%, 71%, of 30% of patients alive at 5 years for well-, moderately, and poorly differentiated tumors, respectively.[91] Although mucinous appendiceal adenocarcinoma are invasive tumors with distant metastatic potential, the majority of these tumors remain localized to the peritoneal cavity. Even in the subset of patients with aggressive-appearing

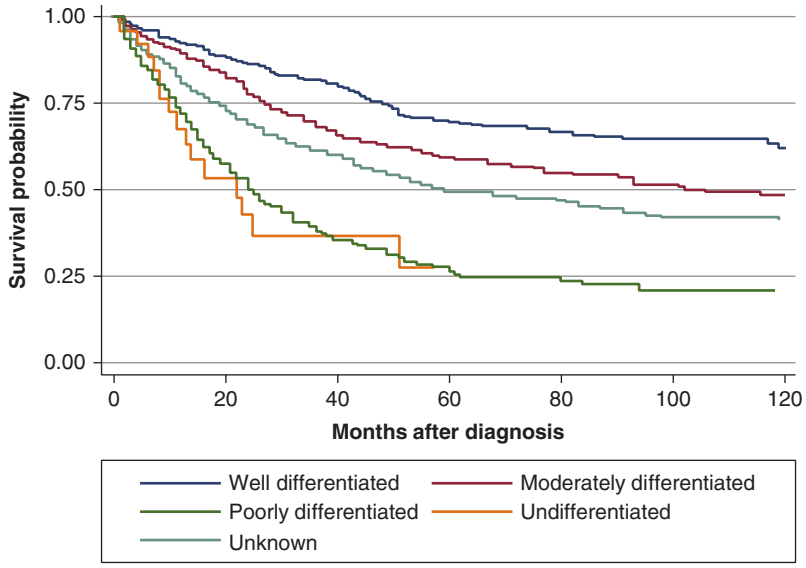

FIGURE 31–6 **Overall survival of appendiceal adenocarcinoma stratified by histological grade. (Reproduced with permission from Overman MJ, Fournier K, Hu CY, et al: Improving the AJCC/TNM staging for adenocarcinomas of the appendix: the prognostic impact of histological grade, *Ann Surg* 2013 Jun;257(6):1072-1078.)**

histologies, the rate of distant hematogenous metastases remains low. In one retrospective study of 90 appendiceal adenocarcinomas with either poor differentiation or signet ring cell morphology, the rate of extraperitoneal metastases was only 17%.[92]

Nonmucinous or Colonic-Type Adenocarcinoma

Occurring somewhat less frequently than mucinous tumors, nonmucinous or colonic-type adenocarcinomas of the appendix demonstrate a different tumor biology than mucinous appendiceal tumors. These cancers are generally more aggressive and less likely be well differentiated and appear to behave more like colonic adenocarcinomas. In a study by Kabbani et al,[93] 43% of patients with nonmucinous appendiceal adenocarcinoma had evidence of extraperitoneal metastases. The patients with nonmucinous carcinomas in this study had a significantly worse OS and DFS than those with mucinous carcinomas, although given the critical importance of grade in determining survival in mucinous tumors, it is difficult to make this direct comparison.

Molecular Profiles

Recent large sequencing studies, including independent cohorts of 703 and 266 appendiceal tumors have revealed several key molecular differences between appendiceal tumors and CRC and between different subtypes of appendiceal tumors.[65] Most notably, *APC* mutation, which is a hallmark feature of CRC, is uncommon in all subtypes of appendix cancer. Similarly, appendix tumors have less frequent *TP53* mutation (Fig. 31–7).[66] The frequency of *GNAS* mutation is much higher in appendix cancer, with a particularly strong enrichment in low-grade tumors. Nearly all *GNAS* mutations occur in codon R201, with R201H and R201C being the most common substitutions. Of note, Although *GNAS*-specific chemical inhibitors do not yet exist, the cystine in the R201C mutation could be targeted similar to that in *KRAS* G12C. The frequency of *KRAS* mutation is similar in appendix cancer and CRC. Unfortunately, the incidence of currently "actionable" mutations in genes such as *HER2* and *EGFR* is quite rare in appendiceal tumors, as is microsatellite instability. Importantly, low-grade appendiceal adenocarcinomas have distinct molecular profile from high-grade tumors characterized by frequent mutation in *GNAS* and *KRAS* and absence of *TP53* mutation (Fig. 31–8).[65,66] These molecular differences and the distinct indolent disease course of low-grade tumors suggests strongly that low-grade appendix adenocarcinoma is a distinct disease entity from high-grade appendix adenocarcinoma.

There are limited transcriptomic data on appendiceal cancer, although a pilot study of microarray gene expression profiling of 26 appendiceal adenocarcinomas showed clear differences between appendiceal adenocarcinoma and CRC.[94] A second study of 24 additional tumors identified a 139 gene signature associated with poor prognosis specifically in low-grade tumors.[95] Unsupervised clustering of appendiceal tumors with all of the TCGA tumors and cancer cell lines from the Cancer Cell Line Encyclopedia[96] using the Celligner method[97] has shown that appendiceal tumors cluster

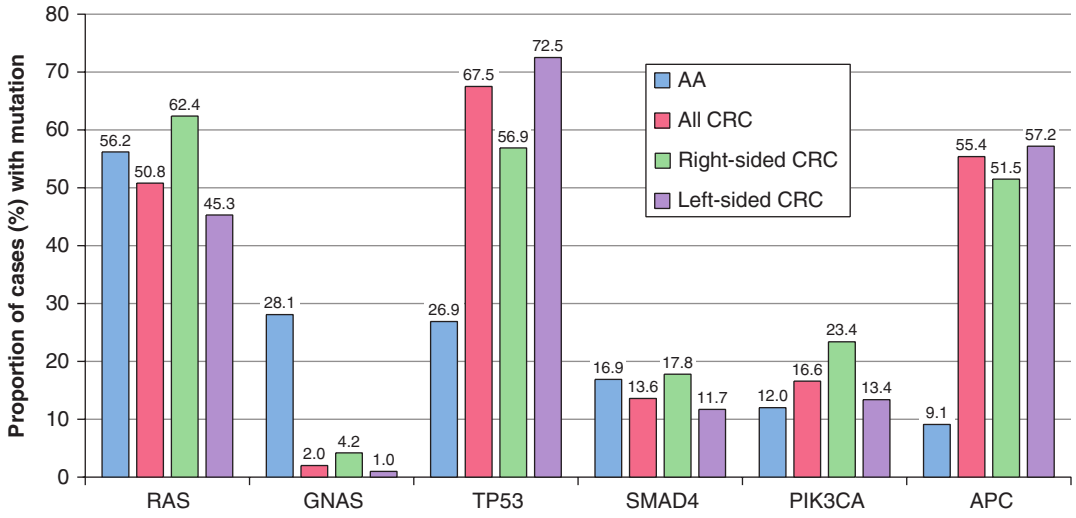

FIGURE 31–7 **Frequency (percentage) of mutations (>3% incidence) in tumor tissue from patients with appendix cancer (a) and distribution of mutation (top six most frequently mutated genes) by grade or differentiation as compared to colorectal cancer (CRC). (Reproduced with permission from Raghav K, Shen JP, Jácome AA, et al: Integrated clinico-molecular profiling of appendiceal adenocarcinoma reveals a unique grade-driven entity distinct from colorectal cancer, *Br J Cancer* 2020 Oct;123(8):1262-1270.)**

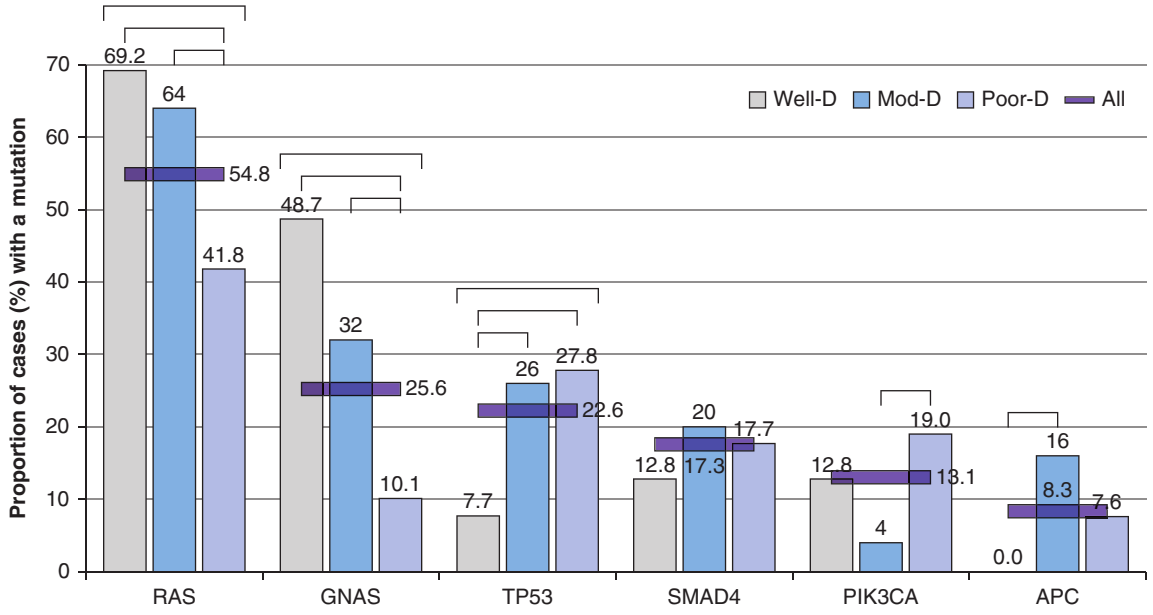

FIGURE 31–8 **Frequency of the top six cancer mutations in appendiceal adenocarcinomas stratified by grade. Comparisons are shown for only significant differences (P <.05). closely together, away from any other tumor type and also away from any cell line model. This indicates that appendiceal cancer is a distinct entity from CRC and that currently, there are no representative cell line models of appendix cancer. Gene Set Enrichment Analysis of appendix cancer transcriptomes has shown upregulation of the eukaryotic translation initiation factor 4E (eIF4E) as well as RAF and EGFR in the RAS-MAPK (mitogen-activated protein kinase) pathway.

The ability to measure circulating tumor DNA (ctDNA) in the blood has proven valuable in many GI malignancies; however, the sensitivity of these "liquid biopsies," particularly in low-grade appendiceal tumors, seems to be low. The ultimate answer to this

question will require a cohort of patients with paired blood and tissue sequencing; however, a 73-gene panel identified a mutation in blood in only 61% of patients versus an expected 94% based on tissue sequencing.[65,98] Interestingly, the disparity was much greater for mutations in gene characteristic of low-grade tumors, such as *GNAS* (34% vs 2.6%, 13-fold), relative to mutations characteristic of high-grade tumors, such as *TP53* (35% vs 23%, 1.5-fold), suggesting that low-grade tumors are less likely to shed DNA into the blood. The prognostic implications of having detectable ctDNA in the blood remain unknown, but this could potentially have value as a biomarker of high-risk disease.

Treatment

Cytoreductive Surgery

Because of the relative rarity of this disease, prospective randomized clinical trials studying the treatment of appendiceal epithelial tumors are lacking. The majority of data evaluating the various treatment modalities in this disease have been derived from retrospective, single-institution studies. Surgical cytoreduction has been the primary mode of therapy for these tumors based on the following factors:

1. Lack of extraperitoneal disease spread
2. Primarily mucinous nature of peritoneal deposits
3. Indolent growth rate (for low-grade tumors)
4. Limited activity of systemic chemotherapy
5. Lack of an effective systemic mucolytic agent

The goal of surgical cytoreduction is complete tumor removal from the peritoneal cavity. Because of the large surface area of the peritoneum, surgical cytoreduction to remove all visible sites of disease can be challenging. Optimal CRS may involve removal of the appendix, right colon, intraperitoneal tumor debulking, resection of multiple abdominal and pelvic organs with peritoneal tumor studding, and stripping of all involved parietal peritoneum.[99] After successful surgical cytoreduction, patients can experience reaccumulation of mucinous peritoneal implants, which may be complicated by fibrosis from prior surgery, requiring repeated surgical cytoreductive procedures.

In a 97-patient series from Memorial Sloan Kettering Cancer Center, in which surgical resection alone represented the primary treatment modality in more than two thirds of the patients, the 5-year OS rates were 90% for patients with low-grade and 50% for patients with high-grade tumors.[81] In the 55% of patients who underwent a complete cytoreduction of all visible tumors, 91% had recurrent disease. The average number of surgical cytoreductions that patients underwent in this study was 2.2, with a range of 1 to 6.[81] These findings are contrasted by a retrospective analysis of 512 peritoneal metastatic appendiceal tumors in which only 26% developed recurrence.[100] The median time to recurrence was 26 months. Repeat CRS was attempted in 26% of these patients and was associated with better survival than for recurrent patients who did not undergo a second CRS. These data suggest that in patients who develop recurrence after an extended disease-free interval, repeat CRS can be attempted with favorable results for at least some patients.

Hyperthermic Intraperitoneal Chemotherapy

In an attempt to diminish the rate of disease recurrence after CRS, the administration of intraperitoneal chemotherapy after a surgical cytoreduction has been used to try to treat any residual microscopic disease in the peritoneal cavity. Historically, a number of methods of delivering intraperitoneal chemotherapy have been used, although the most commonly used method is HIPEC administered at the time of cytoreduction. At MDACC, after complete CRS, the standard procedure is to administer heated mitomycin C at a dose of 25 mg/m^2 for patients who are chemotherapy naïve or 20 mg/m^2 for patients who have received previous chemotherapy in a volume of 5 to 6.5 L of electrolyte solution at a flow rate of 3 to 3.5 L/min. Intraoperative hemodynamic monitoring and thermal monitoring are essential for optimal outcomes in these patients. The HIPEC is continued for 90 minutes with vigorous shaking of the closed abdomen. On completion of HIPEC, necessary bowel anastomoses are performed, and gastrostomy and jejunostomy tubes are placed for postoperative management of nutritional deficiencies and prolonged gastric ileus.

Intraperitoneal administration of chemotherapy offers an advantage of providing high local concentrations of drug directly to the targeted peritoneal surfaces, and hyperthermia provides a synergistic antitumor effect when combined with chemotherapy.[101] However, as a locally applied modality, the maximum penetration into tumor tissue is usually limited to 2 to 5 mm from the surface.[102] At present, no randomized study has compared the benefit of adding HIPEC to surgical cytoreduction, although single-institution series have indirectly suggested a benefit when DFS rates of patients treated with surgical cytoreduction and HIPEC (37%–57%)[87,103] are compared with the historical rates of surgical cytoreduction alone (9%–12%).[81,88]

CRS with HIPEC represents an aggressive treatment requiring significant surgical expertise and should only be conducted at centers experienced in performing peritoneal cytoreduction. Operation time is approximately 8 to 12 hours, with an average hospital stay of 20 to 25 days. The 30-day postoperative mortality and morbidity rates range from 0% to 12% and 12% to 56%, respectively.[87,89] In one of the largest retrospective multi-institutional registry-based

study of 2298 patients with PMP originating from an appendiceal mucinous neoplasm undergoing CRS, the reported median OS was 16.3 years, with a 10-year survival rate of 63%.[104] The treatment-related mortality was 2%, and major operative complications occurred in 24% of cases.[104] A high peritoneal carcinomatosis index (PCI), lack of complete cytoreduction, and lack of HIPEC were associated with poorer PFS and OS.[104]

The prognosis for patients undergoing CRS with HIPEC is primarily dependent on two critical factors: histologic classification and completeness of surgical resection. A quantitative score, the completeness of cytoreduction (CC) score proposed by Sugarbaker and colleagues,[82] categorizes the CC based on the size of nodules remaining at the end of surgery: CC-0 (no visible disease), CC-1 (nodules <0.25 cm), CC-2 (nodules 0.25 to <2.5 cm), and CC-3 (nodules ≥2.5 cm). In an analysis of 224 patients with low-grade histology, Sugarbaker et al[82] found that whereas patients with complete cytoreduction (CC-0 or CC-1) had a 5-year OS rate of 86%, patients with incomplete cytoreduction (CC-2 or CC-3) had a 5-year OS rate of 20% (P <.0001) (Fig. 31–9). The importance of CC has been confirmed by other authors, although various methods of categorizing CC have been used.[87,103]

Additional prognostic measures include the PCI, a quantitative measure of the size and distribution of nodules on the peritoneal surface; the previous surgical score, a measure of the extent of prior cytoreduction; and the extent of disease on the small bowel and small bowel mesentery.[81,82,105,106] The prognostic value of these different factors relates primarily to their ability to predict the likelihood of obtaining a complete cytoreduction. For patients who cannot undergo complete CRS, the benefit obtained from an incomplete cytoreduction remains uncertain. If complete CRS cannot be performed, a surgical cytoreduction is generally considered only if there are particular symptoms that can be palliated by tumor debulking. Given that HIPEC has limited tumor penetration, use of HIPEC should be limited to patients with a complete or near-complete CRS.

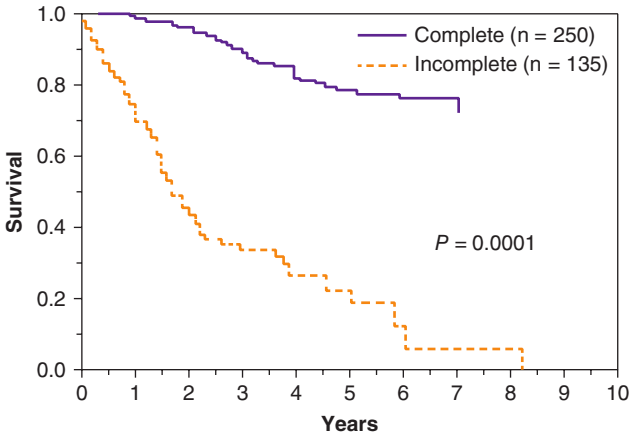

FIGURE 31–9 Overall survival for 385 cases with the mucinous epithelial tumors of the appendix according to completeness of surgical cytoreduction (CC). Complete cytoreduction defined as a CC score of CC-0 or CC-1, and an incomplete cytoreduction is defined as a score of CC-2 or CC-3. (Reproduced with permission from Sugarbaker PH. Results of treatment of 385 patients with peritoneal surface spread of appendiceal malignancy. *Ann Surg Oncol***. 1999;6(8):727-731.)**

Systemic Chemotherapy

The role of systemic chemotherapy has not been well delineated in appendiceal epithelial tumors and has generally been used in patients who are not candidates for surgical cytoreduction.[99] The challenges of using systemic chemotherapy to treat appendiceal tumors are numerous. Because it is a rare disease, it has been difficult to conduct clinical trials specifically for appendiceal tumors. Factors further complicating the development of effective chemotherapy include the marked heterogeneity between low- and high-grade tumors, the relatively slow-growing nature of the disease, the primarily mucinous component of the tumors, and challenges in radiographically measuring disease response. In the absence of data specific to appendiceal adenocarcinoma, chemotherapy developed for CRC has traditionally be used for these tumors. Traditionally, PMP has been considered resistant to systemic chemotherapy, although a phase II study evaluating the use of concurrent mitomycin C and capecitabine in patients with advanced, unresectable high- or low-grade mucinous PMP has suggested a role for systemic chemotherapy.[107] In this study of 39 patients, a clinical benefit rate of 38% was determined based on the definition of either semiquantitative reductions in mucinous deposition or stabilization of previously progressive disease, with a 2-year cancer-related mortality rate of 39%.[107]

There is now growing recognition that given differences in natural history, somatic mutation profiles and gene expression high- and low-grade appendiceal tumors need to be treated as separate entities with respect to chemotherapy. A 2016 review of 25,992 tumors from the SEER database found stage IV well-differentiated mucinous appendiceal adenocarcinomas demonstrated no benefit from systemic chemotherapy.[108] This finding was confirmed by a similar study of 639 metastatic well-differentiated

mucinous appendiceal adenocarcinoma patients showing 5 year survival benefit from surgical resection (HR, 0.4) but not chemotherapy (HR, 1.1).[109] Currently, a randomized trial for well-differentiated appendiceal tumors is underway at MDACC to confirm these findings prospectively; reporting is expected in 2021.

Although colon cancer chemotherapy—namely, fluoropyridines (5-FU, capecitabine) oxaliplatin, and/or irinotecan—is commonly used for patients with high-grade appendiceal cancer, there are few published data to support this practice. Shapiro et al[99] retrospectively reviewed data collected from 54 patients (26 moderate or poorly differentiated) who were suboptimal surgical cytoreductive candidates, showing radiographic stabilization or response to therapy in 55% of patients with median PFS of 7.6 months and median OS of 56 months. The largest study specifically of high-grade appendiceal adenocarcinoma is a retrospective review of 142 patients by Lieu et al.[92] This showed a response rate of 44%, median PFS of 6.9 months, and median OS of 1.7 years. Patients with response to chemotherapy and complete CRS were associated with improved PFS and OS. A small Japanese case series showed disease control in 6 of 8 patients with FOLFOX.[110] Regarding the combination of systemic treatment with surgery, in a study of 109 high-grade tumors, adjuvant chemotherapy after CRS plus HIPEC was associated with improved PFS (12.6 months vs 6.8 months; P <.01), but interestingly, no benefit was seen from neoadjuvant treatment.[111] There are also retrospective reports suggesting that combining bevacizumab with chemotherapy may improve survival outcomes in surgically unresectable appendiceal epithelial neoplasms.[112,113]

The MD Anderson Approach to Epithelial Appendiceal Tumors

Unlike CRC, appendiceal epithelial malignancies have a more indolent natural history that is determined primarily by their underlying histopathology. At MDACC, patients with LAMN and well- to moderately differentiated mucinous adenocarcinoma are evaluated initially for CRS. Patients with a complete cytoreduction (CC-0 or CC-1) are treated with HIPEC using intraperitoneal mitomycin at 42°C. If a complete CRS is not obtained, if radiographic imaging indicates that obtaining a complete cytoreduction is highly unlikely, or if medical comorbidities preclude a surgical procedure, then patients are considered for systemic chemotherapy. Also, HIPEC is used at MDACC for the control of refractory ascites in select patients with low-grade tumors. We have found that the use of HIPEC in patients who have undergone an incomplete CRS can provide long-term control of ascites and should be considered in patients with refractory ascites.

Given the indolent nature of well- to moderately differentiated mucinous adenocarcinoma, systemic chemotherapy is generally reserved for patients who either have clear evidence of disease progression on radiographic imaging or have significant tumor-related symptoms. Frontline chemotherapy is fluoropyrimidine based, and additional agents may be added based on the perceived tolerance of more aggressive combinations. Given the generally good prognosis of these patients and limited data supporting the efficacy of CRC-like chemotherapy in these tumors, it is critical that treatment is closely aligned with quality of life and that cumulative toxicities are kept to a minimum.

The use of multiagent systemic chemotherapy, as administered in patients with CRC, is the treatment of choice for patients who have signet ring cells, poorly differentiated tumors, or nonmucinous tumors. Because patients with poorly differentiated or signet ring cell appendiceal adenocarcinomas have consistently shown worse outcomes after aggressive CRS, our approach has been only to consider surgical cytoreduction in these patients after initial treatment with systemic chemotherapy. In a retrospective study from MDACC, Lieu et al showed that patients with stage IV poorly differentiated or signet ring cell morphology appendiceal adenocarcinomas had a median OS of 24 months, similar to the known OS for patients with metastatic CRC.[92] With regard to targeted agents, it is not standard practice at MDACC to use either VEGF inhibitors or EGFR inhibitors in appendiceal epithelial tumors. MSI-H is rare in appendiceal cancer, but these patients are treated with immunotherapy similar to those with MSI-H colon cancer. Given the lack of data supporting systemic chemotherapy and lack of a true standard-of-care regimen, patients should be enrolled on clinical trials whenever possible. To help facilitate trial enrollment, all metastatic appendiceal tumors are routinely molecularly profiled for somatic mutation in common cancer genes, microsatellite instability, and HER2 overexpression. Now that it is possible to obtain these data in a Clinical Laboratory Improvement Amendments (CLIA) fashion, moving forward this molecular profiling will include RNA_Seq.

Because of the rarity of appendiceal tumors, our understanding of these tumors is limited, and further research into the molecular characteristics of these tumors is needed. The role of CRS is well established for appendiceal epithelial tumors. The use of systemic chemotherapy in patients with appendiceal epithelial tumors needs further study, in particular for low-grade tumors in which CRC-like chemotherapy seems to provide no benefit.

MD ANDERSON PRACTICE TIPS: SMALL BOWEL CANCER

- Predisposing conditions for SBA should be considered; specifically, testing for both mismatch repair and celiac disease should be done.
- Approach adjuvant therapy for SBA similar to the general principles from colon adenocarcinoma, but stage for stage, outcomes for SBA tend to be worse.
- All patients with metastatic disease should be profiled as a number of targetable alterations can be identified such as HER2 alterations and mismatch repair deficiency.
- For metastatic SBA, start with 5-FU–based chemotherapy (FOLFOX, FOLFIRI, or FOLFOXIRI). Use of concomitant bevacizumab can be considered, but use of anti-EGFR drugs (cetuximab and panitumumab) appears to have limited activity.
- Taxane-based therapy has demonstrated activity and can be considered in later lines of therapy in the absence of clinical trials, but referral to clinical trials is always preferred.

MD ANDERSON PRACTICE TIPS: APPENDICEAL TUMORS

- Grade is critical in all mucinous appendiceal neoplasms for both prognosis and management. Ensure adequate sampling has occurred, and if uncertainty exists, consider discussion with pathology.
- Given the mucinous nature of these cancers in most cases (especially low-grade tumors) and the desire for peritoneal cavity evaluation, PET scans should not be used in routine care.
- For low-grade (well-differentiated) mucinous adenocarcinomas, ensure multidisciplinary discussions and early surgery referral because they represent a favorable prognostic entity that is best managed with surgery.
- Avoid use of chemotherapy in patients with low-grade (well-differentiated) mucinous adenocarcinomas because these tumors tend to be nonresponsive to chemotherapy.
- In nonmucinous and high-grade mucinous appendiceal adenocarcinomas, systemic 5-FU–based chemotherapy should be used because these histologic types are chemoresponsive, and the benefit from upfront CRS is uncertain.

KEY CONCEPTS

- Although the overall incidence of incidence of colorectal cancer (CRC) has decreased, its incidence in those younger than 50 years of age (ie, early-onset CRC) has significantly increased over the past 2 to 3 decades, accounting for an estimated one of every 10 cases currently being diagnosed in the United States.
- Surgery is the cornerstone of curative therapy in locoregional CRC. Adjuvant chemotherapy with a fluoropyrimidine typically in combination with oxaliplatin is standard-of-care adjuvant therapy for patients with stage III and IV and high-risk stage II colon cancer. Recent data support tailoring duration of therapy (3 months vs 6 months) based on pathologic stage for stage III colon cancer.
- In patients with locally advanced rectal adenocarcinoma, the paradigm has shifted to a total neoadjuvant therapy approach in which systemic chemotherapy in addition to neoadjuvant radiation is administered before surgery. Ongoing studies are evaluating deintensifying such trimodality therapy by omitting surgery or radiation in select patients.
- Biomarker testing that includes mismatch repair deficiency should be performed in all patients with CRC; expanded *RAS* (*KRAS* and *NRAS* exons 2,3, 4), $BRAF^{V600E}$ mutation, and *HER2neu* amplification should be performed in all patients with metastatic CRC. *NTRK* fusion and *POLE* mutations are rare but targetable aberrations in metastatic CRC (mCRC). All patients with mCRC should be evaluated for resectable disease at diagnosis and at each restaging.
- Most patients with mCRC are treated with fluoropyrimidine-based combination chemotherapy with oxaliplatin, irinotecan, or both in the first- and second-line settings. Monoclonal antibodies (mAbs) against the vascular endothelial growth factor axis or epidermal growth factor receptor (EGFR) may be used in combination with such chemotherapy. The use of anti-EGFR antibodies should be limited to *RAS* wild-type patients and to those with tumors arising in the left colon at least in the first-line setting. Patients with incurable metastatic disease should be considered for periods of less intensive therapy during their treatment course as the clinical situation warrants. Patients with mismatch repair–deficient mCRC are responsive to immunotherapy and should be treated with such agents, including in the first-line setting.
- A biologic doublet therapy of encorafenib (BRAF inhibitor) in combination with cetuximab (EGFR mAb) is now standard of care for patients with previously treated $BRAF^{V600E}$ mutant mCRC. Regorafenib and TAS-102 are oral agents for patients with refractory disease in later lines of therapy. Ongoing trials are evaluating role of anti-Her2neu therapy in patients with *Her-2neu* amplification and rechallenge with anti-EGFR antibodies in patients with prior clinical benefit and subsequent progression.

Colorectal cancer (CRC) is currently the third most common cancer in incidence in the United States and accounts for about 8.5% of all cancer-related deaths (nearly 148,000 new cases and 53,000 deaths each year).[1] This chapter reviews our current understanding of CRC; describes the known genetic mutations and risk factors; and outlines emerging screening, prevention, and therapeutic strategies, with particular emphasis on the approach taken at MD Anderson Cancer Center (MDACC).

EPIDEMIOLOGY AND ETIOLOGY OF COLORECTAL NEOPLASIA

Carcinogenesis: The Adenoma–Adenocarcinoma Sequence

Colorectal neoplasia results from three different pathways driving carcinogenesis, including chromosomal instability, microsatellite instability (MSI),

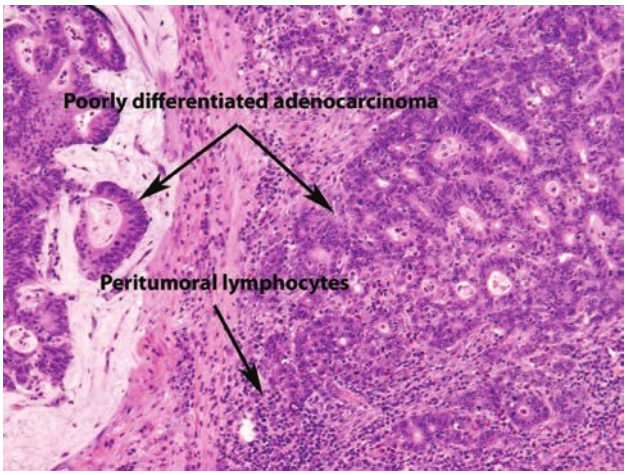

FIGURE 32–1 **Photomicrograph of a tumor with microsatellite instability. *Upper arrows* point to poorly differentiated malignant cells with some glandular differentiation and mucin. *Lower arrow* shows peritumoral lymphocytes clustering near areas of malignant cells and permeating the local stroma. CAPOX, capecitabine and oxaliplatin; dMMR, deficient mismatch repair; 5-FU, 5-fluorouracil; FOLFOX, 5-fluorouracil, leucovorin calcium, and oxaliplatin; LV, leucovorin.**

and CpG island methylation. The chromosomal instability pathway identifies early mutations in genes such as the tumor suppressor *APC* and the K-*ras* oncogene and later genetic events, including *PIK3CA* oncogene and the tumor suppressor gene *p53*. Histology that suggests an MSI tumor may include mucinous features, poor differentiation, or the presence of tumor-infiltrating lymphocytes (Fig. 32–1).

Consensus Molecular Subtype Classification

Patterns in RNA expression have been shown to define four molecular subtypes of CRC, with important prognostic differences.[2] The first consensus molecular subtype (CMS), CMS1, defines a subgroup with immune activation, and encompasses the majority of MSI and *BRAF*-mutated tumors. CMS2, or the canonical subgroup, is the most common and includes features of MYC activation and *TP53* mutations. CMS3 is a less common subtype with metabolic dysregulation and high rates of *KRAS* mutation. CMS4 is an immune-excluded subtype with active stromal features, including transforming growth factor β signaling. The ability of these subgroups to define treatment response has been proposed but is not yet integrated into treatment guidelines.[3]

TABLE 32–1 Lifetime Risks of Colorectal Cancer

Characteristic	Incidence (%)
General population	5
Personal history of colorectal cancer	15–20
Inflammatory bowel disease	15–40
Adenomatous polyps: personal	Variable
Hereditary nonpolyposis colorectal cancer mutation	70–80
Familial adenomatous polyposis	>95

Risk Factors

Genetic predisposition, acquired (somatic) or inherited genetic (germline) mutations, interplay with further environmental, dietary, or other less-well-understood factors in CRC carcinogenesis. Personal or family histories of CRC or polyps, older age, and inflammatory bowel disease (IBD) have all been associated with an increased risk of CRC (Table 32–1).

Modifiable Risk Factors

A diet rich in saturated fat, tobacco use, and excess alcohol use have been associated with an increased risk of colon cancer. Fiber has previously been associated with lower CRC risk; however, after correction for other dietary factors, it is no longer considered protective.[4]

Obesity and Insulin Resistance

Increased body mass index (BMI) and central obesity are risk factors for CRC. The Framingham Study found that a BMI above 30 increases the risk of colon cancer by 50% among middle-aged (30–54 years) individuals and by 2.4-fold for those aged 55 to 79 years, and waist circumference was a stronger predictor than BMI.[5] Independent of body mass index, insulin resistance and diabetes mellitus have also been associated with CRC.[6]

Adenomatous Polyps

Carcinoma is present in 5% of adenomas, in which the potential for malignant transformation is 8 to 10 times higher for villous and tubulovillous adenomas than tubular adenomas. Just over 1% of adenomatous polyps smaller than 1 cm in size are malignant, whereas up to 40% of adenomas larger than 2 cm are malignant.

Inflammatory Bowel Disease

Patients with IBD (ulcerative colitis or Crohn disease) are at increased risk of developing CRC based on the duration and extent of active disease, colitis,

and mucosal dysplasia. Recognizing the increased risk of CRC for patients with IBD, appropriate screening should be instituted.

Familial Syndromes

About 20% of all CRC cases are attributed to inherited autosomal dominant syndromes, including familial adenomatous polyposis (FAP), Gardner syndrome, and hereditary nonpolyposis colorectal cancer (HNPCC) (see Table 32–1).

Familial Adenomatous Polyposis

FAP is caused by a mutation of *APC* leading to the functional loss of both *APC* alleles, one inherited as a germline mutation and the other mutated in early childhood. FAP has high penetrance, manifesting as thousands of adenomatous polyps; some invariably progress to cancer, thereby warranting a prophylactic colorectal resection. The onset of malignancy in untreated patients occurs at about 42 years, with invasive cancer developing 20 to 30 years later.

Hereditary Nonpolyposis Colorectal Cancer

HNPCC (also known as Lynch syndrome) is caused by germline mutations in the DNA mismatch repair genes. Additional mutations involving tumor suppressor genes and oncogenes rapidly accumulate within these DNA repair–deficient cells, leading to malignant transformation in only 3 to 5 years.

MUTYH-Associated Polyposis

MutY homolog–associated polyposis is caused by biallelic mutations in the base excision repair gene *MUTYH*. Patients with the syndrome are characterized by oligopolyposis, usually more than 15 but fewer than 100 polyps. The onset of adenomas is older than in those with classic FAP but similar to attenuated adenomatous polyposis (45–55 years of age).

Early-Onset Colorectal Cancer

In contrast to the declining incidence of CRC in screening-eligible patient (age older than 45–50 years), the incidence of CRC in younger adults has substantially increased over the past 2 to 3 decades. It is now estimated that 1 in 10 diagnoses in the United States are in younger patients, with the number of young patients with rectal cancer representing as much as 1 in 5 diagnoses.[7] The cause of this increase in not clear because hereditary syndromes do not appears commonly in these patients. Efforts to understand the environmental exposures, comorbidities, and lifestyle factors are ongoing.

SCREENING FOR COLORECTAL NEOPLASIA

The current recommendation of the US Preventative Services Task Force is to use any accessible screening method, recognizing the major hurdles to improving outcomes are caused by poor screening compliance and less about specific testing characteristics.[8] At MDACC, we recommend colonoscopy screening starting at the age of 45 to 50 years as a preferred modality.

Detection Methods

Stool-Based Testing

Meta-analysis of four randomized trials investigating the role of fetal occult blood testing (FOBT) demonstrated an increased detection of early-stage CRCs and a reduction in CRC mortality.[9] Fecal immunohistochemistry tests (FITs) use antibodies for hemoglobin and appear more sensitive than FOBT; however, studies demonstrating mortality reduction have not been completed. DNA testing of stool uses detection of mutation and methylation markers from shed epithelial cells from adenomas or adenocarcinomas. Although sensitivity appears higher than FIT, mortality reduction has not been directly confirmed with this screening approach.

Blood-Based Testing

Carcinoembryonic antigen (CEA) is not recommended as a screening test because of poor sensitivity and specificity. Septin 9 DNA testing in blood is approved by the Food and Drug Administration (FDA) for patients refusing a colonoscopy but not recommended as a screening method because of low sensitivity.

Sigmoidoscopy

Flexible sigmoidoscopy is relatively safe and inexpensive suitable for screening large populations at low risk in combination with FOBT. However, adenomas in the distal colon are not indicative of proximal lesions, and sigmoidoscopy may miss nearly 50% of all colonic lesions.[10] Patients with adenomas detected by flexible sigmoidoscopy should have a full colonoscopy.

Computed Tomography Colonography (Virtual Colonoscopy)

Virtual colonoscopy (VC) involves reconstruction of three-dimensional images of the colon from the two-dimensional data obtained by a spiral computed tomography (CT) scanner. Bowel preparation is required, but the technique is less invasive and does not require sedation. However, VC lacks the advantage of a colonoscopy for direct access to colonic tissue for biopsies.

Colonoscopy

Colonoscopy not only enables full visualization of the entire colon but also allows for biopsy or removal of any suspicious lesions.

Despite widespread use, the colonoscopy for the purposes of cancer screening has not been studied in a randomized prospective trial until the Nordic-European Initiative on CRC (Nordic) study (NCT00883792). This multinational trial randomized patients aged 55 to 64 years to either once-only screening colonoscopy with removal of all lesions or no screening, which is the standard of care in these trial countries.[11] After a 15-year follow-up period, the primary endpoints of cumulative CRC–specific death and incidence will be evaluated. Preliminary results showed that 0.5 of the participants were diagnosed with CRC, and 30.7% had adenomas, of which 10.4% were high-risk adenomas. Detection rates were similar in the proximal and distal colon.[12]

Genetic Testing and Counseling

Genetic testing for *APC* mutations, *MUTYH* mutations, and DNA mismatch repair gene mutations are now available to identify carriers. A patient with classic FAP or with oligopolyposis but negative *APC* mutation testing should undergo *MUTYH* mutation testing given the incidence (7%–29%) of biallelic *MUTYH* in patients with polyposis with negative *APC* testing results.[13]

All patients with CRC at MDACC are screened for MSI. MSI, which is a hallmark of HNPCC, also occurs in about 15% of spontaneous colon cancers.

Immunohistochemical (IHC) stains done on sections from the diagnostic biopsy assess tumors for loss of heterozygosity in hMSH2, hMSH6, or hMLH1 gene loci. Further testing for germline mutations may follow an uninformative IHC stain. In particular, the absence of the MLH1 protein on IHC staining calls for the testing of the *BRAF* gene, in which a *BRAF* mutation signifies the downregulation of *MLH1* gene expression not through a germline mutation but rather somatic promoter hypermethylation. Furthermore, up to 10% of all MSIs may be missed through conventional IHC methods, highlighting MSI testing by polymerase chain reaction (PCR) if suspicion is high.[14] At MDACC, all young patients with CRC are offered the opportunity to meet with a genetic counselor to discuss the option and implications of genetic testing.

PREVENTION STRATEGIES

Primary Prevention

In primary prevention, broad-based interventions may decrease the risk of CRC for those at average risk. Americans currently have a 1 in 20 lifetime risk of developing CRC. Consequently, primary preventive strategies may have a significant impact on the overall incidence of CRC.

Nonsteroidal Antiinflammatory Drugs

For more than 20 years, data suggested that nonsteroidal antiinflammatory agents such as sulindac slow or prevent the formation of adenomatous polyps, particularly in patients with FAP.[15] Prostaglandin E_2, an important modulator of cell proliferation and malignant transformation, is formed by the catalytic activity of two predominant isoforms of cyclooxygenase. Cyclooxygenase 1 (COX-1) is constitutively active and widely expressed; it appears to regulate tissue repair and homeostasis. COX-2 is an inducible enzyme that appears to play a role in inflammation and tumor promotion. In a study of patients with FAP, the selective COX-2 inhibitor celecoxib at a higher dose significantly reduced the number of adenomas compared with placebo or a lower dose of celecoxib.[16] A prospective, placebo-controlled study of 600 mg aspirin per day in patients with HNPCC, a secondary per protocol analysis suggested that it may reduce cancer incidence, although further validation is required.[17]

However, the increased incidence of stroke and myocardial infarctions make the use of COX-2 inhibitors as primary chemoprevention unclear.[16] Aspirin has primary chemopreventive properties, with the risk of CRC substantially reduced among women who were regular users of aspirin for at least 20 years.[18] An additional prospective cohort study of male physicians followed over 4 years showed that regular users of aspirin (≥2 times per week) had a lower risk of developing CRC during the study period (relative risk [RR], 0.68; 95% confidence interval [CI], 0.52–0.92).[19]

Secondary Prevention

Aspirin also has secondary chemopreventive benefits. In a large randomized, placebo-controlled trial, aspirin demonstrated a benefit for patients with a prior history of CRC, showing a significantly reduced risk of developing adenomatous polyps compared with the placebo group (RR, 0.65; 95% CI, 0.46–0.91), a finding that was confirmed in other studies.[20,21] In contrast, the Cancer and Leukemia Group B (CALGB)/SWOG 80702 study evaluating the role of celecoxib for prevention of recurrence did not show any improvement in progression-free survival (PFS) or overall survival (OS) in the adjuvant setting in patients with stage III colon cancer.[22]

DIAGNOSTIC EVALUATION AND STAGING

Clinical Presentation

Colonic lesions in any location can cause change in bowel habits and bleeding, which may manifest as

melena, hematochezia, a positive hemoccult test result, or iron deficiency anemia in addition to weight loss, anorexia, and other constitutional symptoms. Unexplained iron deficiency anemia warrants an evaluation of the gastrointestinal (GI) tract.

Preoperative Staging for Colonic Neoplasms

In patients found to have a colonic neoplasm not requiring urgent surgery, a complete history, physical examination, and full colonoscopy with biopsies should be performed. Laboratory evaluation should include a complete blood cell count with differential, electrolytes, liver function studies, CEA level, serum urea nitrogen (BUN), and creatinine. Imaging studies should include CT of the chest and CT scan or magnetic resonance imaging (MRI) of the abdomen and pelvis.

Rectal Cancer Staging

Patients with newly diagnosed rectal cancer at MDACC are staged with endorectal ultrasonography (EUS) or pelvic MRI. The EUS is more accurate than CT for assessing the depth of tumor invasion into the bowel wall and perirectal lymph node involvement. A pelvic MRI to evaluate the mesorectal planes and perirectal lymph nodes allows improved accuracy of preoperative staging. At MDACC, patients also receive a CT scan of the chest and abdomen, with a dedicated MRI of the pelvis with rectal protocol in the preoperative setting.

Pathology

More than 95% of all colorectal malignancies are adenocarcinomas that are well differentiated, moderately differentiated, poorly differentiated, and undifferentiated. Other subtypes include mucinous and signet ring cell, which confer a poorer prognosis. These tumors are more likely to be present in younger patients and more commonly spread to the peritoneum. Treatment, however, does not differ from the more typical adenocarcinoma subtypes.

Pathologic Staging

Currently, the widely accepted system is the American Joint Committee on Cancer tumor, node, metastasis classification system (Table 32–2) to guide treatment.

MANAGEMENT OF NONMETASTATIC COLON CANCER

Although surgery is the cornerstone of curative intent therapy for patients with CRC, almost half of such patients undergoing curative resection will ultimately die of subsequent development of metastatic disease. Further systemic therapy is administered in these patients to improve survival by eliminating residual microscopic disease not evident at the time of surgery.

Surgical Management of Colon Cancer

Resection for localized colon cancer involves en bloc removal of the affected segment of bowel along with the adjacent mesentery to the origin of the primary feeding vessel inclusive of the draining lymph nodes. Care should be taken to have proximal and distal margins of at least 5 to 7 cm and at least 12 lymph nodes in the resected specimen. In patients with locally advanced T4 tumors involving adjacent organs, en bloc, multivisceral resection without disturbing the plane of adherence is vital and is associated with improved local and distant relapse rates.[23–27] Colectomy may done via open or laparoscopic approaches; multiple, randomized trials and meta-analyses suggesting comparable outcomes with the two approaches but with faster recovery with the latter. In the Clinical Outcomes of Surgical Therapy (COST) trial, 872 patients with colon adenocarcinoma were randomly assigned to open versus laparoscopic colectomy. In the laparoscopic group, although the operative time was longer, duration of

hospital stay and parenteral analgesia were slightly shorter.[28,29] Of note, 21% of the laparoscopic cases had to be converted to an open procedure however.[28,29] Other studies have also shown improved quality of life and higher likelihood of initiating adjuvant chemotherapy with laparoscopic over open colectomy.[30] The COST trial and several other randomized studies have also shown no difference in long-term outcomes including local recurrence, disease-free survival and OS rates between the two approaches.[28,29,31–34] Data also suggest that outcomes are significantly better in hospitals with higher annual case volumes.[29] Such data highlight the importance of adequate experience with this technique for optimizing outcomes. More recently, robotic approaches have been evaluated against laparoscopic approaches in observational studies. These studies suggest that robotic approaches are more expensive and are associated with longer operating time but possibly with better short-term outcomes such as blood loss, hospital stay, and return of postoperative bowel function.[35–38] Our recommendation is that minimally invasive surgeries only be performed in centers with high volumes and by experienced surgeons. These approaches should be avoided in complex situations involving extensive adhesions, obstruction, perforation, or involvement of adjacent organs.

Evidence Regarding Adjuvant Therapy for Colon Cancer

Although there are no randomized data defining the optimal time interval to starting adjuvant therapy after surgery, it is usually started after complete recovery from surgery, typically 4 to 8 weeks after surgery and as mandated by most completed adjuvant trials.[39–44]

Patients with stage III colon cancer typically receive 3 to 6 months of adjuvant chemotherapy with a fluoropyrimidine in combination with oxaliplatin. Improvement in DFS with addition of oxaliplatin to fluoropyrimidine was demonstrated by two large phase III trials. The European MOSAIC (Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer) trial randomized 2246 (60% with stage III) patients to FOLFOX (infusional 5-fluorouracil [5-FU], leucovorin calcium, and oxaliplatin) versus 5-FU and leucovorin. This trial demonstrated an improvement in the primary endpoint of 5-year DFS from 67% to 73% for patients with the addition of oxaliplatin to 5-FU.[43] An OS benefit was noted in the stage III subgroup (10-year, OS 67% vs 59%; hazard ratio [HR], 0.80; $P = .016$).[43] The North American NSABP C-07 trial that randomized 2407 patients (70% with stage III) to bolus weekly 5-FU/LV bolus 5FU, leucovorin (bFU/LV) with (FLOX) or without oxaliplatin also showed an improvement in the primary endpoint of 5-year DFS with the addition of oxaliplatin (69% vs 64%; HR, 0.82; 95% CI, 0.69–0.93).[40] However, this was at a cost of increased GI toxicities related to bFU/LV (≥grade 3 diarrhea, 32% vs 38%; vomiting, 8% vs 13%; and dehydration 12% vs 17% with bFU/LV vs FLOX) and thus the preferred method of administration of 5-FU is ambulatory infusional therapy.[40] Both the MOSAIC and National Surgical Adjuvant Breast and Bowel Project (NSABP) CO-7 trials mandated a total duration of adjuvant therapy for 6 months that is associated with significant toxicities, especially oxaliplatin-related neuropathy. More than 90% of patients in the MOSAIC trial developed neuropathy during chemotherapy, including 13% with grade 3 or greater symptoms. After a follow-up period of 48 months, grade 1, 2, or 3 neuropathy was persistent in 12%, 3%, and 0.7% of patients, respectively. Although all these trials used 5-FU, other randomized trials and pooled analyses convincingly support the substitution of 5-FU with capecitabine in the adjuvant setting.[45–47]

The IDEA (International Duration Evaluation of Adjuvant Chemotherapy) Collaboration was a prospective combined analysis of six international phase III trials investigating noninferiority of 3 versus 6 months of adjuvant chemotherapy (either FOLFOX or CAPOX [capecitabine and oxaliplatin] per physicians' choice) for stage III colon cancer with the primary endpoint of 3-year DFS.[48] The study narrowly failed to show noninferiority of 3 months of adjuvant therapy compared with 6 months (3-year DFS, 74.6% vs 75.5%; HR, 1.07; 95% CI, 1.00–1.15; noninferiority HR boundary, 1.12). However, prespecified subgroup analyses based on type of regimen suggested that noninferiority for 3 months was noted with CAPOX (0.95; 95% CI, 0.85–1.06) but not with FOLFOX (HR, 1.16; 95% CI, 1.06–1.26). Furthermore, an exploratory analysis in low-risk (T1–T3 and N1) patients demonstrated noninferiority of 3 versus 6 months (3-year DFS, 83.1% and 83.3%, respectively; HR, 1.01; 95% CI, 0.90–1.12) and superiority of 6 months over 3 months in those with high-risk (T4 or N2) disease (3-year DFS, 64.4% vs 62.7%; HR, 1.12; 95% CI, 1.03–1.23).[48] After a longer follow-up period, updated results showed that the 5-year DFS was 69.1% versus 70.8% (HR, 1.08; 95% CI, 1.01–1.15; false discovery rate adjusted $P = .22$); 5-year OS rate was 82.4% versus 82.8% (HR, 1.02; 95% CI, 0.95–1.11), and absolute 5-year OS rate difference was -0.4% (95% CI, -2.1% to 1.3%).[49] Together, these data suggest highlight the implications of risk stratification based on the pathologic and the potential for shortening duration of therapy with CAPOX, especially in low-risk patients.

The evidence for adjuvant therapy for patients with stage II disease is less robust (Fig. 32–2). To date, the largest randomized study of patients with stage II disease, QUASAR (Quick and Simple and Reliable),

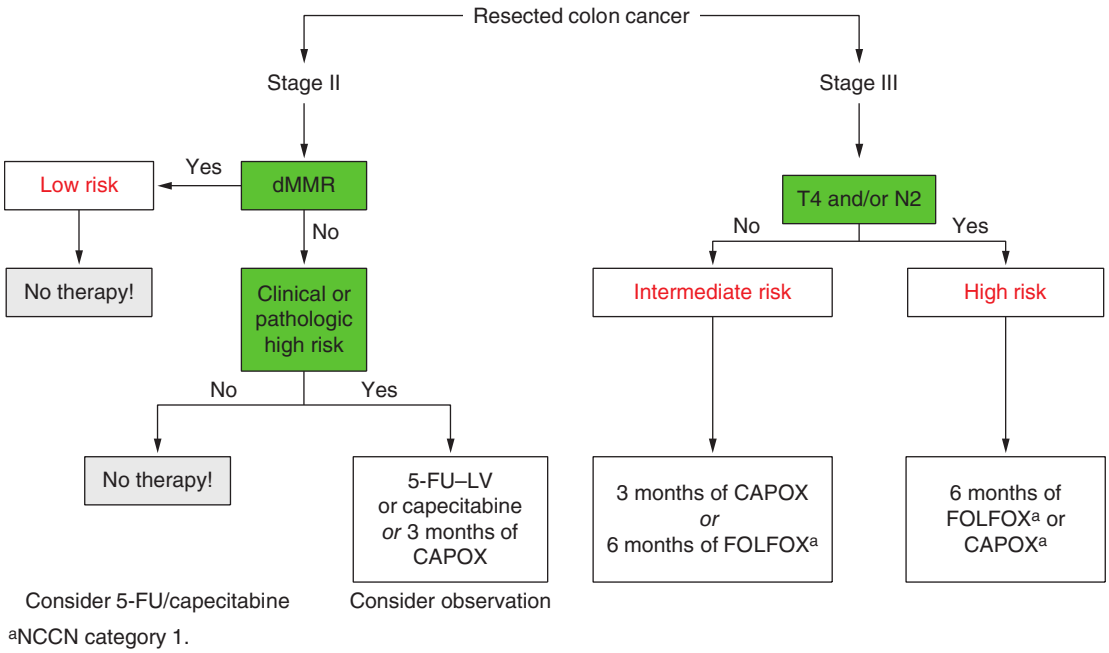

FIGURE 32–2 **Decision algorithm for adjuvant therapy in colon cancer.**

showed a modest survival benefit of 3.6% in patients receiving adjuvant 5-FU versus observation after surgical resection.[50] However, this study had several critical limitations, including enrollment of patients with rectal cancer (29%), limited number of lymph nodes evaluated (median, 6) and use of radiation in some patients (14%).[50] Other pooled analyses have shown small improvements in DFS (5%–10%) but without improvement in OS for adjuvant 5-FU over observation in stage II colon cancer.[51–54] Subgroup analyses of stage II patients from the MOSAIC and NSABP C-07 trials showed no statistically significant benefit in either OS or DFS with the addition of oxaliplatin to 5-FU.[43] These findings were also supported by a pooled analysis of the Adjuvant Colon Cancer End Points (ACCENT) database.[55–57] However, a subset of stage II patients at a higher risk of recurrence may be identified based on histopathological features. These features are defined by the National Comprehensive Cancer Network (NCCN) as T4 tumors (stage IIB/IIC); poorly differentiated histology (excluding microsatellite instability–high [MSI-H] cancers); lymphovascular invasion; perineural invasion; bowel obstruction; localized perforation; margins that are close, indeterminate, or positive; and inadequate sampling of lymph nodes (<12 nodes examined).[58] Data from randomized trials suggest that such patients with high-risk stage II colon cancer may derive modest benefit from the additional of oxaliplatin to a fluoropyrimidine. In exploratory analyses of the MOSIAC trial, there was a trend toward improvement in DFS (82% vs 77%) and OS (85% vs 83.3%) without reaching statistical significance in this subset.[43] A preplanned pooled analyses of 3273 patients with high-risk stage II colon cancer from four trials within the IDEA collaboration failed to show noninferiority of 3 versus 6 months of adjuvant therapy (80.7% vs 84%; DFS HR, 1.18; 80% CI, 1.05–1.31; $P = .404$; noninferiority boundary, 1.2). As with the stage III patients, toxicities were significantly lower in the 3-month group, and there appeared to be a trend toward difference in DFS based on type of regimen (CAPOX: HR, 1.02; 80% CI, 0.88–1.17; $P = .087$ and FOLFOX: HR, 1.42; 80% CI, 1.19–1.70; $P = .894$).[59]

Approximately 20% to 25% of stage II and 10% to 15% of stage III patients are MSI-H deficient mismatch repair (dMMR) that has prognostic and perhaps predictive implications for adjuvant therapy.[60–62] Substantial data suggest that patients with dMMR have a decreased likelihood to develop recurrent disease with some studies suggesting that the recurrence rate may be as low as half that of proficient mismatch repair (pMMR) tumors.[63] This positive prognostic effect of dMMR also appears to be more pronounced in stage II rather than in stage III colon cancer.[60–62] Some of these studies have also suggested that dMMR may also be a negative predictive marker for benefit from single-agent fluoropyrimidine, although some other studies have suggested otherwise.[60,64–66]

Irinotecan has no established role in the adjuvant setting. Three randomized phase III trials failed to show an improvement in DFS or OS in the adjuvant setting. Furthermore, data have not supported the addition of bevacizumab, cetuximab, or panitumumab in the adjuvant setting.[41,44,67–72]

Emerging Directions

Role of Immunotherapy in Adjuvant Therapy

Although immunotherapy is rapidly emerging as the cornerstone for management of patients with metastatic dMMR CRC, whether it has benefit in the adjuvant setting is being explored in an ongoing trial (Alliance A021502; NCT02912559).

Role of Neoadjuvant Therapy

The role of neoadjuvant chemotherapy in colon cancer is unclear but may be considered in patients with locally advanced tumors in whom margins may be compromised or in whom surgery may need to be delayed because of comorbidities or other causes. The FOxTROT trial randomized 1052 patients with T3–T4 N0-2 colon cancer to surgery upfront followed by 6 months of adjuvant oxaliplatin-based chemotherapy or to 6 weeks of preoperative oxaliplatin-based chemotherapy followed by surgery and then 18 additional weeks of chemotherapy. There was only a trend toward improvement in the primary endpoint of 2-year DFS (13.6% vs 17.2%; HR, 0.75; 95% CI, 0.55–1.04). However, the preoperative chemotherapy group had lower rates of incomplete resection (5% vs 10%; $P = .001$) and improved histologic downstaging of both pathologic tumor and nodal stage (including a 4% pathological complete response rate [pCR]) without increased perioperative complications.[73]

Role of Circulating Tumor DNA

Circulating tumor DNA (ctDNA) are short fragments of DNA (130–150 base pairs) released by cancer cells through apoptosis, necrosis, or secretion into the circulation.[74] Given the short half-life between 16 minutes to 2.5 hours, ctDNA is a sensitive real-time marker of tumor burden.[74] The presence of ctDNA after curative intent therapy, minimal residual disease (MRD) likely represents existence of radiographically undetectable micrometastases.[75–79] Rapidly accumulating data suggest very high specificity and positive predictive value (90%–100% for both) for clinical recurrence in patients with ctDNA-defined MRD.[75–80] The sensitivity of ctDNA for detection of MRD is also improving with newer methods and assays providing increasing lead time between detection of ctDNA and clinical recurrence approaching 8 to 9 months currently.[75,76,81] Given the high specificity and positive predictive value coupled with the lead time allowing for intervention, ongoing trials are evaluating escalation of therapy in patients with stage II MRD-positive colon cancer and similar efforts are being planned in stage III colon as well.[80,81] As sensitivity of MRD assays further improves, it is likely that they may be used for de-escalation of adjuvant therapy in stage III patients. Together, we anticipate that these data will likely establish ctDNA as an integral biomarker in the adjuvant setting.[80,81]

The MDACC Approach to Nonmetastatic Colon Cancer

When patients present to MDACC with a diagnosis of colon cancer, a detailed history, including family history; routine laboratory tests, including CEA level; and imaging (CT of the chest; CT or MRI of the abdomen and pelvis) are obtained. Previous endoscopic findings and pathology are reviewed and are tested for MSI. Patients without metastatic disease or contraindications to surgery should undergo primary resection with curative intent (Fig. 32–3). Surgery may consist of segmental resection or subtotal colectomy, depending on the underlying colonic pathology (multifocal cancer, FAP, HNPCC, and so on); pathologic staging is then determined from the surgical specimens. Patients with stage 0 or I tumors are placed on surveillance only. Patients with stage II colon cancer have a 75% to 80% chance of long-term DFS with surgical resection alone. For stage II patients, a thorough discussion regarding the evidence and morbidity associated with treatment while taking into consideration high-risk features, mismatch repair (MMR) testing results, and patient preferences. In patients with dMMR stage II colon cancer and without high-risk features, observation is recommended. Few data are available for the benefit of adjuvant therapy in dMMR stage II patients with high-risk features, and a thorough discussion is required, especially in those with T4b tumors. All patients with dMMR undergoing adjuvant therapy should receive a fluoropyrimidine in combination with oxaliplatin. In patients with standard-risk pMMR stage II colon cancer, a thorough discussion is recommended, and patients are advised that any 5-year survival benefit is likely to be less than 5%. After such a discussion, if wishing to proceed with adjuvant therapy, they are offered single-agent fluoropyrimidine for 3 to 6 months. Patients with pMMR and high-risk stage II colon cancer may be offered adjuvant chemotherapy for 3 to 6 months, and the inclusion of oxaliplatin needs to be individualized based on the observed risk factors, patient preferences, and comorbidities. Stage III patients are offered combination chemotherapy with fluoropyrimidine and oxaliplatin irrespective of MMR status. Patients with low-risk disease (T1–T3 and N1) are offered 3 months of CAPOX or 3 to 6 months of FOLFOX. Patient with high-risk disease are offered 3 to 6 months of CAPOX or 6 months of FOLFOX. Adjuvant therapy should begin within 4 to 8 weeks after surgery unless postoperative complications warrant a delay.

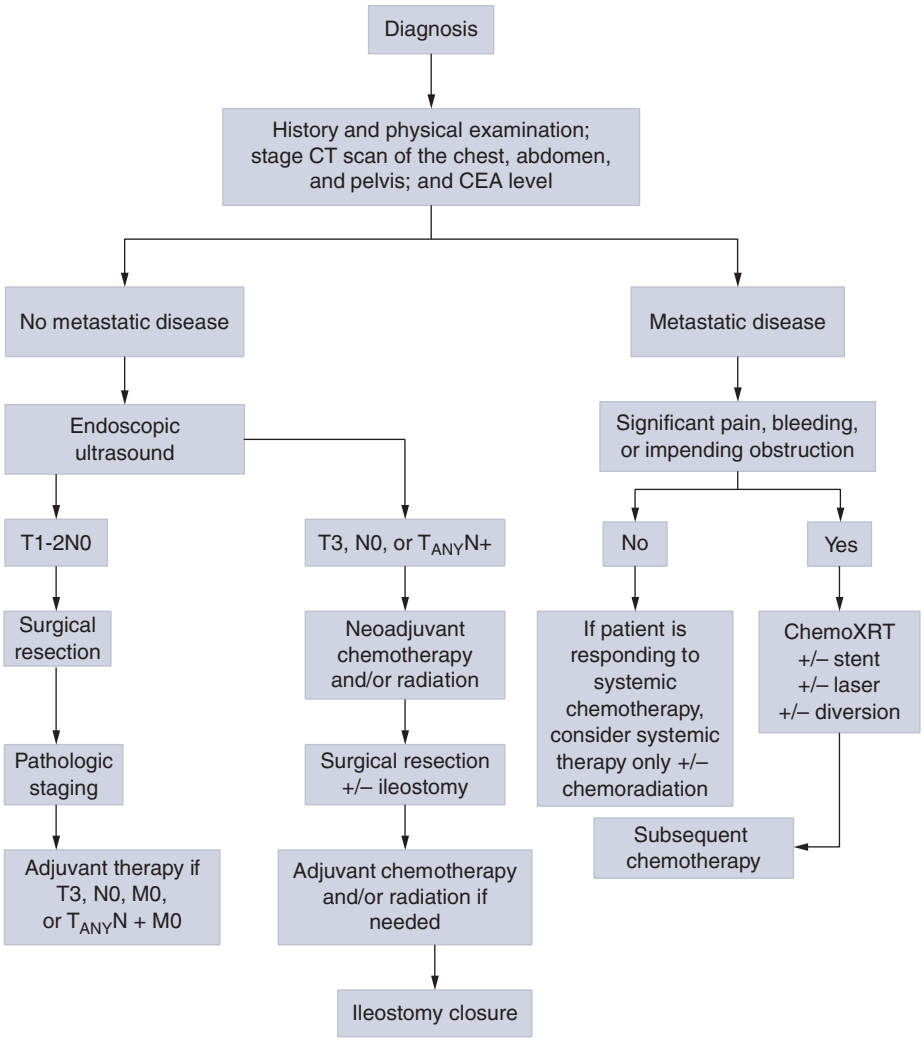

FIGURE 32–3 **Diagnostic and therapeutic algorithm for rectal cancer. CEA, carcinoembryonic antigen; Chemo-XRT, chemotherapy and radiation; CT, computed tomography.**

Surveillance for Patients with Resected Colon Cancer

After active therapy is completed, patients undergo clinical evaluations every 3 to 6 months for the first 3 years during the period of highest risk of recurrence, then every 6 and 12 months for the following 2 years, and annually thereafter. Of all recurrences, 80% occur within the first 3 years after surgical resection.[56] Colonoscopy is recommended 1 year after surgery and every 3 years thereafter at a minimum. Laboratory studies, including CEA level, are checked every 3 to 6 months; abdominopelvic CT or MRI and chest radiography or CT of the chest are obtained every 6 to 12 months. At 5 years, patients are followed with surveillance colonoscopy (every 3 years), annual physical examination, and CEA level.

MANAGEMENT OF NONMETASTATIC RECTAL CANCER

Given the higher risk of locoregional recurrence with rectal cancer compared with colon cancers, most patients with stages II and III rectal cancer undergo neoadjuvant therapy followed by surgery with total mesorectal excision (see Fig. 32–3). A total mesorectal excision (TME) involves an en bloc removal of the mesorectum through sharp dissection, including associated vascular and lymphatic structures, fatty tissue, and mesorectal fascia, while sparing the autonomic nerves. In general, more than two thirds of the patients with rectal cancer will be able to have a sphincter-saving procedure, whether it is a low anterior resection

or a proctectomy with a coloanal anastomosis. An abdominoperineal resection (APR), which includes removal of the rectum, anus, sphincter muscles, and a permanent colostomy, is reserved for patients with tumor involvement of sphincter muscles or with poor preoperative sphincter function.

Perioperative Therapy for Rectal Cancer

Two European studies have supported the use of preoperative therapy for resectable rectal cancer. The German Arbeitsgemeinschaft Internistische Onkologie (AIO) trial comparing preoperative and postoperative chemoradiation in T3 or T4 tumors showed a lower pelvic recurrence rate in the preoperative chemoradiation arm (6% vs 13% postoperatively, respectively; $P = .0006$).[82] In patients who were believed to require APR, chemoradiation also led to increased sphincter preservation rates (39% vs 19%; $P = .004$). Only 54% of patients in the postoperative arm received the full radiation dose, and 50% received full-dose chemotherapy compared with 92% and 89%, respectively, in the preoperative arm ($P < .001$).[82]

Standard radiotherapy doses are 45 Gy in 25 fractions followed by a 5.4-Gy boost. Concurrent chemotherapy with a fluoropyrimidine, typically capecitabine (over infusional 5-FU) is recommended as a radiosensitizer. Addition of agents other than a fluoropyrimidine to chemoradiation must be within the context of clinical trials. Results of multiple, large, randomized trials that evaluated addition of oxaliplatin and irinotecan to a fluoropyrimidine during chemoradiation have all shown increased toxicities without a convincing improvement in pCR, DFS, or OS.[83–96] Data from small, nonrandomized trials suggest that addition of anti–vascular endothelial growth factor (VEGF) agents may increase pCR rates but at the cost of postoperative complications. However, studies with anti-EGFR antibodies are mixed, perhaps related to lack of appropriate biomarker-based patient selection.[97–101]

Preoperative short-course radiotherapy (ie, 25 Gy administered over five fractions) has consistently shown to improve local control over surgery alone.[102–105] However, the initial studies that evaluated this approach suggested high rates of long-term toxicities, including fecal incontinence, bowel obstruction, and sexual dysfunction.[106–109] ore recent trials have allayed these concerns and have also provided additional data suggesting that this approach is comparable to conventional long-course chemoradiation for rates of local, distant recurrences, DFS, OS, and toxicities.[110,111]

An alternative approach to preoperative therapy, especially in patients with high-risk tumors such as those at risk for margin-positive resection, advanced disease (T4, node positive) or with low-lying tumors may be considered for total neoadjuvant therapy (TNT) in which systemic chemotherapy is administered before surgery in addition to neoadjuvant radiation. The rationales for this approach are to improve downstaging of tumors in the short term and to improve DFS and OS by better treatment of systemic disease through increased compliance to chemotherapy that is also administered earlier in the treatment course. The phase III PRODIGE (Partenariat de Recherche en Oncologie Digestive) 23 trial randomized 461 patients with locally advanced rectal cancer to neoadjuvant long-course chemoradiation versus induction FOLFIRINOX for six cycles followed by long-course chemoradiation before surgery.[112] Patients were allowed to receive additional adjuvant chemotherapy (capecitabine or FOLFOX) for a total of 6 months of perioperative chemotherapy. This trial showed an improvement in the primary endpoint of 3-year DFS with the TNT approach (75.7% vs 68.5%; HR, 0.69; 95% CI, 0.49–0.97). There was also an improvement in the pCR rate (27.5% vs 11.7%; $P < .001$) with the TNT approach.[112] The phase III RAPIDO (Rectal Cancer And Pre-operative Induction Therapy Followed by Dedicated Operation) trial randomized 920 patients with locally advanced rectal cancer to long-course chemoradiation versus short-course radiation followed by consolidation FOLFOX or CAPOX followed by surgery and subsequent adjuvant chemotherapy (for a total of 6 months of perioperative chemotherapy).[113] Similar to the PRODIGE 23 trial, the TNT arm in the RAPIDO trial also showed a statistically significant improvement in the primary endpoint of 3-year disease-related treatment failure (19.8% vs 26.6%; HR, 0.69; 95% CI, 0.53–0.89) and in the pCR rate (27.7% vs 13.8%; $P < .001$).[113] Both trials showed that the TNT approach did not affect compliance to chemoradiation, adjuvant therapy, or risk of surgical complications. Together, these data show the safety and benefit of the TNT approach. However, the optimal sequencing of radiation and chemotherapy ("induction" vs "consolidation" chemotherapy), modality of radiotherapy (short course vs long course), and chemotherapy regimen (fluoropyrimidine with oxaliplatin with or without irinotecan) remain to be defined.

Alternative approaches aiming to eliminate a component of the trimodality approach, either radiation or surgery, are also under investigation. Data from multiple nonrandomized studies suggest that patients with a complete clinical response (cCR) at the completion of neoadjuvant therapy may undergo careful observation (ie, "watch and wait") in lieu of radical surgery.[114–120] The largest of these studies was a registry that included 880 patients with cCR who underwent watch and wait. After a median follow-up period of 3.3 years, 88% of all local regrowth was diagnosed within 2 years with the 2-year cumulative incidence of local regrowth being 25.2% (97% within the bowel

wall).[121] Of the 213 patients with local recurrence, details regarding salvage surgery was available in 148 with 78% of these patients requiring a TME and the rest having local excision. Five-year disease-specific survival for the entire group was 94%, and 5-year OS was 85%.[121] Some studies have raised concern about increased risk of distant recurrence with the wait-and-watch approach compared with those noted to have pCR with surgery; whether these distant recurrences may have be prevented with surgery is uncertain. Several randomized trials are current underway evaluating this approach in patients with cCR.

Given the concern for radiation related side effects in both the short and long terms, upfront chemotherapy to enable selective use of radiation in those with inadequate response is also being evaluated. This approach is being tested in the ongoing phase II/III Alliance (N0148) trial that is evaluating chemoradiation therapy versus induction FOLFOX in patients with mid–high-lying rectal cancers (NCT01515787).

Adjuvant Therapy for Rectal Cancer

In patients receiving neoadjuvant short-course radiation or chemoradiation without further neoadjuvant systemic chemotherapy, most expert groups and consensus guidelines recommend adjuvant chemotherapy for up to 4 months. Although data from randomized trials comparing adjuvant therapy with observation do not convincingly show a survival benefit, these trials have several limitations. First, a significant proportion of patients (25%–50%) never start adjuvant therapy because of postoperative complications, slow recovery, patient preference, or other factors.[85,86,122] Second, even in those starting adjuvant therapies, there may be a significant delay in initiating therapy. There is also significant debate whether adjuvant chemotherapy may be tailored based on the degree of pathological response. Robust nonrandomized data convincingly show that patients with pCR have a very low risk of recurrence and adjuvant therapy maybe deintensified in these patients to fluoropyrimidine alone. Whether adjuvant therapy may be omitted completely with pCR is uncertain. In patients with poor pathologic response, data show benefit with addition of oxaliplatin. The ADORE (Adjuvant Oxaliplatin in Rectal cancer) trial randomized 321 patients with pathologic stage stage II or III tumors postoperatively (and hence avoiding dropout before initiation of adjuvant therapy) to 5-FU or FOLFOX and showed an improvement in the primary endpoint of 3-year DFS (71.6% vs 62.9% 0.657; 95% CI, 0.434–0.994; $P = .047$).[123] These findings were also supported by a meta-analysis of three randomized trials comparing adjuvant 5-FU with or without oxaliplatin after neoadjuvant chemoradiation with improvement in DFS (HR, 0.85; 95% CI, 0.73–0.99).[124]

In patients treated with TNT and receiving neoadjuvant chemotherapy for at least 4 months, no further adjuvant chemotherapy is recommended.

The MDACC Approach to Nonmetastatic Rectal Cancer

Patients are evaluated with history, including family cancer history, physical examination with a digital rectal examination, inguinal lymph node exam, proctoscopy, and cross0sectional imaging studies of the chest, abdomen (typically CT with contrast) and pelvis. MRI of the pelvis (and EUS as needed) are obtained in all patients as pretreatment staging. The patency of the colonic lumen is evaluated by proctoscopy, flexible sigmoidoscopy, or colonoscopy before starting therapy. Given the limitations with delivery of adjuvant therapy as discussed and robust prospective data showing improvement in both sphincter preservation and DFS with neoadjuvant chemotherapy, our practice patterns have increasingly shifted toward the TNT approach. Treatment decisions are based on risk stratification and made in a multidisciplinary fashion involving radiation, medical, and surgical oncologists; pathologists; radiologists; and gastroenterologists. In patients with rectal cancer deemed low risk (T3N0, mid–high rectum, without EMVI or threatened CRM) neoadjuvant chemotherapy with FOLFOX or CAPOX is offered for 3 months followed by surgery. For patients with low-risk but low-lying tumors wanting sphincter preservation and for those with high-risk features, the TNT approach with chemotherapy for 4 months in addition to radiotherapy is recommended. In these patients, the choices of chemotherapy (FOLFOX, CAPOX, FOLFIRINOX), radiotherapy regimens (long-course chemoradiation vs short-course radiation) and sequencing modalities are made based on the clinical situation and patient preferences while awaiting further data.

In patients receiving neoadjuvant chemoradiation, capecitabine is given as the radiation sensitizer (825 mg/m^2 twice daily, Monday–Friday, on days of radiation therapy only). Bowel exclusion techniques during simulation minimize the small bowel in the field. We conduct a toxicity evaluation every 1 to 2 weeks during radiation to ensure symptom control. Electrolytes, renal function, and hematologic parameters are checked weekly. Topical barrier creams are prescribed for grades 1 to 3 perineal radiation dermatitis. If grade 2 or higher nonhematologic toxicity develops (excluding radiation dermatitis), concurrent chemotherapy is held until resolution, but radiation is continued. After chemoradiation, perianal pain and ulceration, anorexia, and diarrhea typically subside within 2 to 3 weeks.

Approximately 8 to 10 weeks after completion of neoadjuvant therapy, patients undergo repeat evaluation

with physical examination, proctoscopy, MRI of the pelvis, and then surgical resection.

In the adjuvant setting, chemotherapy is offered to those who received radiotherapy alone as neoadjuvant therapy. Patients with stage III rectal cancer and no contraindication to oxaliplatin are advised to receive it as a component of FOLFOX or CAPOX. Patients with a pCR after preoperative 5-FU–based chemoradiation may receive single-agent 5-FU–based adjuvant therapy rather than FOLFOX. The choice of adjuvant therapy may vary based on degree of response to single-agent fluoropyrimidine-based therapy and the patient's underlying comorbidities.

Postoperative Chemoradiation

Patients who have undergone surgery as their initial intervention may require postoperative chemoradiation and systemic therapy when they present to MDACC after surgery. For patients with T3N0M0 or T2N1 disease, radiotherapy is often omitted if the tumor was located in the high pelvis (>10 cm from the anal verge), there is good nodal sampling (>12 lymph nodes), and the radial margin is negative (>2 mm) because pelvic tumor control is excellent without the use of chemoradiation.[125,126] In all other stage II and III rectal cancer cases, local failure is high enough to warrant the use of chemoradiation. In addition, 4 months of systemic therapy with either capecitabine or 5-FU–leucovorin is typically integrated with chemoradiation. Patients at higher risk of distant metastasis often receive chemotherapy first with FOLFOX.

Surveillance for Patients with Rectal Cancer

Follow-up for patients with resected rectal cancer is very similar to that for colon cancer. Patients with a sphincter-preserving procedure also require periodic proctoscopies for local relapses and anastomotic strictures. A rising CEA without other clinical or CT evidence of relapse prompts a pelvic MRI or positron emission tomography (PET)–CT, particularly for local recurrence.

In patients with cCR defined as no apparent residual tumor on endoscopy, MRI and CT after completion of neoadjuvant therapy wishing for a watch-and-wait approach, a thorough discussion of the pros and cons, including the current evidence, is done. Patients are additionally monitored with a proctoscopy every 3 to 4 months for the first 2 years and every 6 months for the next 3 years.

Management of Locally Recurrent Disease

Locally recurrent rectal cancer presents a therapeutic challenge for which salvage surgery may not be feasible. The collective experience at MDACC suggests that systemic therapy has limited activity against locally recurrent disease with few durable responses. Palliative radiation is delivered as external-beam radiotherapy or brachytherapy catheters. Aggressive use of narcotics and intrathecal analgesics or neurolytic blocks is used for pain control concurrently with aggressive bowel management.

For the subset of patients who may be surgical candidates, treatment planning is vetted in our multidisciplinary conference. In our experience, pelvic MRI is superior to CT for distinguishing posttreatment changes from viable tumor while identify resectable disease. Biopsy confirmation of recurrence is always recommended; EUS has not been particularly useful with locally recurrent rectal tumors.

Before salvage surgery, additional chemoradiation may be considered using a hypofractionated schedule to a total dose of 39 Gy (if at least 1 year has elapsed since prior pelvic radiation). Radiosensitization with 5-FU or capecitabine is also considered. Approximately 6 to 8 weeks after completion of chemoradiation, a final decision about surgery is made. In most cases, the operative strategy may also include intraoperative radiotherapy or insertion of brachytherapy catheters for high-dose afterloading. Postoperative chemotherapy after aggressive preoperative chemoradiation is at the discretion of the treating physician. However, there is broad agreement that surgery for locally recurrent disease is not indicated in patients with unresectable metastatic disease, given the overall poor prognosis, significant morbidity, and prolonged recovery associated with this complex pelvic surgery.

SYSTEMIC THERAPY FOR METASTATIC DISEASE

Since the late 1950s, systemic chemotherapy with 5-FU has been the mainstay of palliative treatment for patients with metastatic disease. During the ensuing decades, a variety of 5-FU schedules have been used, including bolus injections administered either weekly (Roswell Park regimen) or daily for 5 days (Mayo regimen) and continuous infusion given via central catheter and portable pump. When 5-FU is administered as a bolus injection, leucovorin is often added to enhance binding of 5-FU to its target, thymidylate synthase. After a long period of uncertainty regarding the optimal dose and schedule of 5-FU with leucovorin, infusional 5-FU regimens have been recognized as superior to bolus regimens.

Oncologists now have access to several drugs with activity in the first-, second-, and third-line settings. It is important for oncologists to have a general understanding of these drugs and their roles in the treatment of metastatic disease.

Capecitabine: An Orally Bioavailable Fluoropyrimidine

Capecitabine is an oral fluoropyrimidine that is converted to 5-FU primarily in tumor tissues by the enzyme, thymidine phosphorylase (TP). Concentrations of TP are relatively higher in tumor tissue than normal tissue, which accounts for the preferential intratumoral release of 5-FU. Two large phase III trials compared capecitabine with a bolus regimen of 5-FU, and the results were subsequently pooled.[127,128] The response rates were superior with capecitabine, and the median survival was equivalent, with less neutropenia and mucositis among patients receiving capecitabine.

In patients with contraindications to combination chemotherapy, capecitabine monotherapy is a reasonable alternative to 5-FU and leucovorin in the metastatic setting. However, caution should be taken when prescribing capecitabine to patients with end-stage renal disease, and capecitabine should be held if the creatinine clearance is lower than 30 mL/min. Furthermore, it is of note that patients in the United States do not tolerate the capecitabine doses used in Asian and European trials, perhaps because of the higher nutritional folate intake in the United States.[129] Thus, we commonly dose-reduce capecitabine by about 20% without any apparent decrease in efficacy but with greatly improved tolerance.

IRINOTECAN

Irinotecan, an inhibitor of topoisomerase I, is a component of frontline therapy in patients with metastatic CRC (mCRC). Two large, randomized trials were conducted in the United States and Europe comparing 5-FU and leucovorin with 5-FU, leucovorin, and irinotecan as first-line treatment of patients with mCRC.[130,131] Both studies demonstrated that the response and OS rates for the group treated with triple-drug therapy were superior to those for the group treated with 5-FU and leucovorin. These results prompted the FDA in 2000 to approve the use of these irinotecan-based combinations for first-line treatment of patients with CRC.

Oxaliplatin

Oxaliplatin is a third-generation platinum derivative that has shown additive or synergistic antitumor activity in combination with a variety of antineoplastic agents, including 5-FU; oxaliplatin is ineffective without 5-FU.[132] In 2000, de Gramont and colleagues[133] reported the results of a phase III trial of infusional 5-FU–leucovorin and oxaliplatin (FOLFOX4) versus 5-FU–leucovorin alone as first-line treatment in patients with advanced CRC. PFS and response rates were significantly better for the FOLFOX arm compared with the 5-FU–leucovorin arm (9.0 months and 50% vs 6.2 months and 22%, respectively). Even though the FOLFOX arm experienced more grade 3 and 4 neutropenia, diarrhea, and neurosensory toxicity, this did not impair quality of life.

Goldberg and associates[134] subsequently compared the activity and toxicity of three different drug combinations in untreated patients with mCRC. A total of 795 patients were randomized to receive IFL, FOLFOX, or IROX (irinotecan + oxaliplatin). The results favored FOLFOX for all endpoints, including time to progression, response rate, and OS. Median survival times in the FOLFOX, IFL, and IROX groups were 19.5, 15.0, and 17.4 months, respectively.

Tournigand and colleagues[135] answered the important question of how to sequence these regimens. They reported the results of a phase III study investigating 5-FU, leucovorin, and irinotecan (FOLFIRI) followed by FOLFOX6 (Table 32–3) on progression of disease versus the opposite sequence (FOLFOX6 followed by FOLFIRI). The two sequences were equivalent in terms of PFS and OS, although the toxicity profiles were different. The median survival times were 21.5 months in the FOLFIRI-FOLFOX arm ($n = 109$) and 20.6 months in the FOLFOX-FOLFIRI arm ($n = 111$) ($P = .99$).

TABLE 32–3 Summary of Common Chemotherapy Regimens Used at MD Anderson Cancer Center for Patients with Colorectal Cancer

Adjuvant Chemotherapy
Capecitabine: 1000 mg/m^2 by mouth twice daily on days 1–14 (3-week cycle, total eight cycles)
5-FL–leucovorin: leucovorin 400 mg/m^2 IV on day 1; 5-FU 400 mg/m^2 IV bolus on day 1 followed by 5-FU 2400 mg/m^2 IV continuous infusion over 46 hours (2-week cycle, total 12 cycles)
Modified FOLFOX 6: oxaliplatin 85 mg/m^2 IV on day 1; leucovorin 400 mg/m^2 IV on day 1; 5-FU 400 mg/m^2 IV bolus on day 1 followed by 5-FU 2400 mg/m^2 IV continuous infusion over 46 hours (2-week cycle, total 12 cycles)
CAPOX: oxaliplatin 130 mg/m^2 on day 1; capecitabine 850 mg/m^2 by mouth twice a day on days 1–14 (3-week cycle, total eight cycles)
Therapy for Metastatic Disease
Capecitabine: 1000 mg/m^2 by mouth twice a day on days 1–14 (3-week cycle)
• With or without bevacizumab (7.5 mg/kg IV every 3 weeks)

TABLE 32–3 Summary of Common Chemotherapy Regimens Used at MD Anderson Cancer Center for Patients with Colorectal Cancer *(Cont.)*

5-Fluorouracil–leucovorin: leucovorin 400 mg/m^2 IV on day 1; 5-FU 400 mg/m^2 IV bolus on day 1 followed by 5-FU 2400 mg/m^2 IV continuous infusion over 46 hours (2-week cycle)
• With or without bevacizumab (5 mg/kg IV every 2 weeks)
Modified FOLFOX 6: oxaliplatin 85 mg/m^2 IV on day 1; leucovorin 400 mg/m^2 IV on day 1; 5-FU 400 mg/m^2 IV bolus on day 1 followed by 5-FU 2400 mg/m^2 IV continuous infusion over 46 hours (2-week cycle)
• With or without bevacizumab (5 mg/kg IV every 2 weeks)
• With or without cetuximab[a] (400 mg/m^2 IV first infusion followed by 250 mg/m2 IV weekly or 500 mg/m2 IV every 2 weeks) or panitumumaba (6 mg/kg IV every 2 weeks)
CAPOX: oxaliplatin 130 mg/m^2 on day 1; capecitabine 850 mg/m^2 by mouth twice a day on days 1–14 (3-week cycle)
• With or without bevacizumab (7.5 mg/kg IV every 3 weeks)
• With or without cetuximaba (400 mg/m2 IV first infusion followed by 250 mg/m2 IV weekly or 500 mg/m2 IV every 2 weeks) or panitumumab[a] (9 mg/kg IV every 3 weeks)
Modified FOLFIRI: irinotecan 180 mg/m^2 IV on day 1; leucovorin 400 mg/m^2 IV on day 1; 5-FU 400 mg/m^2 IV bolus on day 1 followed by 5-FU 2400 mg/m^2 IV continuous infusion over 46 hours (2-week cycle)
• With or without bevacizumab (5 mg/kg IV every 2 weeks)
• With or without cetuximaba (400 mg/m^2 IV first infusion followed by 250 mg/m^2 IV weekly) or panitumumab[a] (6 mg/kg IV every 2 weeks)
Irinotecan: 180 mg/m^2 IV on day 1 (2-week cycle) or 300–350 mg/m^2 IV on day 1 (3-week cycle)
Cetuximab[a]–irinotecan
• Cetuximab[a] 400 mg/m^2 IV first infusion followed by 250 mg/m^2 IV weekly plus irinotecan 350 mg/m^2 IV on day 1 (3-week cycle) or 180 mg/m^2 IV on day 1 (2-week cycle)
• Cetuximaba 500 mg/m^2 IV every 2 weeks ± irinotecan 180 mg/m^2 IV every 2 weeks
Panitumumab[a]: 6 mg/kg IV every 2 weeks or 9 mg/kg IV every 3 weeks
FOLFOXIRI: oxaliplatin 85 mg/m^2 IV on day 1; irinotecan 165 mg/m^2 IV on day 1; leucovorin 400 mg/m^2 IV on day 1; followed by 5-FU 2400 mg/m^2 IV continuous infusion over 46 hours (2-week cycle)
• With or without bevacizumab (5 mg/kg IV every 2 weeks)
• With or without cetuximab[a] (400 mg/m^2 IV first infusion followed by 250 mg/m^2 IV weekly or 500 mg/m^2 IV every 2 weeks) or panitumumab[a] (6 mg/kg IV every 2 weeks)
Trifluridine–tipiracil: trifluridine–tipiracil 35 mg/m^2 (trifluridine component) orally twice daily on days 1–5 *and 8–12 (28-day cycle)*
Regorafenib: regorafenib 160 mg once daily for 21 days; then 1 week off (28 day cycle). Recommend starting with 80 to 120 mg once daily for 21 days; then 1 week off for first cycle to determine tolerability
Pembrolizumab[b]: pembrolizumab 2 mg/kg IV every 3 weeks (21-day cycle); or pembrolizumab 200 mg IV every 3 weeks (21-day cycle); or pembrolizumab 400 mg IV every 6 weeks (6-week cycle)
Nivolumab[b]: nivolumab 3 mg/kg IV on day 1 every 14 days (14-day cycles); or nivolumab 240 mg IV on day 1 (14-day cycle); or nivolumab 480 mg IV on day 1 every 28 days (28-day cycle)
Nivolumab–ipilimumab[b]: nivolumab 3mg/kg (30-minute IV infusion) on day 1; ipilimumab 1 mg/mg (30-minute IV infusion) on day 1 (21-day cycle) for four doses; then nivolumab 3 mg/kg IV every 14 days or nivolumab 240 mg IV every 14 days or nivolumab 480 mg IV every 28 days
Cetuximab–encorafenib[c]: cetuximab 400 mg/m^2 IV first infusion followed by 250 mg/m^2 IV weekly; encorafenib 300 mf PO daily; binimetinib 45 mg PO twice daily (28-day cycle)
Pertuzumab–trastuzumab[d]: pertuzumab 840 mg IV loading dose cycle 1 day 1, with subsequent doses 420 mg IV every 21 days; trastuzumab 8 mg/kg IV loading dose cycle 1 day 1, with subsequent doses 6 mg/kg IV every 21 days (21-day cycle)
Larotrectinib[e]: 100 mg PO twice daily (28-day cycle)
Entrectinib[e]: 600 mg PO once daily (28-day cycle)

[a]Cetuximab and panitumumab are indicated only in patients with *RAS* wild-type tumors.
[b]Pembrolizumab, nivolumab, and ipilimumab are only indicated in patients with deficient mismatch repair (dMMR)/microsatellite instability–high tumors.
[c]The combination of cetuximab and encorefenib is only indicated in patients with BRAF V600E mutated tumors.
[d]The combination of pertuzumab and trastuzumab is only indicated for HER2 amplified tumors that are *RAS* and *BRAF* wild type.
[e]Larotrectinib and entrectinib are only Indicated In patients with an NTRK gene fusion.
Concurrent chemotherapy and radiation therapy (rectal cancer):
Continuous infusion of *5-fluorouracil (5-FU)*: 250–300 mg/m^2 IV daily (Monday–Friday on days of radiation therapy only).
Capecitabine: 825 mg/m^2 by mouth twice a day (Monday–Friday on days of radiation therapy only)
FOLFOX, 5-fluorouracil, leucovorin calcium, and oxaliplatin; FOLFIRIIV, 5-FU, leucovorin, irinotecan, oxaliplatin; intravenous; PO, oral; CAPOX, capecitabine and oxaliplatin.

An aggressive approach is the combination of oxaliplatin, irinotecan, and 5-FU–leucovorin (FOLFOXIRI).[136] In the randomized phase III TRIBE study, upfront use of FOLFOXIRI plus bevacizumab resulted in an improvement in RR, PFS, and OS compared with FOLFIRI plus bevacizumab (OS, 29.8 months vs 25.8 months). In the *RAS/RAF* wild-type (WT) population, there was an even greater benefit, with an OS of 37.1 months compared with 25.6 and 13.4 months in the *RAS* MT and *BRAF* MT populations treated with FOLFOXIRI plus bevacizumab, respectively.[137] Concerns about this regimen are largely due to discussion of limited options for second-line therapy if the patient's disease progresses. However, this was disproven in the TRIBE2 trial that evaluated upfront FOLFOXIRI plus bevacizumab followed by the preplanned reintroduction of the same agents after progressive disease. This approach was shown to provide statistically significant, and clinically relevant PFS and OS benefits compared with the preplanned sequential administration of FOLFOX plus bevacizumab and FOLFIRI plus bevacizumab (PFS, 19.1 months vs 16.4 months; $P = .002$; and OS, 27.6 months vs 22.6 months; $P = .033$, respectively).[138]

Regorafenib

Regorafenib, a small-molecule inhibitor of multiple kinases that are involved with various processes, including tumor growth and angiogenesis, has documented efficacy in a salvage therapy setting in advanced CRC. The phase III CORRECT trial randomized 760 patients who progressed on standard therapy to best supportive care (BSC) or regorafenib. The trial met its primary endpoint of OS (6.4 months vs 5.0 months for regorafenib and placebo, respectively; HR, 0.77; $P = .005$). PFS was also significantly but modestly improved (1.9 months vs 1.7 months; $P < .001$).[139] Unfortunately, although response rates to regorafenib are low, adverse events are high. The most common severe toxicities observed with regorafenib were hand-foot skin reaction, fatigue, diarrhea, and hypertension. In a meta-analysis of four studies, the incidence of all-grade hand-foot skin reactions in 500 patients with CRC was 46.6%.[140] To address this, the phase II ReDOS trial investigated the use of an alternative dosing schedule to reduce the toxicities related to regorafenib treatment. Rates of several of the most common adverse events were lower among the dose-escalation group compared with the standard dosing group. Based on these results, the dose-escalation strategy is an appropriate alternative approach for regorafenib dosing.[141]

Trifluridine–Tipiracil (TAS-102)

Trifluridine–tipiracil is an oral combination drug consisting of a cytotoxic thymidine analog trifluridine and a TP inhibitor, tipiracil hydrochloride, which prevents the degradation of trifluridine. Results of the double-blind, randomized, controlled, international phase III RECOURSE trial were published in 2015 followed shortly thereafter by approval of TAS-102 by the FDA.[142] The primary endpoint of OS was met in 800 patients receiving TAS-102 in the third-line setting versus placebo (7.1 months vs 5.3 months, respectively; $P < .001$). Improvement, albeit slight, was also seen in the secondary endpoint of PFS (2.0 months vs 1.7 months; HR, 0.48; $P < .001$). The most common adverse events were grade 3/4 neutropenia (38%) and leukopenia (21%).

Thus, TAS-102 and regorafenib, are reasonable salvage therapies, FDA approved in mCRC to be used after failure of 5-FU, oxaliplatin, irinotecan, VEGF inhibitor, and an anti-EGFR monoclonal antibody (mAb) in *RAS* WT.

Common chemotherapy regimens for both colon and rectal carcinoma are listed in Table 32–3.

Monoclonal Antibodies

Cetuximab

Cetuximab is a chimeric immunoglobulin G1 (IgG1) mAb directed against the epidermal growth factor receptor (*EGFR*). Compared with BSC in a treatment-refractory patient population, single-agent cetuximab resulted in superior OS (6.1 months vs 4.6 months) and quality of life. Two phase III randomized trials subsequently confirmed the efficacy of cetuximab in combination with irinotecan in previously treated patients, with response rates of approximately 20%.[143,144] Improvement in OS versus BSC has since been validated in heavily pretreated patients.[145]

However, anti-EGFR mAbs do not benefit patients with mCRC with oncogenic *RAS* mutations.[146,147] *KRAS* mutations initially identified in codons 12 and 13 of exon 2 result in constitutive activation of the RAS-RAF-MEK-ERK (mitogen-activated protein kinase [MAPK]) pathway.[148–150] Activating mutations in *KRAS* are detected in approximately 40% of mCRC cases[151,152] with good concordance between primary tumors and distant metastases.[153] Expanded *RAS* mutations in *KRAS* exon 3 or 4 or in *NRAS* exon 2, 3, or 4 have also been noted to predict a lack of benefit from anti-EGFR mAbs, increasing the prevalence of all innate *RAS* mutations to 50% to 55%.[148,154,155]

The phase III trial CRYSTAL randomized nearly 1200 patients with untreated mCRC to FOLFIRI with or without cetuximab. Median PFS (8.9 months vs 8.0 months) and RR (47% vs 39%) were modestly improved with cetuximab. Unplanned retrospective analyses showed that clinical benefit was limited to patients with *KRAS* WT tumors. In this group of patients, cetuximab improved the RR from 43% to 59%, median PFS from 8.7

months to 9.9 months, and OS from 20.0 months to 23.5 months.[149,156] In addition, OPUS, a randomized phase II trial in treatment-naïve patients, compared FOLFOX4 plus cetuximab with FOLFOX4 alone and showed improvement in response rate and PFS with cetuximab. Again, analysis revealed that this benefit was restricted to patients without *KRAS* mutations.[157]

The most significant toxicities associated with cetuximab include diarrhea, hypomagnesemia, hypocalcemia, and an acneiform rash. Traditionally, the risk of an allergic hypersensitivity reaction is reported to be less than 5%. However, life-threatening anaphylactic hypersensitivity reactions have been reported in up to 30% of patients residing in select geographic locations.[158]

Cetuximab is currently FDA approved with FOLFIRI in first line, in combination with irinotecan after progression of disease (although it is routinely used in combination with FOLFOX as well), as monotherapy for patients with mCRC who are intolerant of irinotecan-based regimens, and in combination with irinotecan after progression of disease.

Panitumumab

Panitumumab is a fully human IgG2 mAb directed against *EGFR*. In a randomized phase III trial, patients with refractory metastatic disease received BSC with or without panitumumab. The RR and SD rate with panitumumab were 10% and 27% compared with 0% and 10%, respectively, with BSC alone. An OS difference could not be demonstrated in this trial, likely because of crossover from the BSC group.[159] Subsequent analysis revealed that only patients with *KRAS* WT tumors benefited from panitumumab.[146] Although cetuximab and panitumumab have not been compared head to head, they appear to have similar efficacy and toxicity in patients. Infusion reactions are uncommon with panitumumab because it is a fully human mAb. A large randomized phase II trial (ASPECCT) (n = 1010) found that panitumumab is noninferior to cetuximab (Z score, -3.19; P = .0007) and that these agents provide similar OS benefit in patients with chemotherapy-refractory disease (10.0 months vs 10.4 months, respectively). Thus, it is now FDA approved as a single agent for patients failing irinotecan- and oxaliplatin-based chemotherapy. Two phase III trials have also been reported of FOLFOX or FOLFIRI with or without panitumumab for both treatment-naïve and previously treated patients, respectively.[160,161] Both studies reported superior response and PFS for the combination and resulted in approval in combination with chemotherapy in the front- and second-line settings.

Anti-EGFR Antibody Rechallenge

Among patients with mCRC who initially respond to EGFRi, acquired abnormalities eventually develop and result in secondary resistance. Growing use of plasma ctDNA testing has allowed for the noninvasive detection of heterogeneous molecular alterations underlying the evolution of resistance to targeted therapies in advanced CRC.[162,163] Such analyses have uncovered the role of acquired *RAS* mutations in resistance to anti-EGFR mAbs but have also implicated subclonal mutations in the *EGFR* ectodomain in the development of acquired resistance to anti-EGFR therapy.[164]

Several groups have shown that in the absence of continued selective pressure from EGFR inhibition, the prevalence of *RAS* and *EGFR* mutant clones declines with a half-life of approximately 4 months.[165,166] These data are consistent with several prospective trials demonstrating clinical benefit with anti-EGFR rechallenge. In the CRICKET single-arm phase 2 study, patients with tissue-based *RAS* and *BRAF* WT tumors with a PR and PFS of at least 6 months to first-line cetuximab plus irinotecan were studied and found to have RR, SD, and DCR rates of 21%, 32%, and 54%, respectively, to anti-EGFR rechallenge. There was a statistically significant correlation between benefit from the first anti-EGFR therapy and rechallenge.[167] All patients achieving a PR were ctDNA *RAS* WT before rechallenge with EGFRi, and these patients experienced a significantly longer PFS compared with patients with ctDNA *RAS* MT (4 months vs 1.9 months). There are several large-scale clinical trials currently ongoing that will hopefully better inform the rechallenge practice.

Tumor Sidedness

Primary tumor location in mCRC is now considered a clear prognostic and predictive tool to guide management. Right-sided tumors are defined as those that arise in the cecum to the hepatic flexure, and left-sided tumors represent those from the splenic flexure to the rectum. The initial indication that sidedness impacted clinical outcomes were noted in a first-line chemotherapy trial highlighting right-sided tumors exposed to 5-FU–based chemotherapy had worse survival than left-sided tumors, with a difference of at least 5 months.[168] More recently, these findings have been further supported by analysis of two randomized phase III clinical trials using front-line chemotherapy with bevacizumab for treatment-naïve mCRC, AVF2107g and NO16966. Interestingly, right-sided tumors were identified as negative prognostic indictors regardless of mutational status or tumor histology.[169] Furthermore, post-hoc analysis of FIRE-3, PEAK, PRIME, and CRYSTAL all found that OS and PFS benefit from anti-EGFR therapy for *RAS* WT mCRC was limited to left-sided tumors alone.[169–172] To date, CALGB/SWOG 80405 represents the most compelling evidence for predicting the lack of

response to anti-EGFR therapy in relation to tumor sidedness.[173] In this trial, among patients with *RAS* WT tumors treated with chemotherapy and cetuximab, a statistically significant reduction in OS of 13.6 months for right-sided cancers was noted compared with 39.3 months for left-sided cancers ($P = .001$; HR, 0.55). Of note, this stark difference was not appreciated for bevacizumab exposure, consistent with an agnostic impact on survival outcomes between *RAS* WT left-sided versus right-sided tumors ($P = .50$) with anti-VEGF therapy.

because of the retrospective analysis of CALGB 80405 highlighting sidedness as a biomarker of response and selection criteria for EGFR inhibition, both the NCCN and ESMO guidelines support deferring anti-EGFR therapy for patients with *RAS* WT right-sided tumors in the first-line setting. To date, there is no clear consensus on therapy after the front-line setting; however, one trial, CO.17, solidified a lack of benefit with cetuximab compared with best supportive care for refractory *KRAS* mutant tumors. Patients with right-sided tumors had no statistically significant benefit with cetuximab compared with left-sided tumors.[174] Additional studies are needed to determine whether patients with *RAS* WT right-sided tumors can glean any benefit from EGFR inhibition in subsequent lines of therapy.

Bevacizumab

Bevacizumab is a humanized mAb that binds all isoforms of circulating VEGF, thereby inhibiting permeability and angiogenesis mediated by this factor.

In the phase II TREE-2 study, Hochster and colleagues[175] demonstrated the safety and efficacy of bevacizumab in combination with oxaliplatin-based chemotherapy (mFOLFOX6, bFOL, or CAPOX). This trial was not powered for direct comparisons among the three arms, but time to progression (9.9 and 10.3 months, respectively) and OS (26.1 and 24.6 months, respectively) were virtually identical in the mFOLFOX6 and CAPOX arms. In the NO16966 trial, untreated patients were randomized in a 2 × 2 design to FOLFOX4 or CAPOX (noninferiority) with or without bevacizumab.[176] The pooled analysis revealed superior median PFS (9.4 months vs 8.0 months; $P = .002$) in the bevacizumab-containing groups, but a difference in response and OS did not achieve statistical significance. Surprisingly, when PFS was stratified by chemotherapy regimen, the CAPOX regimen fared better. In both of these trials, bevacizumab did not increase the toxicities of chemotherapy. The most significant adverse events associated with bevacizumab were hypertension; proteinuria; thrombosis; and rare instances of bleeding (mostly epistaxis), delayed wound healing, and GI perforation.

The efficacy of bevacizumab as an adjunct to chemotherapy has been validated in the second-line setting as well. ECOG 3200 randomized more than 800 patients with mCRC previously treated with 5-FU and irinotecan (but not oxaliplatin or bevacizumab) to one of three arms: FOLFOX4, bevacizumab, or the combination.[177] The arm receiving bevacizumab as monotherapy was closed to accrual after an interim analysis revealed inferior outcomes compared with the other two arms. Ultimately, the addition of bevacizumab to chemotherapy resulted in improved PFS (median, 7.3 months vs 4.7 months; $P < .0001$) and OS (median, 12.9 months vs 10.8 months; $P = .0011$).

Bevacizumab is now FDA approved for use in combination with fluorouracil-based regimens as a first- or second-line treatment for patients with mCRC.

Two large phase III trials (CAIRO2 and PACCE) examined the efficacy of dual biologic therapy (bevacizumab with anti-EGFR antibody and chemotherapy) in mCRC. Both trials unexpectedly showed worse outcomes with the combination approach.[178,179] In light of these data, dual VEGF and *EGFR* inhibition currently has no role in the treatment of patients with CRC and should not be pursued outside a clinical trial.

Ramucirumab

Ramucirumab, another antiangiogenic agent, is a human mAb that blocks VEGF signaling. In the multicenter, phase III RAISE trial, 1072 patients with mCRC whose disease progressed on first-line therapy with 5-FU, oxaliplatin, and bevacizumab were randomized to FOLFIRI with either ramucirumab or placebo. The primary endpoints of OS were met at 13.3 months and 11.7 months in the ramucirumab and placebo groups, respectively ($P = 0.02$). PFS was also improved slightly with the addition of ramucirumab (5.7 months vs 4.5 months, $P < .0005$).[180]

Aflibercept

Aflibercept is a recombinant fusion protein of portions of human VEGFR 1 and 2 extracellular domains fused to the Fc portion of human IgG1. In the phase III VELOUR trial, 1226 patients with oxaliplatin-refractory mCRC were randomly assigned to aflibercept or placebo plus FOLFIRI. Median OS, the primary endpoint was significantly longer in patients treated with aflibercept irrespective of prior bevacizumab exposure (13.5 months vs 12.1 months).[181]

Considering the results of the RAISE and VELOUR trials, ramucirumab or aflibercept are second-line treatment options in combination with FOLFIRI or irinotecan after progression on therapy not containing irinotecan and are FDA approved for this indication.

Biomarkers and Targeted Therapy for Colorectal Cancer Management

Microsatellite Instability–High Metastatic Colorectal Cancer

Deficient mismatch repair (dMMR) or MSI-H account for only 4% to 5% of all patients with mCRC but represent a unique cohort with a distinct prognosis and treatment option in the form of immunotherapy (Table 32–4).[182]

Considering the hypermutated phenotype of dMMR tumors, the use of checkpoint inhibitors has offered an exciting new treatment strategy for patients with advanced CRC. Targeting programmed death ligand 1 (PD-L1) on tumor cells or programmed cell death protein 1 (PD-1) on T-cells has dramatically impacted patient outcomes. Pembrolizumab and nivolumab are two IgG4 mAbs that target PD-1, both FDA approved for patients with MSI-H mCRC after demonstrating durable clinical activity. The CheckMate-142 study investigated the use of nivolumab alone or in combination with ipilimumab, a fully human IgG1 mAb that targets cytotoxic T-cell lymphocyte antigen-4 (CTLA-4). The overall response rate (ORR) was 31.3% with nearly 70% of patients achieving disease control at 12 weeks and a median OS of 73% at 1 year for the monotherapy arm.[183] In the doublet arm, although grade 3 and 4 treatment-related adverse events were increased to 32%, the ORR was 55% with a disease-control rate of 80% and a 1-year OS of 85%.[184] Single-agent data for pembrolizumab was first reported in a landmark phase II study investigating its efficacy among 41 patients with advanced CRC with or without mismatch-repair deficiency.[182] Both immune-related ORR and PFS were noted to be 40% and 78%, respectively, among patients with dMMR mCRC compared with 0% and 11% for those with pMMR mCRC. At the time of the report, the median PFS and OS were not reached for the dMMR cohort and were 2.2 and 5.0 months for the pMMR cohort, respectively.

Based on this data, MSI status is a definitive predictive biomarker for response to immune checkpoint blockade (Figs. 32–4 and 32–5). NCCN has included single-agent pembrolizumab, nivolumab, or nivolumab plus ipilimumab as viable treatment options for patients with dMMR mCRC in a second- or third-line setting as well as those deemed "not appropriate for intensive therapy."[58]

Of note, the randomized open-label international phase III KEYNOTE-177 trial comparing the anti–PD-1 antibody pembrolizumab with investigator's choice standard chemotherapy in combination with biologic therapy (anti-EGFR or anti-VEGF) for 307 patients with treatment-naïve MSI-H mCRC has been presented.[185] The study met its primary endpoint of PFS with a statistically significant improvement to 16.5 months with pembrolizumab compared with 8.2 months with chemotherapy (HR, 0.60; P = .0002). ORR was also improved to 43.8% with the pembrolizumab arm compared with 33.1% with chemotherapy (P = .0275). OS analysis is pending. Based on these results, the FDA has now approved pembrolizumab for patients with unresectable or metastatic MSI-H/dMMR CRC as first-line treatment.

TABLE 32–4 Prognostic and Predictive Biomarkers in Metastatic Colorectal Cancer

Biomarker	Prognostic	Predictive
dMMR/MSI-H	+	+
Tumor sidedness	+	+ (for left-sided RAS WT)
RAS^{WT}	+	+
RAS $_{mutant}$	-	+
BRAF^{V600E}	+	+
HER2 amplification	-	+
NTRK fusions	Unknown	+
Atypical non-*V600 BRAF*	Unknown	Unknown
POLE	Unknown	Likely

dMMR, deficient mismatch repair; MSI-H, microsatellite instability–high; WT, wild type.

BRAF^{V600E} Mutation

BRAF is a serine threonine kinase that is downstream of RAS in the MAPK pathway and is predominantly mutually exclusive from concurrent *RAS* mutations. The most common BRAF mutation occurs at codon 600 with a valine to glutamic acid change (c.1799T>A or p.V600E) producing a constitutively active protein. In clinical practice, approximately 7% to 14% of all patients with mCRC carry a *BRAF*^{V600E} mutation, and this portends a poor prognosis.[186] Patients with *BRAF*^{V600E} mCRC have a distinct clinical presentation accompanied with hallmark pathologic features that include older women, right-sided T4 tumors, high-grade mucinous histology, sporadic MSI-H phenotype, and predominantly distal nodal involvement with peritoneal disease.[187]

BRAF^{V600E} mCRC is associated with tumorigenesis via the serrated/methylated pathway traditionally through a serrated adenoma precursor. This results in a hypermethylated phenotype with subsequent inactivation of MLH1 yielding sporadic MSI-H/dMMR.[188] Therefore, it is critical to be aware of the MMR status of all patients with *BRAF*^{V600E} because of can have clear clinical implications regarding sequencing of their cancer therapy. Additionally, BRAF mutational status

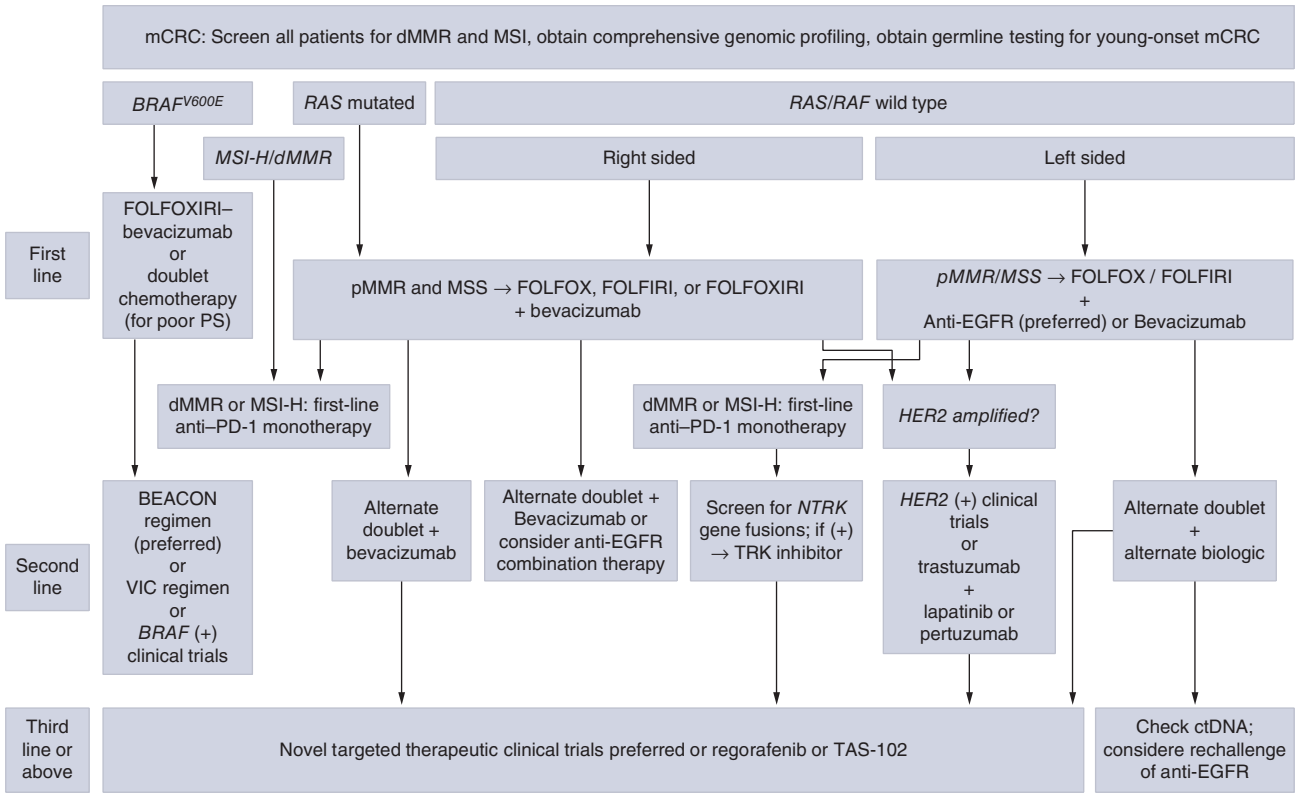

FIGURE 32–4 Biomarker-based decision algorithm for systemic therapy in metastatic colorectal cancer. BEACON; ctDNA, circulating tumor DNA; dMMR, deficient mismatch repair; EGFR, epidermal growth factor receptor; FOLFIRI, ????; FOLFOX, 5-fluorouracil, leucovorin calcium, and oxaliplatin; FOLFOXIRI, ????; mCRC, metastatic colorectal cancer; MSI, microsatellite instability; MSI-H, microsatellite instability–high; PD-1, programmed cell death protein; pMMR, proficient mismatch repair; PS, performance status; TAS-102, trifluridine–tipiracil; VIC, vemurafenib, irinotecan, cetuximab.

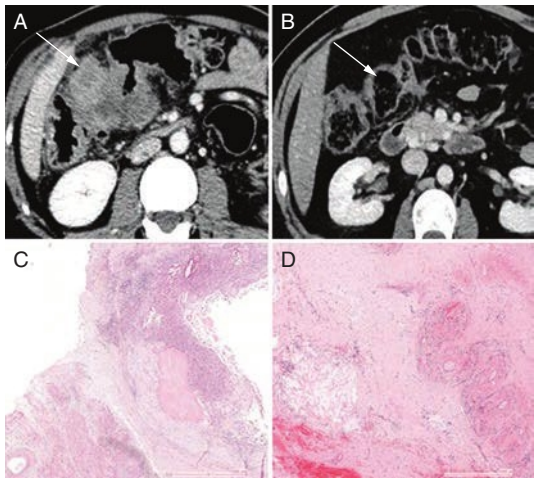

FIGURE 32–5 Radiographic and pathologic response of a microsatellite instability–high colon tumor treated with immunotherapy. **A.** Pretreatment computed tomography (CT) image of the abdomen with arrow depicting a bulky right colon mass (*arrow*). **B.** CT image obtained after 26 months of therapy with ipilimumab and nivolumab demonstrating complete radiographic resolution of the colonic tumor (*arrow*). **C.** Photomicrograph of a right hemicolectomy specimen resected after immunotherapy. The normal muscularis propria bundles are interrupted by fibroelastic tissue containing areas of eosinophilic necrosis, as well as a polymorphic inflammatory infiltrate including cholesterol clefts surrounded by giant resorptive cells (×25 magnification). **D.** The fibrous scar contained many vessels, some with associated thrombosis. Acellular mucin was also visible. (Reproduced with permission from Ludford K, Cohen R, Svrcek M, et al: Pathological Tumor Response Following Immune Checkpoint Blockade for Deficient Mismatch Repair Advanced Colorectal Cancer, *J Natl Cancer Inst* 2021 Feb 1;113(2):208-211.)

remains a prognostic factor in terms of OS in both the early-stage and advanced settings.[189] In the metastatic setting, patients with a *BRAF*^{V600E} mutation are refractory to traditional chemotherapy with an OS of only 10 to 12 months.[186,190]

Considering this, initial therapeutic decisions are paramount for patients presenting with metastatic disease. There are data to support the use of triplet chemotherapy in combination with bevacizumab for *BRAF*^{V600E} mCRC based on the TRIBE study, which compared FOLFOXIRI–bevacizumab versus FOLFIRI–bevacizumab for treatment-naïve patients with mCRC.[137] In this study, the primary endpoint of PFS was met with an improvement of 2.4 months for all patients who received the triplet regimen compared with doublet. Specifically regarding *BRAF*,^{V600E} 28 patients were included in this trial of which 16 were randomized to the triplet arm. Subgroup analysis revealed that the triplet regimen resulted in improvement of OS to 19 months compared with 10.7 months with the doublet regimen for *BRAF*^{V600E} patients. Therefore, in the first-line setting for *BRAF*^{V600E} mCRC patients with adequate performance status, FOLFOXIRI in addition to bevacizumab is a reasonable treatment choice. Of note, in this same study, the RAS/RAF WT cohort that received triplet therapy had a median OS of nearly 42 months, highlighting the innate aggressiveness of *BRAF*^{V600E} mCRC.

In addition to its underlying resistance to standard chemotherapy, the use of anti-EGFR therapy for *BRAF*^{V600E} mCRC is no longer recommended as monotherapy or in combination with chemotherapy because of a lack of benefit. This is based on the collective assessment of multiple studies because individual studies were limited by retrospective nature and small numbers.[191] A meta-analysis of nine phase III and 1 phase II trial (six first-line studies, two second-line studies, and two chemotherapy-refractory studies) evaluated 463 *BRAF*^{V600E} patients to address the impact of EGFR mAbs. This revealed that when anti-EGFR therapy was added to chemotherapy or best supportive care, there was no improvement in PFS, OS, or response rate compared with control regimens.[192] Based on these available data, NCCN, ESMO, and ESMO Asia all recommend the use of EGFR antibodies exclusively for RAS/BRAF WT mCRC patients.

In light of the limitations of chemotherapy and EGFR inhibition for *BRAF*^{V600E} mCRC, the need to develop effective targeted therapies against the mutated protein itself was clear. Unfortunately, although exciting results for *BRAF*^{V600E} mutant metastatic melanoma was achieved with BRAF inhibition, this success was not realized with either vemurafenib or encorafenib in early-phase studies for mCRC, with response rates of 5% and 0%, respectively.[193] Distinct from melanoma, reactivation of EGFR signaling is the most prominent mechanism of resistance in mCRC after single-agent BRAF inhibition supporting the development of rational combination therapies.[194,195] Initial clinical studies exploring the efficacy of BRAF and EGFR targeted therapies revealed disease response in 52% and 67% of treatment-refractory patients.[196,197] Most notably, when this dual targeted approach was combined with chemotherapy (vemurafenib, irinotecan, cetuximab) in the SWOG 1406 study, superior PFS (4.4 months vs 2.0 months) and ORR (16% vs 4%) were achieved among patients exposed to the three-drug combination arm compared with those who received irinotecan and cetuximab alone, supporting its initial insertion into treatment guidelines.[198,199]

MEK is a downstream effector of BRAF, and initial efforts exploring dual BRAF and MEK inhibition reported modest efficacy with response rates of 12% and one complete response (CR) in a cohort of 43 treated patients.[200] The first randomized phase III trial for previously treated *BRAF*^{V600E} mCRC, known as the BEACON CRC study, has been completed and published with updated survival data reported.[201] This pivotal trial evaluated the efficacy of a BRAF inhibitor encorafenib plus cetuximab with or without the MEK inhibitor binimetinib compared the control arm of irinotecan–FOLFIRI plus cetuximab. Initial safety lead-in data reported an ORR of 48% with good tolerability among 29 patients who received the triplet regimen.[202] Interestingly, updated survival data revealed that the doublet regimen (encorafenib–cetuximab) was no less efficacious than the triplet regimen. The doublet arm revealed an improved median OS of 8.4 months compared with 5.4 months for the control arm (HR, 0.60; P = .0003) as well as an improved median PFS of 4.2 months compared with 1.5 months for control (HR, 0.40; P <.0001). Additionally, ORR was noted to be 20% for the doublet arm compared with 2% for the control arm (P <.0001). Based on these data, FDA approval was granted for the doublet regimen on April 8, 2020. Considering these data, the NCCN has recommended the BEACON regimen of encorafenib in combination with cetuximab for previously treated patients with *BRAF*^{V600E} mCRC, reflecting the first time a completely targeted therapeutic approach is available for these high-risk patients.

HER2 Amplification

Human epidermal growth factor receptor (HER2) is a member of the EGFR receptor family and aberrant signaling is known to occur via genomic amplifications promoting upregulation of phosphoinositide 3-kinase (PI3K) and MAPK pathways. In CRC, *HER2* amplification is noted in 3% to 5% of patients, mutually exclusive from *RAS/RAF* mutations and may be associated with de novo resistance to EGFR mAbs. In breast

cancer, HER2 amplifications occur at an increased frequency and has been a focus of therapeutic targeting via mAbs trastuzumab and pertuzumab. Serving as a precedent, this approach was pursued in CRC trials with success. The HERACLES trial accrued patients with CRC with HER2 positivity defined as 3+ HER2 score in greater than 50% of tumor cells by immunohistochemistry (IHC) or with 2+ HER2 score and a HER2:CEP17 ratio greater than 2 in more than 50% of cells by fluorescence in situ hybridization (FISH). In this study, trastuzumab in combination with lapatinib (an oral dual HER2–EGFR kinase inhibitor) was used to treat 27 patients with refractory HER2 mCRC. Nearly 30% of patients had an objective response with 1 patient developing a CR.[203] In the phase II MyPathway study, 57 refractory HER2-amplified patients with mCRC were treated with a combination dual-HER2 targeted approach of pertuzumab and trastuzumab, revealing a 32% ORR and 1 patient with a CR.[204] Considering these two positive landmark studies, the NCCN has added HER2 targeted therapy with trastuzumab and lapatinib or trastuzumab and pertuzumab as viable options for patients with refractory HER2-amplified mCRC. Based on early reports of HER2 amplification representing a negative predictive biomarker for EGFR mAbs, we await results from the ongoing phase II SWOG 1613 study (NCT03365882) evaluating patients with chemotherapy-refractory, anti-EGFR-naïve, HER2-amplified, RAS/RAF WT mCRC randomizing to trastuzumab and pertuzumab versus cetuximab and irinotecan.

The DESTINY-CRC01 trial evaluated trastuzumab deruxtecan (T-DXd), an antibody–drug conjugate consisting of an anti-HER2 antibody, a cleavable tetrapeptide-based linker, and a cytotoxic topoisomerase I inhibitor, in 78 patients with previously treated unresectable or mCRC that was HER2 expressing and *RAS/BRAF* WT mCRC with a primary endpoint of RR. Patients with HER2-positive with IHC scoring 3+ or IHC 2+/in situ hybridization+ had RR of 45.3% and stable disease in another 37.7%. Median PFS was 6.9 months in cohort A, and median OS was not reached. Of note, interstitial lung disease is an important adverse event with T-DxD noted in 6.4% of patients in this trial.[205]

NTRK Fusions

Neurotrophic receptor tyrosine kinase fusion (NTRK) genes encode for TrkA, TrkB, and TrkC receptor tyrosine kinases that are responsible for baseline function in human neuronal tissue with activation via MAPK and PI3K pathways. Fusions can be aberrant resulting in oncogenic addiction with a rare prevalence of 0.2% to 2.4% of all CRC with data suggesting higher yield (approaching 3%) in the MSI-H subpopulation.[206] In a landmark study, 55 adult and pediatric patients with NTRK fusions achieved an ORR of 75% with 55% of patients remaining progression-free at 1 year. Among three patients enrolled with CRC, two achieved an objective response.[207] These data have resulted in FDA accelerated tissue agnostic approval to use larotrectinib for all patients with refractory solid tumors and an NTRK fusion. The NCCN has since recommended testing for NTRK gene fusions in mCRC and supports the administration of larotrectinib for this rare cohort of patients.

Evolving Biomarkers of Interest in Metastatic Colorectal Cancer

BRAF$^{non\text{–}V600}$ Mutation

Atypical, non-V600 BRAF mutations are an increasingly recognized molecular subset, representing nearly 2.2% of all patients with mCRC.[208] Unlike *BRAF*,^{V600E} patients with atypical BRAF mCRC have a distinct clinicopathologic profile with most patients having microsatellite stable (MSS) disease, left-sided primary tumors, lower grade histology, and nonperitoneal disease and are commonly co-mutated with RAS. Patients with atypical BRAF mCRC have been reported to have an improved median OS of 60.7 months compared with 11.7 months for those with traditional *BRAF*^{V600E} mutations.[208] Furthermore, preclinical data have described BRAF mutations as unique classes based on their underlying signaling biology. Whereas class I reflects traditional *BRAF*^{V600E} mutations that signal via BRAF monomers with high kinase activity and are non–RAS dependent, atypical non-*V600 BRAF* mutations signal via BRAF dimerization and have been categorized into class II and III subtypes.[209,210] Whereas class II mutations have intermediate to high kinase activity without RAS dependency, class III mutations have low kinase activity and are RAS dependent.

Currently, there are no guidelines to direct the management of patients with atypical *BRAF* mutations with clinical trials recommended after failure of standard cytotoxic chemotherapy. Regarding biologic therapy, although there have been some data to suggest class III mutations may benefit from EGFR inhibition, additional studies have been less convincing.[210,211]

POLE Mutations

The *POLE* gene is located in 12q24.33 and encodes the proofreading exonuclease domain of polymerase epsilon.[212] Somatic mutations in *POLE* are a rare event in CRC, estimated at less than 1%.[213] However, *POLE* mutations are important to highlight considering patients with these mutations have an increased rate of hypermutated tumors with higher neoantigen load, thereby potentially representing a predictive biomarker to immunotherapy in a non–MSI-H setting,

although deciphering between passenger and driver *POLE* mutations is of importance in regards to predicting successful outcomes with checkpoint inhibition.[214,215] Although an evolving area in CRC, there are no guidelines because of limited data to date. However, in clinical practice, identifying the presence or absence of these mutations reflects a potential therapeutic target in the refractory setting.

DECISION MAKING FOR POTENTIAL SURGICAL RESECTION IN PATIENTS WITH METASTATIC COLORECTAL CANCER

Despite therapeutic advances, the estimated 5-year OS for patients unable to be surgically resected remains less than 15%. Although randomized data are limited, retrospectively, surgery has shown 5-year OS in excess of 30%.[216,217] Therefore, multidisciplinary discussions for surgical resection in mCRC should be initiated early if there is a potential for surgery with curative intent. Diagnostic imaging (MRI, PET-CT, and volumetric) has an important role when considering surgical resection. The use, choice, and duration of neoadjuvant chemotherapy should be determined by the treating medical oncologist and surgeon in a multidisciplinary fashion and is typically limited to less than 3 months. Patients who have response or stable disease on neoadjuvant therapy fare better than those with progression.[218] Perioperative and adjuvant therapy (5-FU-based) versus observation has shown a trend toward improved DFS but not OS with hepatic resection.[219–221] This benefit comes at risk of increased postoperative complications from chemotherapy-induced steatohepatitis and hepatic sinusoidal injury.[219,222] Additionally, although bevacizumab is used, we do not use anti-EGFR mAbs in perioperative setting because of inferior OS and PFS seen with the EPOC study.[223] Others challenges are the timing and role of radiotherapy and surgery in patients with metastatic disease in the presence of a primary rectal cancer. At MDACC, our approach is to perform liver metastasectomy first after a course of neoadjuvant chemotherapy followed by chemoradiation and then primary resection.

Follow-up for Patients with Resected Metastatic Colorectal Cancer

After metastasectomy, patients are followed closely with physician visits, CEA level, and diagnostic imaging every 3 to 4 months for the first 3 years, every 6 months for the following 2 years, and annually thereafter. Colonoscopy should continue to be completed every 3 years thereafter (or more frequently based on endoscopic findings). CT (or MRI) is the standard recommended cross-sectional imaging modality. PET-CT may be used for inconclusive findings or if a rising CEA level is noted without measurable disease on CT or MRI. All patients are encouraged to maintain a relationship with a primary care physician for optimal surveillance and health care.

CHALLENGING CLINICAL MANAGEMENT PROBLEMS

Management of the Older Adult Population and Colorectal Cancer

Age-related decline in organ functions and reserves, medical comorbidities, and quality of life considerations often complicate management of older adult patients with CRC. Although essential principles of management in CRC do not vary with age, increased risks of chemotherapy in older adult patients, sometimes perceived and sometimes palpable, may alter the approach to these patients. Despite their underrepresentation in clinical trials, a systematic review of phase III randomized trials (n = 345) for older adult patients (65 years of older) demonstrated that appropriately selected patients can derive equivalent benefits from therapy without a substantial increase in toxicity.[224]

The AVEX study in older adult patients (aged 70 years and older) with untreated mCRC, deemed not to be candidates for aggressive chemotherapy showed that combination bevacizumab and capecitabine was effective (significantly longer median PFS, 9.1 months vs 5.1 months) and well tolerated (treatment-related adverse events of grade 3 or worse, 40% vs 22%) compared with capecitabine alone.[225] Treatment of patients with CRC should be based on a comprehensive assessment of risk–benefit encompassing performance status, comorbidities, and consideration of toxicities rather than age alone. Special emphasis should also be placed on defining molecular subsets such as dMMR mCRC, wherein targeted therapies can provide clinical benefit with lower toxicity compared with conventional cytotoxic chemotherapy.

Malignant Polyps

On occasion, an endoscopically removed polyp may demonstrate invasive adenocarcinoma within a villous or tubular adenoma. Treatment recommendations in this situation should be individualized based on features, including negative margins, no evidence of invasion beyond the submucosa, well- or moderately differentiated adenocarcinoma, and no evidence of lymphatic or vascular invasion. In this setting, the risk of lymph node metastases is low (5%), and follow-up with periodic colonoscopic examinations is reasonable. Unfortunately, retrieval of a sessile or bulky polyp

distorts the depth of invasion or margin status. Furthermore, if pathology demonstrates poor differentiation, invasion into the muscularis, or lymphovascular invasion, surgical resection is advised. In particular, T2 tumors have a 20% likelihood of lymph node metastases, so continued endoscopic follow-up without further surgical intervention is not appropriate.

A malignant polyp in the distal or midrectum is often not amenable to further local staging because endoscopic rectal polypectomy leads to unreliable EUS imaging. Definitive surgical resection should be considered for a resected rectal polyp without clear margins or with adverse pathologic features. If margins are equivocal without muscle invasion, transanal excision may be feasible. Even when laparotomy is considered, a sphincter-preserving procedure is usually possible. Occasionally, an adequately informed patient will refuse surgery, or medical comorbidities preclude surgery as an option. In these special circumstances, nonstandard combined-modality chemoradiation is an alternative to definitive resection.

Nonsurgical Options for Partially Obstructing Tumors

Bowel resection or diverting ostomy may be appropriate, but in patients with poor performance status, nonsurgical management should be considered, which includes expandable metal stents, especially in the rectosigmoid region. Obstructing sites higher in the colon can pose technical barriers to stent insertion. An endoscopically placed colonic decompression tube *proximal* to the obstruction may provide temporary relief. Endoscopic electrosurgical procedures, including argon plasma coagulation, may recanalize the lumen. External-beam radiotherapy may then prevent complete obstruction while alleviating partial obstruction. Patients with impending bowel obstruction are hospitalized for bowel rest, nasogastric tube decompression, and intravenous hydration followed by multidisciplinary evaluation by a gastroenterologist, surgical oncologist, medical oncologist, and radiotherapist.

Multidisciplinary Management of Poor Bowel Function After Curative Treatment

Segmental bowel resections leads to permanent alterations in the frequency and character of bowel movements. Loss of the rectal vault and radiotherapy lead to compromised stool storage and stricture formation at the anastomotic site, and sphincter function may not return to baseline, leading to functional and mechanical dysfunction manifesting as small, frequent bowel movements, with episodic fecal incontinence.

In general, patients are advised that bowel habits may improve for up to 1 year from the time of surgery or up to 6 months after completion of all adjuvant therapy. For patients with more chronic and severe problems (innumerable small bowel movements or fecal incontinence), a multidisciplinary team of surgeons, gastroenterologists, and enterostomal nursing staff recommends a personalized detailed bowel regimen that, with adequate adherence, can improve quality of life and satisfaction with sphincter preservation. On rare occasions, when a sphincter-preserving procedure leads to unbearable dissatisfaction with bowel function, a colostomy or ileostomy may be recommended to improve functional status and quality of life.

MD ANDERSON PRACTICE TIPS

- It is difficult to articulate a general treatment algorithm for patients with metastatic disease, but individual consideration of each patient's case is always considered. Whenever possible, patients with good performance status should be offered therapy as part of a clinical trial.
- Previous analyses have suggested a survival advantage for patients treated with all three active conventional cytotoxic agents (5-FU, irinotecan, and oxaliplatin) during the course of their treatment.[226] Tumor mutation status has become a core part of treatment decision making and should be performed in all patients with metastatic disease. At MDACC, if tumor tissue is unavailable or not amenable for biopsy, ctDNA-based profiling is done to guide therapy.
- Broad principles have emerged as the foundation for therapeutic decisions at MDACC:
- *Asymptomatic patients with metastatic disease are usually offered systemic therapy*. With advent of newer, more efficacious agents, frontline therapy is better tolerated and more likely to be beneficial in asymptomatic patients with good performance status. An exception to this principle is patients with known metastatic disease that is either not evaluable or extremely low volume. In these cases, close follow-up with frequent imaging may be an appropriate initial strategy. Therapy is then initiated when measurable disease is evident or, in the oncologist's judgment, further expectant follow-up is likely to lead to symptoms. Patients with a rising serum CEA level are usually not recommended to undergo treatment in the absence of clear clinical or radiographic evidence of metastatic disease and are followed closely.

MD ANDERSON PRACTICE TIPS

- *The initial treatment for patients with metastatic disease may depend on the timing and residual toxicities of prior adjuvant therapy.* Many patients who develop metastatic disease have received prior adjuvant therapy consisting of oxaliplatin. When patients relapse, they should be considered refractory to this combination if fewer than 12 months have elapsed since the completion of adjuvant therapy. Irinotecan often becomes the primary cytotoxic agent in the treatment of patients with relapsed disease after recent adjuvant therapy.
- *Patients should be treated to maximal benefit or until therapy becomes intolerable.* When patients are receiving systemic therapy for metastatic disease, we usually continue treatment until progression, unacceptable toxicity, or patient's deferment of therapy. Patients receiving oxaliplatin in conjunction with capecitabine or 5-FU, as part of a FOLFOX or CAPOX regimen, may develop unacceptable peripheral neuropathy. In such cases, there is no disadvantage to discontinuation of oxaliplatin, provided maintenance therapy continues. Oxaliplatin may be reintroduced as a component of the regimen when neuropathic symptoms subside or the tumor starts to progress.[227]
- *The benefit of maintenance therapy must be weighed against potential toxicity, and patient preference must be considered as well.* Therefore, a chemotherapy treatment holiday may be appropriate for select patients after prolonged response or stability of disease.
- *The need for local control should always be considered.* Recent experience with combination therapies suggested that the primary tumor may respond well to systemic therapy in some cases, obviating the need for local therapies. As a rule, however, locally recurrent tumor at a site of previous surgery or radiotherapy is not particularly responsive to systemic therapy. Therefore, oncologists must continuously reassess whether local tumor control should take priority over treatment for disseminated disease. Such decisions are usually made with input from a multidisciplinary team.
- *Whenever feasible a multidisciplinary approach should be considered, including role of surgical resection in metastatic disease:* Surgical resection appears to confer a significant survival benefit compared with systemic therapy alone in appropriately selected patients. When possible, a curative-intent metastasectomy (especially liver and lung) should be incorporated in the treatment plan with early discussion between surgical and medical oncologists.

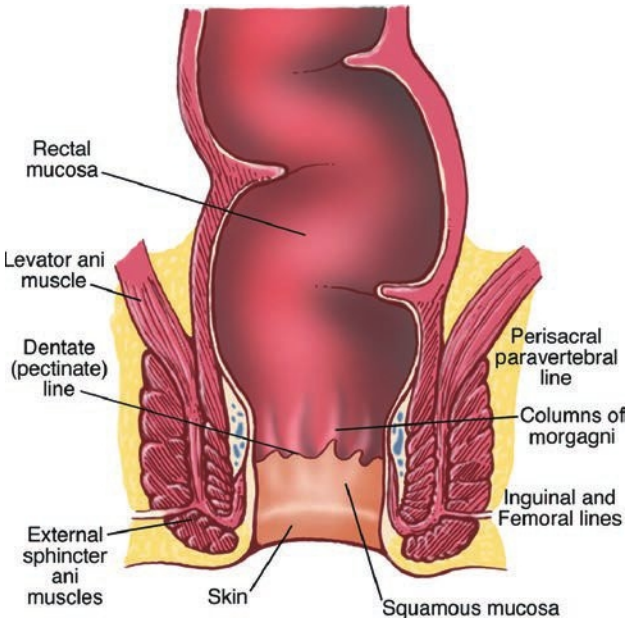
33 Anal Cancer

Emma Holliday
Van Morris
Craig A. Messick



KEY CONCEPTS

- Despite the introduction of a preventive human papillomavirus vaccine, both the incidence of anal cancer and the anal cancer–specific mortality rate continue to rise in the United States.
- Concurrent chemoradiation remains the standard of care for curative-intent therapy for patients with newly diagnosed, locoregional anal cancer.
- To date, there are no data to support benefit with chemotherapy before or after chemoradiation for patients with locoregional anal cancer.
- Salvage surgery with abdominoperineal resection remains the standard of care for patients with nonmetastatic, locoregional anal cancer that recurs after chemoradiation.
- Combination chemotherapy is the current treatment recommendation in the frontline setting for patients with inoperable, metastatic anal cancer.
- Immune checkpoint blockade therapies, either as monotherapy or as a clinical trial option, should be considered for patients with treatment-refractory anal cancer.

Carcinoma of the anal canal is extremely rare, representing approximately 2% to 3% of all gastrointestinal (GI) malignancies. It was estimated that in 2020, 8590 patients (5900 female) would be diagnosed with carcinoma of the anal canal in the United States, resulting in 1350 deaths.[1] The incidence of this disease continues to rise steadily. Over the past 20 years, increasing rates of advanced (metastatic) stage at initial presentation have been reported in the United States and are linked to a rise in cancer-specific mortality rates.[2] Still, a practicing oncologist will evaluate and treat less than one such patient per year. The majority of anal cancer is squamous cell carcinoma (SCC) and typically arises within the anal mucosa.[3] Traditionally, more than 70% of locoregional anal canal caners are cured with the combined modalities of chemoradiation,[4] reserving an abdominoperineal resection (APR) for salvage therapy of patients with persistent or recurrent disease.[5] This chapter focuses on the multimodality treatment of SCC of the anus (SCCA) and the emerging role of immunotherapy in management of patients with this disease.

ANATOMY

Optimal treatment of patients with SCCA requires sound understanding of the anatomy of the anus, which includes the anal canal, anal verge (AV), and anal margin (AM). The anal canal is variable in length and is 2 to 3 cm long in women and 3 to 5 cm in men. The AV is the visible portion of the anus seen with gentle traction applied to the buttocks, and the AM is a region that extends 5 cm radially from the AV around the anal skin (Fig. 33–1). Nomenclature is vital, and accurate description of the tumor location is critical for optimal management. Although classification of these tumors by their histologic definition may offer a more consistent approach to guide diagnosis and treatment,[3] meaningful data suggest such a singular approach to all SCCA may be inadequate, and a tailored approach to these cancers may be more important. For example, malignancies of the AM that do not involve the anal sphincter complex and are smaller than 2 cm are often treated as primary skin cancers, surgically excised with a wide local excision (WLE). This is not to be applied to T2 tumors outright

IGURE 33–1 **Anatomy of the anal canal.**

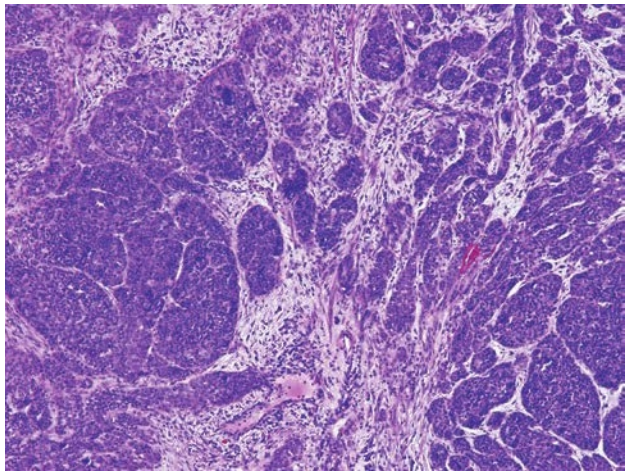


FIGURE 33–2 **Nonkeratinized squamous cell carcinoma of the anal canal.**

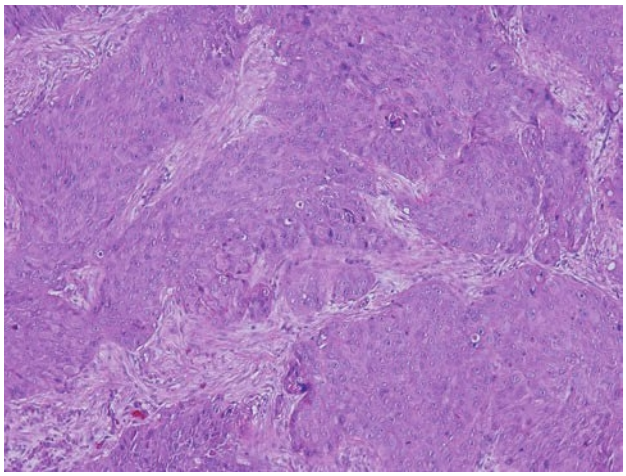

FIGURE 33–3 **Keratinized squamous cell carcinoma of the anal canal.**

CHAPTER 33

and especially those in the anal canal, but T2 tumors that are very small or far away from the sphincters could also conceivably managed with WLE with adequate counseling that T2 tumors may carry up to a 24% risk of positive LN at the time of diagnosis.[6,7]

The anal canal can be divided into two parts by a third part, the anal transition zone (ATZ). The proximal anal canal is composed of rectal mucosa, or columnar epithelium, which transitions to an ill-defined ATZ made of both cuboidal and columnar epithelium (6–12 mm in length) and extends to the dentate line.[8] The dentate line is a visible anatomic site that represents the separation of columnar epithelium (columns of Morgagni) of the proximal half of the anal canal and the squamous epithelium of the distal half of the anal canal extending to the AV. The AV is the convergence of squamous epithelium and the dermis and epidermis of the AM. Importantly, the ATZ mucosa, historically referred to as the cloacogenic mucosa, is the location for approximately 66% of nonkeratinizing SCCAs (Fig. 33–2),[8] whereas tumors distal to the dentate line are keratinizing SCCAs (Fig. 33–3).

The vascular supply of the anal canal consists of the superior, middle, and inferior rectal vessels that originate from the inferior mesenteric, internal iliac, and internal pudendal arteries, respectively. Lymphatic drainage for tumors located cranially to the dentate line is identical to rectal carcinomas draining to the perirectal and paravertebral nodes. Tumors located caudal to the dentate line drain to the inguinal and internal iliac and obturator lymph nodes. A complete physical examination should include examination of the lymph nodes of the groins.

RISK FACTORS

Several risk factors have been previously associated with the development of SCCA. Some of those relate to sexual activity, including a history of more than 10 sexual partners; anal receptive intercourse (especially men having sex with men [MSM]); having a prior sexually transmitted disease, including condyloma acuminata (genital warts, attributed to human papillomavirus [HPV]), gonorrhea, herpes virus, hepatitis, or *Chlamydia trachomatis* infection; and being human immunodeficiency virus (HIV) positive.[9–11] Another well-documented risk factor is immune suppression caused by chronic anti–organ rejection medication as seen in transplant recipient patients. Patients with these risk factors have been designated "high risk" for HPV-related disease development and are the most

commonly screened portion of the population for preinvasive disease. Recently, patients who have been diagnosed with HPV-related disease at a prior organ site (cervix, vagina, vulva, penis, scrotum, or oropharyngeal) are considered to be at greater risk that the general population and have been designated "at risk."[12–14] Although benign conditions such as hemorrhoids, fissures, and anal fistulas are often associated with HPV-related disease of the anus, they have not been determined to be causative.[15] Instead, their associated nonspecific symptoms such as bleeding per rectum, pain, fullness in the anal canal, or incomplete emptying simply overlap with SCCA.

Despite a previous emphasis on HPV being only sexually transmitted, it is now understood that HPV can be transmitted outside of sexual activity. Although transmission remains predominantly through sexual activity and is the most common sexually transmitted infection,[16] acquisition of the virus requires only direct contact with either the virus or viral-laden sloughed squamous cells. Other documented mechanisms of transmission include vertical (maternal–fetal)[17–19] and indirect through fomites.[20] Indirect transmission may be more important because the anus turns over its cellularity every 4 days,[21] one of the fastest in the body, and the body loses approximately 40,000 squamous cells every minute, or roughly 500 million each day, leaving substantial potential for patient exposure. Regardless of mode of transmission, the pathogenic changes leading to SCCA are directly related to the chronic infection with high-risk types, most commonly HPV-16 or HPV-18. Women with a history of cervical, vaginal, or vulvar cancer are three to five times more likely to develop anal cancer as opposed to stomach or colon cancer.[22] Until recently, this relationship was only explained by sexual activity; however, a recent study in women showed significant relationship between front-to-back wiping and HPV local transmission compared with blotting (dabbing) and back-to-front wiping.[23] Although this does not negate the notion of sexual transmission, it offers additional explanation for the large disparity in anal cancer between women and men for women who deny anal receptive intercourse.

Human Papillomavirus

Because HPV is the most common sexually transmitted disease in the United States and strongly associated with the development of anal carcinoma,[16] it is estimated that 75% of men and women of reproductive age have been exposed to HPV at some point in their lives. A well-cited epidemiological study by Giuliano et al[24] in 2008 revealed that in an international cohort of men, who were never received the HPV vaccine, had never practiced anoreceptive intercourse, were HIV-negative, and otherwise not recognized as high risk, the HPV positivity rate was 65.2%. High-risk HPV subtypes (16 and 18) are associated with approximately 85% to 90% of all SCCA case and develop through a precursor lesion termed *high-grade anal squamous cell intraepithelial lesions (HSIL)*. However, HSIL is a premalignant condition for which standard anal screening methods currently have not been universally recommended and have been limited to individuals considered high risk. Two international studies (ANCHOR [NCT02135419] and SPANC [NCT02007421]) are designed to address the question that treating HSIL prevents SCCA development in high-risk patients.

To confirm causation of HPV with SCCA development, a cohort of patients with metastatic SCC of the anal canal at the University of Texas MD Anderson Cancer Center (MDACC) revealed the presence of HPV, via detectable HPV DNA or expression of the protein p16, in 68 (95%) of 72 tumor samples analyzed.[25] Therefore, HPV appears to be found in the vast majority of SCCA regardless of the initial stage of presentation, yet some types are not completely associated with HPV, including basaloid or verrucous types.

The presence of HPV also has been reported to be a positive prognostic biomarker for patients with nonmetastatic SCC of the anal canal. In one study of patients with stages I to III anal cancer, HPV was detected in 120 (88%) of 137 tumors analyzed. In a multivariate analysis, p16 expression was determined to be associated with an improvement both in overall survival (OS) and disease-specific survival relative to patients with HPV-negative tumors.[26]

In 2006 and 2009, introduction of the prophylactic vaccines Gardasil and Cervarix, respectively, directed against primary infection by HPV demonstrated efficacy in reducing precancerous anogenital lesions caused by the high-risk subtypes HPV-16 and -18.[27–29] In late 2014, the U.S. Food and Drug Administration (FDA) approved the introduction of a nonavalent vaccine targeting nine HPV subtypes (6, 11, 16, 18, 31, 33, 45, 52, and 58).[30] A large, double-blind placebo-controlled study in MSM between 16 and 26 years of age demonstrated that use of the quadrivalent vaccine against HPV was both safe and well tolerated but also decreased the incidence HSIL.[29] These findings generated optimism that this preventive approach may decrease the incidence of this disease in the future. Originally approved for use in female adolescents, HPV vaccines have now received extended FDA approval as being "gender neutral" (given to both male and female patients) after their efficacy was shown in both genders, a now very promising primary prevention strategy for SCCA.[30]

Human Immunodeficiency Virus

Although a direct relationship between HIV and SCCA has not been clearly established, a strong correlation exists between HIV and HPV. Compared with

HIV-negative patients, HIV-positive patients are two to six times more likely to be diagnosed with HPV regardless of sexual practices and are also more likely to have a persistent infection.[31,32] HIV-positive men and women exposed to HPV are less likely to "clear" the virus and become HPV-negative.[32,33] For HIV-positive patients, the prevalence of SCCA is greater and presents at a younger age of onset than in HIV-negative patients.[34]

Chronic Immunosuppression

Solid organ transplantation has been associated with a 10-fold increased risk of developing SCCA and a 20-fold increased risk for vulvar and vaginal cancers.[35] A population-based cohort study conducted using the Danish National Patient Registry and the Danish Cancer Registry from 1978 to 2005 found that HIV infection, solid organ transplantation, hematologic malignancies, and a range of specific autoimmune diseases were strongly associated with increased risk of SCCA.[36]

Tobacco Use

Prior case-control studies have indicated that chronic tobacco use may result in a two- to fivefold increased likelihood of developing SCCA.[37] Moreover, tobacco smoking appears to be associated with SCCA recurrence and increased mortality; thus, smoking cessation should be encouraged when a diagnosis of SCCA is confirmed.[38]

PRESENTATION AND DIAGNOSIS

The mean age of diagnosis is approximately 62 years.[39] The most common presenting complaint is rectal bleeding. Other symptoms may include tenesmus, pain, local irritation, discharge, or a change in bowel habits as mentioned earlier. Clinically enlarged inguinal lymph nodes are present in 15% to 25% of patients at presentation.[40] Extreme and late patient presentations may include a fungating perianal mass or a verrucous mass.

A diagnostic evaluation should consist of a complete physical examination, including examination of the inguinal lymph nodes, a digital anorectal examination (DARE), and evaluation of the surrounding mucosa of the anus. Diagnostic studies should include proctosigmoidoscopy (rigid or flexible) or anoscopy (side-viewing or flat, on-end anoscope), chest radiography, and computed tomography (CT) of the chest, abdomen, and pelvis or magnetic resonance imaging (MRI) of the abdomen and pelvis to rule out distant disease. A transrectal or transvaginal ultrasound examination may add benefit in staging.[41–44] Histologic confirmation is required, with a tissue biopsy of the primary site with fine-needle aspiration of any palpable inguinal lymph nodes because this may impact the radiation fields. An HIV test should be considered in all patients, and a one-time test for hepatitis C infection may also be considered for patients born before the year 1965 given the disproportionately high risk of incidence of viral infection for patients in this age range.[45]

STAGING AND PROGNOSIS

The staging classification system for anal cancer was adopted by the American Joint Committee on Cancer (AJCC). The tumor (T) stage, unlike most GI malignancies, is not dependent on the degree of tumor tissue penetration but rather on the size of the primary tumor site. Tumors 2 cm or smaller are considered T1, tumors larger than 2 but 5 cm or smaller are considered T2, tumors larger than 5 cm are considered T3, and locally invasive tumors invading adjacent organs are considered T4. The eighth edition of the AJCC staging guidelines went into effect on January 1, 2018.[46] The T stage did not change, but the nodal (N) staging system changed based on the location of positive nodes. Nodal metastases in primary echelon drainage sites such as the inguinal, mesorectal, or internal iliac basins are considered N1a; nodal metastases in the external iliac basins are considered N1b; and lymph node metastases in both N1a and N1b locations are considered N1c.[46]

Both T and N stage have been significantly associated with response to chemoradiation and OS. Results from Radiation Therapy Oncology Group (RTOG) 8704/Eastern Cooperative Oncology Group (ECOG) 1289 showed patients with tumors 5 cm or larger were more likely to have a positive biopsy 6 weeks after completing chemoradiation (17%) compared with only 7% of patients with a tumor smaller than 5 cm.[47] The RTOG 8314 trial showed a significant difference in 3-year local control rates: 84% in patients with tumors smaller than 3 cm and 62% in patients with tumors 3 cm or larger.[48] In the EORTC phase 3 trial, tumor size was not prognostic for survival or local control, but positive lymph nodes at diagnosis was an independent poor prognostic factor for both local control and OS.[49] Subsequent analysis of the long-term results from RTOG 98-11 showed 5-year locoregional failure ranged from 17% for T2N0 disease to 60% for T4N+ disease. OS at 5 years ranged from 82% for patients with T2N0 disease to 42% for patients with T4N+ disease.[50] Patients with T1N0 tumors were not eligible for enrollment on RTOG 98-11, but small retrospective and population-based studies suggest the local control rates for T1N0 tumors range from 90% to 100%, and the 5-year OS ranges from 80% to 90%.[51,52]

HISTORY OF CHEMORADIATION: THE NIGRO REGIMEN

Before the work published by Nigro and colleagues in the 1970s, the preferred treatment for SCCA was radical surgery (APR) with a permanent colostomy. With this surgical approach alone, the local failure rates were unacceptably high. To improve local control rates, Nigro and colleagues gave chemoradiation to patients in a small pilot study in the preoperative setting. The unexpected result was a complete pathologic response in all three patients. This somewhat anecdotal finding led to the pivotal assertion that surgery may not be necessary for curative intent in the treatment of patients with SCCA.[53] The follow-up study published in 1981 by Dr. Nigro's group outlined the results of 19 further patients treated with a regimen consisting of 30 Gy delivered over 15 days. Radiation delivery consisted of a 15- × 15-cm field centered at the patient's midline with the low edge including the ischial tuberosities. 5-Fluorouracil (5-FU) was given 1000 mg/m^2/24 hours as a continuous infusion on days 1 to 4 of radiation and repeated one month later. Mitomycin C (MMC) was given as a 15 mg/m^2 intravenous bolus on day 1. Surgery occurred 4 to 6 weeks after completion of chemoradiation. Patients were examined preoperatively, and 15 of 19 had no apparent tumor; 12 of 19 had a pathological complete.[54] A subsequent publication of outcomes for a total of 28 patients treated with Nigro and colleagues' protocol reported no serious complications resulted from chemoradiation, though they did experience transient proctitis, leukopenia, and thrombocytopenia. Of the 28 patients, 22 remained tumor free and alive one to 8 years after treatment.[55]

The next series of investigations sought to establish the feasibility of treating SCCA with chemoradiation alone as well as to optimize the treatment regimen, including dose of chemotherapy agent, dose, and duration of radiotherapy. One such early report evaluated patients treated definitively with 30 to 45 Gy of radiation given with two cycles concurrent 5-FU and MMC. John and colleagues[56] reported an 86% complete response rate to this regimen, with all three local failures being successfully salvaged with surgery. The speculations of John et al were (1) the optimal dose of radiation would likely be 41.4 to 50 Gy; (2) radiation was best given continuously, rather than a split course, which may have radiobiological disadvantages; and (3) a second dose of MMC may decrease distant failure rates. Subsequent prospective trials sought to further clarify the added benefit of concurrent chemotherapy to radiation, the optimal concurrent chemotherapy agents to give with radiation, and the preferred dose and fractionation schedule for the radiation itself. Ongoing studies seek to tailor treatment to patients based on known prognostic factors such as T and N stage, escalating therapy for those with higher risk of recurrence and deescalating therapy for those with high cure rates to reduce toxicities.

RADIATION VERSUS CHEMORADIATION: THE ROLE OF MITOMYCIN C

ACT I Trial

To evaluate for a benefit for the addition of cytotoxic chemotherapy to radiation, the phase III Anal Cancer Trial (ACT I) randomized patients to radiation alone (45 Gy) versus continuous infusion 5-FU (1000 mg/m^2 on days 1–4 or 750 mg/m^2 on days 1–5) during the first and last weeks of radiation (45 Gy) with MMC (12 mg/m^2 on day 1).[57] After a median follow-up time of 42 months, the 3-year local failure rate was significantly reduced in the chemoradiation arm versus the radiation-alone arm (39% vs 61%; P <.0001), suggesting an oncologic benefit with multimodality therapy. Here, chemoradiation provided a 46% reduction in local recurrence compared with radiation alone. Notably, the 3-year mortality rate in the radiation-only arm was greater than that of the chemoradiation arm (39% vs 28%). Twenty patients (3%) required a palliative colostomy or anorectal excision because of treatment-related morbidities. Early morbidity was significant in the chemoradiation arm. Subsequently, dose reduction of MMC has been recommended if the patient is 70 years or older or if significant medical comorbidities are present.

EORTC Trial

A smaller study completed by the European Organization for Research and Treatment of Cancer (EORTC) explored the role of chemoradiation and its potential benefit in locoregional control (LRC) and colostomy-free interval.[49] A total of 110 patients were randomized to radiation (45 Gy) with or without continuous infusion 5-FU (750 mg/m^2 on days 1–5 and 29–33) and MMC (15 mg/m^2 on day 1).

Again, event-free survival was superior in the combined-modality arm (P = .03). The overall 5-year survival rate was 56% in this patient population. In contrast to the ACT I study, this clinical trial was limited to patients with more locally advanced anal cancer, specifically, T3 or T4 primary tumors or regional nodal positivity on initial imaging. Chemoradiation contributed 18% actuarial improvement in 5-year LRC and an increase in colostomy-free survival (CFS) (36%). Based on these studies, the phase III UKCCCR and EORTC

studies established combined chemoradiation as superior to radiation alone for LRC and CFS. Most medical oncologists in the United States use 5-FU and MMC as the preferred chemotherapy combination in this setting.

THE INTRODUCTION OF CISPLATIN

Despite the evident benefits of MMC in the treatment of patients with SCCA, potential treatment-related toxicities may include leukopenia, thrombocytopenia, and, rarely, hemolytic uremic syndrome and leukemia. Although a review of prior 5-FU/MMC clinical trials in SCCA suggests the potential for superior results to radiotherapy alone, these often come at the cost of treatment-related morbidity and mortality. Therefore, other agents that may reduce treatment-related toxicities without compromising efficacy would be preferable.

Mitomycin C Versus Cisplatin in Combination with 5-Fluorouracil as a Chemosensitizer (ACT II Trial)

The UK ACT II trial is the largest phase III trial conducted in SCC of the anal cancer and is the most direct analysis of 5-FU–MMC versus 5-FU–cisplatin with concurrent radiation therapy. The ACT II trial also evaluated whether maintenance chemotherapy after completion of chemoradiotherapy reduces recurrence-free survival (RFS).[58] Using a 2 × 2 factorial design, 940 patients with T1 to T4 node-negative and -positive disease were randomly assigned to either 5-FU–MMC or 5-FU–cisplatin administered concurrently with continuous radiotherapy of 50.4 Gy. The second randomization was to two courses of 5-FU–cisplatin (same schedule) consolidation chemotherapy or no further treatment. There was a greater incidence of acute grade 3 or 4 hematologic toxicity in the MMC arm (26% vs 16%; P <.001) but no statistical differences in grade 3 or 4 nonhematologic toxicities (Table 33–1).

Results after a 5-year median follow-up period demonstrated no statistically significant difference for the endpoint of 6-month CR rate for concurrent chemoradiation with 5-FU–MMC versus 5-FU–cisplatin (90.5% vs 89.6%, respectively) and no difference in either RFS or CFS, respectively (Table 33–2).

Although investigators failed to fulfill the primary endpoint of superiority for the cisplatin-based regimen, the results indicate that 5-FU–cisplatin is noninferior to 5-FU–MMC in achieving a CR but is associated with fewer significant hematologic toxicities. Maintenance 5-FU–cisplatin chemotherapy showed no added benefit for RFS or OS. Therefore, at this time, additional chemotherapy after definitive chemoradiation, even for patients with higher risk locally advanced SCCA, is not recommended.

A retrospective analysis in 197 patients with TxNxM0 SCC of the anal canal was completed at

MDACC.[59] Patients received weekly cisplatin (20 mg/m^2 intravenously) and 5-FU (300 mg/m^2/day for 120 consecutive hours weekly as a continuous infusion on days of radiation) for the duration of radiation therapy (55 Gy). The median follow-up period was 8.6 years. Complete responses after chemoradiation were observed in 185 patients (94%). The local recurrence rate was 11% with the use of 5-FU and cisplatin, and all patients with a local recurrence underwent salvage APR or diverting colostomies. Only 16 patients (8%) developed distant metastases. OS at 5 years was 86%. Grade 4 acute toxicities (diarrhea, dehydration, and skin ulceration) were infrequent. Therefore, the use of cisplatin and 5-FU with concurrent radiation is safe and effective in patients with locally advanced SCCA and may be an acceptable alternative to the traditional 5-FU–MMC regimen. Based on the finding from the ACT II trial and MDACC's institutional experience, 5-FU–cisplatin remains a preferred regimen because of its efficacy and decreased myelosuppression relative to 5-FU–MMC. This combination also allows for safer treatment of immunocompromised and older patients who otherwise might not tolerate myelosuppressive combinations.

Neoadjuvant (Induction) Chemotherapy

Another common question for the management of locally advanced anal cancer regards the role of systemic induction treatment before chemoradiation decrease the risk of distant disease development and provide an improvement in OS.

Intergroup/ACCORD 03 Trial

The phase III Intergroup/ACCORD 03 trial created a 2 × 2 factorial design to compare standard-dose (45 Gy/25 fractions, boost of 15 Gy) versus high-dose radiation therapy (boost of 20–25 Gy) and the potential benefits of induction chemotherapy with 5-FU (800 mg/m^2 on days 1–4) and cisplatin (80 mg/m^2 on day 1) for two cycles in locally advanced SCC of the anal canal.[60] Patients were required to have greater than 4-cm primary tumor or node-positive disease. A total of 306 patients were allocated to one of four treatment arms: (1) induction with standard-dose radiation therapy, (2) induction with high-dose radiation therapy, (3) control arm of 5-FU–cisplatin plus standard radiation therapy, and (4) control arm of 5-FU–cisplatin plus high-dose radiation therapy. The results were compared in terms of CFS. After a median follow-up period of 43 months, no statistically significant difference in CFS was noted for the induction arm or with the higher dose radiation therapy arm versus the control arm. Overall, no statistical differences were noted across all arms for local control, CFS, event-free survival, or OS. Therefore, induction chemotherapy does not appear to benefit patients with localized anal cancer intended to be treated with chemoradiation.

RTOG 98-11 Trial

The RTOG 98-11 trial was a large phase III multi-institutional randomized trial for locally advanced SCC of the anal canal[4] that randomized 682 patients with T2 to T4 tumors and any nodal status to receive 5-FU–MMC and concurrent radiation (control arm) or induction 5-FU–cisplatin followed by concurrent 5-FU–cisplatin and radiation. It is important to note the treatment imbalance in the two arms such that whereas patients randomized to the experimental group received induction chemotherapy, those randomized to the control arm did not. All patients received 45 to 50 Gy of radiation, with an additional 10 to 14 Gy in 2-Gy fractions given to patients with residual evidence of disease, tumors larger than 5 cm, or tumor invasion of adjacent organs. From a recent long-term update, improved outcomes were noted in the group randomized to 5-FU–MMC and concurrent radiation. Five-year DFS was significantly better in this group (68% vs 58%) compared with those receiving induction 5-FU–cisplatin followed by concurrent 5-FU–cisplatin and radiation, as was 5-year OS (78% vs 71%). Trends in CFS, LRC, and colostomy failure all favored the 5-FU–MMC arm as well, although none reached statistical significance. Grade 3 or 4 hematologic toxicity was observed more

frequently in patients randomized to the 5-FU–MMC arm (62% vs 42%; $P < .0001$).

Despite the initial appearance that 5-FU–MMC treatment is superior for patients with nonmetastatic SCCA, these findings must be interpreted with caution. This study has since been critiqued for the inequality of the two treatment schedules, making a direct comparison of MMC and cisplatin, in combination with 5-FU, difficult because the confounding factor of induction chemotherapy in the investigational arm.[58] Additionally, administration of induction chemotherapy delayed the time to initiation of curative chemoradiation and thereby prolonged the overall treatment time, a metric that, when extended, has been associated with worse clinical outcomes in clinical trials for SCCA. Nonetheless, based on these findings, induction chemotherapy in patients with early-stage SCC of the anal canal is not routinely administered at MDACC.

RADIATION TECHNIQUE, DOSE, AND FRACTIONATION

Evolution of Radiation Technique

The preferred radiation technique has evolved since the 1970s with advances in technology related to imaging, radiation treatment planning, and radiotherapy delivery. Early radiation therapy was delivered using two simple fields in the anteroposterior and posteroanterior directions on a 6-MeV linear accelerator. The intended target included the anal canal as well as elective nodal coverage of the internal iliac, external iliac, perirectal, presacral, and obturator lymph nodes. For patients who had clinical inguinal nodal involvement, the field was extended laterally to cover the groins, and the surface dose was boosted with supplemental electron beams.[56] Limitations to this technique included high rates of G3 and G4 toxicities, necessitating a treatment break in up to 50% of patients given the volumes of normal bone marrow, bowel, and skin exposed.[61] As radiation techniques moved from the two-dimensional (2D) to the three-dimensional era, radiation to doses of 50 to 54 Gy in 1.8-Gy fractions were able to be given continuously without a planned break and without unplanned breaks because of toxicity. Because of the more conformal dose distribution to the target volume better avoids unnecessary dose to nearby organs and tissues. G3 toxicities for bone marrow, bowel, and skin were shown to be much improved in a phase II study from McGill University[62] and were used in RTOG 9811, UK ACT II, and other contemporary trials.

The next technological improvement in radiation delivery was more conformal technology called intensity-modulated radiation therapy (IMRT). It is a technique that uses multiple radiation beams from various angles in which the intensity of each beam is adapted to match the contours of the radiation target and carve unnecessary dose out of nearby organs. This technique allows for "dose painting," also called a simultaneous integrated boost technique, which allows different targets within the field to receive different doses of radiation per day. IMRT was prospectively testing in a phase 2 study, RTOG 0529. Results showed IMRT was able to significantly reduce acute G2+ hematologic and G3+ dermatologic and GI toxicities compared with historic controls from RTOG 9811.[63] The RTOG 0529 trial established IMRT as the standard of care and it remains today.[64] Current investigations are ongoing into different radiation modalities such as proton beam therapy to see if unnecessary dose to normal tissues in the pelvis can be further reduced.[65]

Radiation Dose and Fractionation

The initial dose and fractionation used in the Nigro protocol was 30 Gy in 15 fractions delivered over 3 weeks.[53] Subsequent studies evaluated doses from 45 to 50.4 Gy delivered over 4 to 5 weeks and showed local failure rates of about 25%.[47] RTOG 92-08 sought to decrease local failure by escalating the radiation dose to 59.6 Gy delivered split course over 8.5 weeks with a planned 2-week rest period to allow for recovery of dermal toxicity. Dose escalation in this study did not show improvement in local control and actually had a higher colostomy rate at 1 and 2 years posttreatment (23% vs 6% and 30% vs 7%) compared with RTOG 87-04, which gave 45 to 50.4 Gy without a planned break.[47] The conclusion of that study was that the split course schedule may have eroded any potential benefit of dose escalation, and the 2-week break may have led to a decrement in tumor control as evidenced by the higher need for colostomy.[66] The RTOG 87-04 and RTOG 92-08 studies both used 2D techniques, which limited the ability to conform the dose away from normal pelvic organs, so the side effects of radiation precluded dose escalation in a continuous fashion without a treatment break. A French randomized phase III study, ACCORD 3, had a 2 × 2 factorial design in which one of the randomizations compared standard-dose boost with high-dose boost given 3 weeks after completion of 45 Gy in 25 fractions. The boost was given with EBRT or brachytherapy with 192-Iridium. There was also no benefit to the higher boost dose in this study, but it should be noted that the schedule for ACCORD 3 was essentially split course with a 3-week break between the end of the initial 45 Gy and the beginning of the boost. It should also be noted that the total dose in the "standard-dose" arm was 60 Gy, and the total dose in the "high-dose" arm was 65 to 70 Gy.[67] The doses delivered on RTOG 0529, which used IMRT technique with a continuous radiation

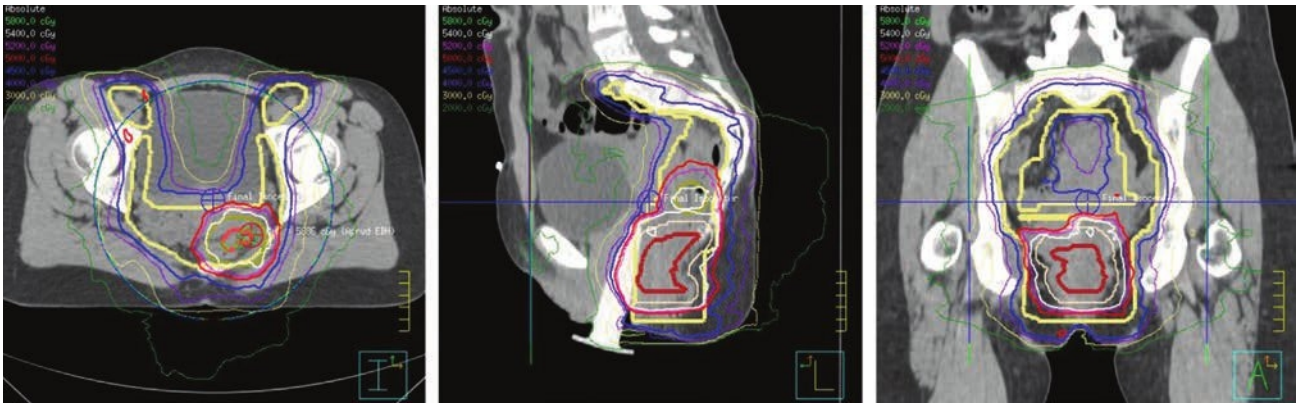

FIGURE 33–4 Representative axial (A), sagittal (B), and coronal (C) slices from a definitive chemoradiation plan for a patient with T2N1a squamous cell carcinoma of the anal canal; 54 Gy in 27 fractions was prescribed to the anal tumor plus margin; 50 Gy in 27 fractions was prescribed to a 1.5-cm presacral lymph node plus margin; and 45 Gy in 27 fractions was prescribed to the elective nodal volume. Note that a vaginal dilator was inserted for planning and daily treatment to displace the anterior vaginal wall and urethra away from the high-dose region.

schedule, depended somewhat on tumor size. T2N0 tumors received a total of 50.4 Gy to the anal tumor with 42 Gy to the elective pelvic lymph nodes in 28 fractions. T3 and T4 tumors received 54 Gy in 30 fractions, and the elective pelvic and inguinal lymph nodes received 45 Gy.[63] Along similar lines, at the MDACC, the current standard uses a moderate dose escalation for T3 and T4 tumors because the analysis of RTOG 98-11 data showed these patients are at highest risk for local recurrence.[50] In total, 50 Gy in 25 fractions for T1 tumors, 54 Gy in 27 fractions for T2 tumors, and 58 Gy in 29 fractions for T3 and T4 tumors are delivered. The doses to the elective pelvic and inguinal nodes are 43 Gy, 45 Gy, and 47 Gy, respectively, in those fractionations. Grossly involved lymph nodes are similarly dosed based on size, with nodes 2 cm or smaller receiving 50 Gy, nodes 2 or larger but 5 cm or smaller receiving 54 Gy, and nodes larger than 5 cm receiving 58 Gy (Fig. 33–4).

With this tailored approach, local recurrence rates have been only 11% despite a disproportionately advanced stage patient population. Furthermore, retrospective multivariate analysis did not show T stage is a poor prognostic factor, potentially because patients with advanced T-stage tumors are treated appropriately more aggressively.[59]

RECURRENT DISEASE

APR is the only effective, definitive treatment option for localized recurrent or residual primary disease after chemoradiation for SCC of the anal canal. Although an often considered aggressive approach to persistence or recurrent disease, APR provides cure in up to 70% of patients.[68–70] In these patients, a typical APR, posterior exenteration or total pelvic exenteration, yields a massive tissue defect that requires reconstruction, and although there are options for tissue rearrangement, a vertical rectus abdominus myocutaneous flap often provides the best reconstruction. There is no role for definitive reirradiation for an in-field recurrence, but neoadjuvant chemoradiation (39 Gy in 26 fractions twice daily with chemotherapy) may be used in cases when there are concerns about the radial margin. When available, consideration of intraoperative radiation may provide an additional option for R1 (tumor 2 mm from margin) disease but has no role if only an R2 (gross tumor at margin) resection is achievable.

The management of patients with nodal recurrences should be individualized based on the extent of disease, prior radiation delivered to the area of recurrence, and performance status of the patient. When patients have been referred to the MDACC with nodal recurrence outside of or at the margin of a prior radiation field, salvage chemoradiation has been effective provided that a full dose of reirradiation is possible. For in-field nodal recurrences, a preoperative chemoradiation to 39 Gy in 26 fractions twice daily followed by surgical resection is typically considered.

METASTATIC ANAL CARCINOMA

Chemotherapy for Metastatic Anal Cancer

Although the majority of patients with SCC of the anal canal will be cured with chemoradiation, a fraction of patients will develop metastatic disease. Median survival from the time of metastatic disease has been estimated between 18 to 24 months.[71] The liver and lymph nodes are among the most common sites for distant

organ involvement, with bone metastases occurring in fewer than 10% of cases.[71] Because of the rarity of metastatic SCCA, a universally accepted treatment approach for the management had been historically based on small case series.[72] However, results from recently completed prospective studies have generated new treatment options for these patients (Table 33–3).

A randomized phase II trial conducted through the National Cancer Institute (NCI)–sponsored International Rare Cancer Initiative (collaboration compared doublet chemotherapy with cisplatin (60 mg/m^2)–5-FU (1000 mg/m^2/day as a continuous infusion for days 1–4) every 21 days or carboplatin (AUC 5)–paclitaxel (80 mg/m^2 on days 1, 8, and 15) every 28 days in patients with previously untreated, unresectable, locally recurrent or metastatic SCCA.[73] In this study (InterAACT) of 91 patients, the primary objective for detecting a 10% difference in response rate was not satisfied. Here, radiographic responses were observed in 57% patients receiving cisplatin–5-FU and in 59% patients receiving carboplatin–paclitaxel. A nonsignificant trend toward improved progression-free survival (PFS) was observed in patients treated with carboplatin–paclitaxel (8.1 months vs 5.7 months; $P = .38$), with an improvement in OS (20 months vs 12 months; $P = .01$). Whereas cisplatin–5-FU had previously been listed as the lone systemic treatment for patients with metastatic SCCA, this study was instrumental in establishing the role of carboplatin–paclitaxel in this setting.

In the InterAACT trial, rates of grade 3 or higher treatment-related adverse events exceeded 70% in both arms, although rates of serious grade 3 or higher adverse events were more common in patients receiving 5-FU–cisplatin every 21 days (62% vs 36%; $P = .02$). Therefore, oncologists should be mindful of anticipated toxicities, especially myelosuppression, nausea and vomiting, and fatigue, when considering these regimens. To mitigate the anticipated treatment-related complications, at our institution, we administer cisplatin (40 mg/m^2) and 5-FU (2400 mg/m^2/day as a continuous infusion over 46 hours) every 14 days. Rates of grade 3 or higher adverse events with this dosing have been reported in single-institution retrospective series to be lower than those noted with the regimens used in the InterAACT trial.[74] This biweekly schedule for cisplatin–5-FU offers a tolerable and effective approach for the treatment of patients with metastatic SCCA.

Recently, the single-arm HPV-EPITOPES-02 trial of docetaxel, cisplatin, and 5-FU for patients with treatment-naïve metastatic anal cancer demonstrated impressive survival outcomes.[75] Here, the overall response rate was reported to be 86% (57 of 66 patients), with complete radiographic responses noted in 44% cases. Median PFS for this regimen was 11 months. As expected for concurrent use of three cytotoxic agents, rates of grade 3 or higher adverse events exceeded 70% but were less common when modified doses were administered every 2 weeks. This regimen appears very effective in the treatment of patients with metastatic SCCA yet should be reserved for patients with a robust performance status who can withstand the likelihood of more pronounced treatment-related toxicity.

Immunotherapy for Metastatic Anal Cancer

Given the paucity of available treatment options for patients with incurable SCCA, the use of immunotherapy is an attractive treatment strategy for this virally driven malignancy. Here, immune checkpoint blockade therapies have been approved for other HPV-associated malignancies, given clinical activity noted in SCC of the head and neck (with or without concomitant chemotherapy)[76–78] and of the cervix.[79]

In the NCI9673 phase II trial of patients with pretreated, unresectable SCCA, radiographic response to the anti–PD-1 (programmed cell death protein 1) antibody nivolumab was observed in 9 of 37 cases (overall response rate, 24%).[80] Including patients with stable disease, the disease control rate with nivolumab was

TABLE 33–3 Clinical Outcomes of Systemic Therapies in Recent Prospective Trials for Metastatic Anal Cancer

Regimen	Trial Name	Line of Treatment	Patients (*n*)	Response Rate (%)	Median PFS (months)	Median OS (months)
Carboplatin–paclitaxel	InterAACT	Frontline	45	59	8.1	20
Cisplatin–5-fluorouracil	InterAACT	Frontline	46	57	5.7	12
Docetaxel–cisplatin/5-fluorouracil	HPV-EPITOPES-02	Frontline	69	86	11	NR
Nivolumab	NCI9673	Refractory	37	24	4.1	12
Pembrolizumab	KEYNOTE-158	Refractory	112	11	2.0	12

NR, not reached; OS, overall survival; PFS, progression-free survival.

72%. Median PFS was 4 months. Nivolumab was well tolerated as a monotherapy in this study. Similarly, the KEYNOTE-158 trial reported an overall response rate of 11% and median PFS of 2 months with single-agent anti–PD-1 antibody pembrolizumab for 112 patients with pretreated metastatic anal cancer.[81] Here, patients who demonstrated a response to pembrolizumab were able to achieve sustained clinical benefit, with PFS exceeding 24 months in more than 90% of this subgroup. Based on these collective findings, nivolumab and pembrolizumab are recommended treatment options for patients with treatment-refractory metastatic SCCA.

Although anti–PD-1 therapies benefit a fraction of patients with incurable SCCA, establishment of a biomarker(s) to identify the subpopulation that derives benefit with this approach is needed. Microsatellite instability and high tumor burden are uncharacteristic of this disease and may not be drivers for response to immune checkpoint blockade.[82] Analysis of pretreatment biopsies from the NCI9673 trial found that higher baseline expression of programmed cell death ligand 1 (PD-L1) on tumor cells and increased numbers of activated cytotoxic T-cells within the tumor microenvironment were both associated with an increased likelihood for response to nivolumab. Coexpression of immune biomarkers LAG-3 and TIM-3 with PD-1 on activated cytotoxic T-cells were also more common for tumors of responding patients. Early results then suggest that immunologically active tumors at baseline may predispose patients with metastatic SCCA to increased benefit of these immunotherapy agents.

Some patients presenting with metastatic disease do achieve excellent long-term survival. For example, a subset of patients at the MDACC with oligometastatic SCCA underwent definitive therapy to limited site(s) of distant metastases, either with surgical resection or with (chemo)radiation. For these patients, OS was prolonged (53 months vs 17 months; $P < .001$), which was likely a reflection of a lower total burden of disease and favorable underlying tumor biology. Consideration of curative-intent surgical resection and/or definitive chemoradiation of oligometastatic SCCA should be considered on an individualized basis through multidisciplinary discussion, most often after demonstration of an upfront response to systemic therapy.

SURVEILLANCE

Although surveillance guidelines are always in flux, current guidelines suggest patients treated with chemoradiation therapy (with curative intent) should be initially evaluated by 3 months upon completion of therapy with an inguinal lymph node examination, DARE, and anoscopy if possible. Review of outcomes from ACT II revealed that 29% of patients without CR by week 11 after completion of definitive chemoradiation did achieve a CR by week 26.[83] Based on these findings, in the presence of improving symptoms or continued tumor regression on evaluation, at the MDACC, patients are allowed 26 weeks to achieve a CR before referral for APR. If clinical progression becomes apparent before this point, then patients are sent promptly for salvage evaluation. After that, routine anal and groin examinations every 3 to 6 months by either the medical, radiation, or surgical oncology providers for 2 years. After 2 years, routine examinations may be performed every 6 months for the remaining 3 years.[84] Biopsy of any scar or questionable residual or recurrent disease before 6 months after chemoradiation is not suggested unless there is clear evidence of residual disease or progression is suspected. If clinical CR is achieved but the posttreatment scar is abnormal yet not suggestive of recurrence, it is important that the surgeon following the patient perform the routine anal examinations to assess for subtle changes and propose biopsy as necessary. Physical examination must include a DARE and assessment for any palpable inguinal lymph nodes. Vaginal dilators may be used three times a week if needed to prevent vaginal strictures. The critical time for the prevention of vaginal stenosis is 3 to 6 months after completion of chemoradiation therapy. Vaginal hormonal creams and suppositories are also useful for treatment of vaginal dryness and dyspareunia. Proctosigmoidoscopy should be performed biannually after a CR for 2 years. Chest radiography and CT of the chest, abdomen, and pelvis or MRI of the abdomen and pelvis should be completed annually for 2 years. Anal cytology collection via a Dacron anal swab (formerly anal pap smears) should continue to be performed annually.

ADENOCARCINOMA OF THE ANAL CANAL

Adenocarcinomas of the anal canal occur less frequently than SCCs and are not to be confused with extramammary Paget disease of the anus.[39] Nonetheless, most of the reports overestimate the incidence of adenocarcinoma of the anal canal because they do not exclude contamination by the more common distal rectal cancer. Its true incidence within all anal cancers is likely less than 10%. The most appropriate management remains to be defined, with no large prospective studies completed to date given its exquisite rarity. The most striking difference between anal adenocarcinoma and SCCA is the high distant metastasis rate in anal adenocarcinoma, which tends to undermine the impact of local tumor control. Retrospective analysis from the MDACC experience with anal adenocarcinoma has suggested a benefit of neoadjuvant chemoradiation

followed by APR (in patients without known metastases) with the consideration of adjuvant chemotherapy analogous to the treatment of rectal cancer.[85]

CONCLUSIONS

Carcinoma of the anus is an uncommon GI malignancy with a rising incidence in the United States despite the introduction of a preventive HPV vaccine. Chemoradiation is provided with curative intent for patients with nonmetastatic disease. Recurrence or persistent disease after curative-intent chemoradiation therapy results in the need for an APR. Hence, it is recommended that all patients diagnosed be initially evaluated at a tertiary cancer center or the equivalent given the rarity of the disease and the potential for permanent loss of sphincter preservation. It is highly recommended that a multidisciplinary team discussion with significant expertise for the most appropriate treatment in this rare malignancy is organized and consulted for management of patients with these diagnoses. Both cytotoxic chemotherapy and immune checkpoint blockade therapies have demonstrated efficacy for patients with metastatic disease. It is expected that the role of immunotherapy will be expanded further in the management of patients with anal cancer in the coming years.

MD ANDERSON PRACTICE TIPS

- Weekly cisplatin and 5-FU is a well-tolerated, clinically efficacious chemosensitizer associated with moderate toxicity for patients with locally advanced anal cancer undergoing chemoradiation.
- For female patients, a vaginal dilator should be used during daily radiation treatments to displace the anterior vaginal wall and urethra from the high-dose region and reduce genitourinary toxicities from treatment. For male patients, the scrotum should be elevated away from the perineum during treatment to reduce skin and testicular toxicity. For both men and women, patients should be treated with a full bladder to displace small bowel from the pelvis and reduce the risk of GI toxicity.
- In the absence of clinical or radiographic progression, patients with locoregional anal cancer can be followed for resolution of their disease up to 26 weeks after completion of chemoradiation. Salvage surgery with APR is reserved for patients with persistent or locally recurrent disease after definitive therapy.
- Patients presenting with oligometastatic anal cancer can be treated successfully with curative intent through multidisciplinary management of the primary tumor and metastatic lesion(s).
- Patients with metastatic anal cancer with/without coexisting altered immunity (eg, HIV/AIDS, concurrent immunosuppressive medications for prior organ transplantation or autoimmune disorder) can safely be treated with a modified, every-14-day regimen of cisplatin–5-FU with a low likelihood for chemotherapy-related myelosuppression.
- At present, immune checkpoint blockade therapies can safely be administered without consideration of tumor mutation burden or PD-L1 status for patients with treatment-refractory metastatic anal cancer, although translational studies seek to characterize biomarkers associated with response to immunotherapy.

KEY CONCEPTS

- Gastroenteropancreatic neuroendocrine tumors (GEP-NETs) are increasing in incidence, but delay in diagnosis is common. Patients may present with specific symptoms related to a functional tumor or vague gastrointestinal symptoms, emphasizing the importance of maintaining a high index of suspicion for this disease.
- The majority of GEP-NETs arise sporadically. Multiple endocrine neoplasia type 1 is the most common inherited syndrome in which nonfunctional pancreatic neuroendocrine tumors (PNETs) predominate.
- ^{68}Ga tetraazacyclododecanetetraacetic acid-DPhe1-Tyr3-octreotate (^{68}Ga-DOTATATE) has excellent sensitivity and specificity for GEP-NETs. It is used to detect the location of unknown primary tumors and to assess for distant disease. It is not used for routine surveillance.
- Surgical resection is the standard of care for localized GEP-NETs. In advanced disease, surgery may be appropriate when R0 resection can be achieved, or cytoreduction is performed for palliation of symptoms.
- In cases in which hepatic metastases are unresectable, hepatic arterial embolotherapies may be used. Peptide receptor radionuclide therapy is efficacious for hepatic and extrahepatic metastases.
- Systemic therapy for advanced extrapancreatic NETs includes somatostatin analogues and the targeted therapy everolimus. In PNETs, FAS (5-fluorouracil, doxorubicin, and streptozocin), capecitabine and temozolomide, and sunitinib are additional options.

Neuroendocrine tumors (NETs) originate from enterochromaffin cells of the diffuse endocrine system. A diverse set of tumors, they most commonly arise from the gastrointestinal (GI) tract, pancreas, lungs, and bronchi. Less common sites include the thyroid, parathyroid, pituitary gland, adrenal glands, and thymus. This chapter focuses on the low- and intermediate-grade gastroenteropancreatic NETs (GEP-NETs) and lung NETs, leaving small cell carcinomas, medullary thyroid cancer, neuroblastoma, and Merkel cell carcinomas (all technically neuroendocrine neoplasms) to other chapters in this text.

NETs may secrete peptides and neuroamines that cause specific clinical symptoms, although this is not universally present even among tumors originating from the same anatomic site. Localized disease is treated surgically for curative intent. Locoregional or metastatic disease not amenable to surgical resection can be managed with somatostatin analogues (SSAs), peptide receptor radionuclide therapy (PRRT), liver-directed therapy, cytotoxic chemotherapy, or targeted therapies. This chapter discusses current diagnostic and management strategies for lung and GEP-NETs.

EPIDEMIOLOGY AND RISK ASSESSMENT

The Surveillance Epidemiology End Results (SEER) database has catalogued a 6.4-fold increase in the incidence of NETs from 1973 to 2012. This increase was consistent across anatomic site, grade, and stage. Globally, NETs remain relatively rare with an age-adjusted incidence of 6.98 per 100,000 individuals.[1] The disease is slightly more common in women (52.7%) and those 65 years old or older (25.3 per 100,000 persons). Among GEP-NETs, the most common site of origin is the small intestine followed by the rectum and pancreas.[1]

The cause of the increased incidence is unknown but often attributed to greater disease awareness and improved diagnostic capabilities. Common behavioral risk factors such as smoking, obesity, and excessive alcohol use do not appear to play a role in the development of these tumors.[2] Genetic predisposition accounts for approximately 20% of GEP-NETs[3] and is discussed later.

PROGNOSIS

Prognosis varies by stage, primary site, and grade. Considering the 64,971 patients included in the SEER database between 1973 and 2012, median overall survival (OS) ranged from more than 30 years in patients with localized NETs to 10 years in those with regional disease and 1 year in those with distant disease. Examined by grade, low- (G1) and intermediate- (G2) grade NET had median OSs of 16 and 8 years, respectively. High-grade neuroendocrine neoplasms (SEER G3 and G4, corresponding to World Health Organization grade 3 neuroendocrine carcinomas [NECs] in modern nomenclature) had significantly worse survival times, with a median of only 10 months.

Among GEP-NETs, the prognosis is most favorable for appendiceal (>30-year median OS) and rectal NETs (24.6 years) and worst for pancreatic NETs (PNETs; 3.6 years). Survival patterns vary when stage is considered with primary site (Table 34–1). In localized disease, small intestine NETs have an OS of approximately 14 years, and localized appendiceal NETs fare even better with a median OS of more than 30 years. In patients with metastatic disease, small intestine NETs fare best with a median OS of 8.6 years. Patients with metastatic colon NETs have a median OS of only 14 months.[1]

TABLE 34–1 Median Survival of Distant Stage G1-G2 Neuroendocrine Tumors[1]

Organ Site	Median Survival (months)
Appendix	NA
Cecum	98
Colon	14
Lung	24
Pancreas	60
Rectum	33
Small intestine	103
Stomach	29

Data from analysis of SEER registry, 2000 to 2012.

PATHOGENESIS, MOLECULAR CLASSIFICATION, AND GENETIC PREDISPOSITION

Innovation in the field of molecular biology has expanded our knowledge of the drivers of NET pathogenesis. In PNETs, *MEN1*, *DAXX*, and *ATRX* are frequently mutated. *MEN1* is a tumor suppressor gene that predisposes to multiple endocrine neoplasia type 1 (MEN1) when mutated either sporadically or in the germline. This mutation causes dysregulation of transcription and cell cycle control. Loss of heterozygosity at this locus on chromosome 11q13 is associated with the development of duodenal, gastric, and pancreatic NETs.[4,5] In 2011 Jiao et al. performed exome sequencing on 58 sporadic, resected PNETs. These experiments revealed *MEN1* mutations in 44% of tumors. DAXX and ATRX, two components of a histone chaperone complex important in chromatin remodeling,[6] were also frequently mutated (43%), though in a mutually exclusive fashion. *DAXX/ATRX* mutations drive the alternative lengthening of telomeres (ALT) phenotype,[7,8] which contributes to a neoplastic cell's immortality in a telomerase-independent fashion.[9] Somatic mutations in genes in the mammalian target of rapamycin (mTOR) pathway are found in approximately 15% of PNETs,[10] and loss of heterozygosity of *PHLDA3* (a regulator of the mTOR pathway) at chromosome 1q31 has been found in approximately 70% of studied PNETs.[11] The mutation status of *MEN1*, *DAXX/ATRX*, and the mTOR pathway in PNETs have an indeterminate impact on prognosis and no clear relationship with targeted therapy benefit.[8,10] Thus far, tumor mutational analysis has yet to demonstrate benefit in the selection of targeted agents.[12]

Fewer pathologic genetic alterations have been found in small intestine NETs. Hemizygous loss of chromosome 18 and arm-level gains of chromosomes 4, 5, 14, and 20 are relatively frequent genomic events.[13–15] More recent studies have shown that alterations of the gene *CDKN1B* occur in 7% to 10% of small intestine NETs. This gene is a haploinsufficient tumor suppressor and plays a role in cell cycle progression.[14–17] Clinical trials are ongoing to investigate the safety and efficacy of CDK inhibitors in patients with small intestine NETs (clinical trials.gov; NCT03891784).

MEN1 is the most common inherited cancer syndrome in NETs. This autosomal dominant disorder features the development of PNETs (80%–100%), multigland hyperparathyroidism (95%–100%), and pituitary adenomas (54%–65%). Hereditary PNETs often behave less aggressively than sporadic tumors and are frequently small and multifocal. The majority of MEN1-related PNETs are nonfunctional, although symptomatic gastrinomas are found in 54% and

insulinomas in 18% of patients. Other familial syndromes associated with NETs are neurofibromatosis type I (NF1), tuberous sclerosis, Cowden syndrome, and von Hippel-Lindau syndrome, though these are far less common than MEN1.[18]

PATHOLOGIC CLASSIFICATION

Neuroendocrine neoplasms are categorized as either well- or poorly-differentiated based on the extent to which the neoplastic cells resemble their non-neoplastic counterparts. Well-differentiated NETs are uniform, with characteristic "organoid" arrangements of cells in nesting, trabecular, or gyriform patterns. These cells tend to produce large amounts of neurosecretory granules, which can be detected by immunohistochemical (IHC) staining for common markers such as chromogranin A (CgA) and synaptophysin (Table 34–2). In cases in which the location of the primary NET is unknown, IHC can be used on biopsied metastases to offer some insight into the site of origin.[19,20] Poorly-differentiated NEC have a more sheetlike or diffuse architecture, irregular nuclei, and less cytoplasmic granularity and can take on small cell or large cell morphology in many cases. Expression of common neuroendocrine immunomarkers is often more limited in poorly-differentiated NEC, and thus IHC may be less useful during the diagnostic workup.[21] In cases in which the location of the primary tumor is unknown, IHC can be used on biopsied metastases to elucidate the site of origin.[19,20] Figure 34–1 compares the histologic appearance of a well-differentiated NET versus poorly-differentiated NEC.

Neuroendocrine neoplasms are also described by their grade, which includes three categories (G1–G3) based on proliferation rate. Poorly-differentiated NEC is uniformly grade 3. Grade can be determined either by calculating the mitotic rate (mitoses per 10 high-power fields) or by an IHC method that reports the percentage of neoplastic cells that stain for the proliferation antigen Ki-67. Currently, it is most common for pathologists to define grade via Ki-67. Low-grade (G1) GEP-NETs are defined by a Ki-67 index of 2% or less, intermediate grade (G2) 3% to 20%, and high grade (G3) greater than 20%.[21,22] Regardless of grade, the reproducibility of this test on either biopsy or surgical specimens is greater than 90%.[23]

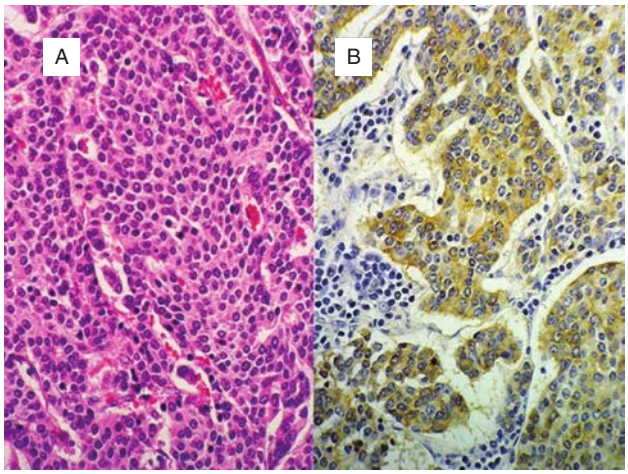

FIGURE 34–1 Histologic appearance of neuroendocrine tumors (NETs). Microscopic appearance of a low-grade NET. A. Standard microscopy showing few mitoses, no necrosis, and a large number of tumor vessels *(arrows)*. B. Immunohistochemical staining for chromogranin A (*brown-colored cells*).

TABLE 34–2 Immunohistochemical Markers of Neuroendocrine Tumors[19]

Marker	Significance
Synaptophysin	Presynaptic vesicle membrane glycoprotein, present on normal and neoplastic neuroendocrine cells
Chromogranin A	Universal marker for neuroendocrine tissue
Cytokeratin(s)	Lack of cytokeratin expression suggests the tumor is either an anaplastic neoplasm or may not be a carcinoma
CDX2 (caudal type homeobox 2)	Transcription factor expressed by epithelial cells of the bowel distal to the stomach; expression is highly sensitive for jejunoileal or appendiceal NET origin
TTF-1 (thyroid transcription factor-1)	Transcription factor critical in lung, thyroid, and brain development; expressed on type II pneumocytes; highly specific marker for lung NET
PAX8 (paired box gene 8)	Expressed in islets of Langerhans and thus useful for identification of PNET
Islet1	Expressed in mesenchymal cells of the dorsal pancreatic bud, in islet cells, chromaffin cells, and in some CNS tissue; positive staining in PNETs and rectal and duodenal NETs

CNS, central nervous system; NET, neuroendocrine tumor; PNET, pancreatic neuroendocrine tumor.

In general, clinical behavior and management are dictated by cellular differentiation and grade. Well-differentiated tumors are typically low or intermediate grade and behave in a more indolent manner. GEP-NETs in this category are typically slower to metastasize, and even in advanced stages patients can live for many years. High-grade tumors, often termed NECs, behave aggressively with an associated poor prognosis.[21,24] Recently, a subset of GEP-NETs with a well-differentiated cellular appearance but high proliferation rate were described. Although series are small, these well-differentiated tumors seem to have a better prognosis compared with poorly-differentiated NEC. In one series of 31 GEP-NETs, median disease-specific survival (DSS) was 55 months, whereas a comparison group of poorly-differentiated G3 tumors demonstrated a DSS of 11 months.[25]

Neuroendocrine neoplasms arising in the lung adhere to different classification and nomenclature standards than those of the GI tract. Whereas typical carcinoids approximate grade 1 GEP-NET and are defined by less than 1 mitosis/2 mm^2 and the absence of necrosis, atypical carcinoids approximate grade 2 GEP-NET and are defined by 2 to 10 mitoses/2 mm^2 or the presence of necrosis. Small cell lung cancer and large cell lung cancer, which are classified morphologically, are equivalent to poorly-differentiated G3 NEC, but well-differentiated G3 NET currently has no analogous entity.[22]

CLINICAL PRESENTATION, DIAGNOSTIC WORKUP, AND CLINICAL STAGING

NETs are best known for their hormonal syndromes, but the pathognomonic triad of diarrhea, wheezing, and flushing is far from universal. More commonly, patients are asymptomatic or develop vague GI symptoms that can be misinterpreted for years before a diagnosis of GEP-NET is confirmed.[26] Timely diagnosis and treatment of GEP-NETs requires a high index of suspicion and referral to a high-volume center with specialized multidisciplinary NET teams.

Laboratory Tests and Biomarkers

Biochemical testing is used in some centers to monitor response to therapy, disease progression, and recurrence. For extrapancreatic GI NETs, both the North American Neuroendocrine Tumor Society (NANETS) and European Neuroendocrine Tumor Society (ENETS) recommend considering measurement of CgA and urine 5-HIAA (u5-HIAA) for these purposes.[27,28] However, the added utility of biomarkers in the era of high-quality cross-sectional imaging remains debated. Furthermore, these tests lack the sensitivity and specificity to be used for diagnosis.

CgA is a 457–amino acid peptide that is widely distributed in neuroendocrine tissues, present in normal islet cells, and co-secreted with serotonin. Its sensitivity and specificity for detection of disease are assay dependent but range between 67% to 93% and 85-% to 96%, respectively. Serum levels of CgA can correlate with tumor burden, and thus this marker is used in some centers to determine the success of debulking procedures, disease recurrence, or progression. Levels can be falsely elevated by SSAs or proton pump inhibitors, or in patients with atrophic gastritis or renal, hepatic, or cardiac dysfunction.

5-HIAA is a metabolite of serotonin that is measured via a 24-hour urine collection or via plasma assays. It has high sensitivity (>95%) but low specificity (35%) for detection of GEP-NETs. Limitations of the test include inconvenience for the patient and false elevations caused by a number of substances—tryptophan-rich foods (cheese, mockernuts, tomatoes, pineapples, spinach), wine, caffeine, and various medications (acetaminophen, monoamine oxidase inhibitors, isoniazid, and 5-fluorouracil [5-FU]). Plasma serotonin levels do not correlate with tumor burden and are not relied on for diagnosis or surveillance.[29]

Some centers use biomarkers such as pancreastatin (a derivative of CgA) and neurokinin A for prognosis, especially in patients undergoing surgery for cytoreductive or curative intent, but supporting data are limited.[30,31]

PNETs may produce insulin, gastrin, glucagon, somatostatin, vasoactive intestinal peptide (VIP), pancreatic polypeptide (PP), or serotonin. Serum measurement of these hormones can aid diagnosis as hypersecretion can produce specific syndromes that are discussed in the sections that follow.

Imaging

Imaging is essential for the diagnostic workup, staging, and surveillance of GEP-NETs. Modalities such as endoscopy, computed tomography (CT), and magnetic resonance imaging (MRI) are used to locate the primary tumor, define resectability, and monitor for progression or recurrence. Nuclear medicine studies (somatostatin-targeted imaging, positron emission tomography [PET]) are used to evaluate tumor functionality and the presence of distant metastases. Complete diagnostic workup typically the requires use of multiple modalities.

Endoscopy

Endoscopic procedures are used to detect primary tumors, for local staging, to provide tissue for diagnosis, and for treatment. Gastric, duodenal, and proximal jejunal tumors can be visualized with

esophagogastroduodenoscopy. Colonic, rectal, and tumors in the terminal ileum can be seen with colonoscopy. Combining an endoscopic procedure with ultrasound (EUS) allows for local staging and tissue diagnosis via fine-needle aspiration. In PNETs, EUS localizes primary tumors with 93% sensitivity and 95% specificity. It is less useful for detecting duodenal NETs with detection rates of 45% to 60%.[32] In cases in which the location of the primary tumor is unknown but the small bowel is suspected, double balloon enteroscopy or capsule endoscopy can be used to visualize the midportion of the small intestine. Unfortunately, with detection rates less than 50%, neither modality is very efficient in this task.[33,34]

Computed Tomography and Magnetic Resonance Imaging

CT is excellent for surgical planning and useful for disease staging and surveillance. Studies examining its utility in detecting primary GEP-NETs report sensitivities ranging from 43% to 90%.[35–37] Regardless of primary tumor site, a multiphase study with intravenous (IV) contrast should be obtained because GEP-NETs are most frequently hypervascular tumors that are best visualized in the early arterial phase of a triple phase scan. A dedicated thin-slice, triphasic (arterial, late arterial, portal venous phases) "pancreas protocol" CT scan can be helpful for locating small, multifocal PNETs and to clearly define the relationship of tumors in the head of the pancreas to mesenteric vascular structures. Detection of small bowel, colon, or rectal NETs can be enhanced with the use of oral or rectal (or both) radiopaque contrast. This modality is also useful for detecting hepatic and soft tissue metastases with detection rates in this context reported at approximately 80%.[36,38,39]

MRI is the favored modality for detailing hepatic metastatic tumor burden (sensitivity, 95.2%)[40] and the pancreatic ductal system before surgery. It is also useful in patients with renal failure or an allergy to iodinated contrast. Optimal imaging requires use of IV gadolinium contrast because most GEP-NET metastases are hyperintense on arterial phases.

Somatostatin Receptor Imaging

Somatostatin is an endogenous peptide with a half-life measured in minutes that inhibits the proliferative and secretory functions target cells throughout the body. There are five subtypes of somatostatin receptors (SSTR1–SSTR5) that are the foundation of somatostatin-targeted imaging and treatment because more than 80% of well-differentiated NETs express a combination of these receptors.[41,42]

Somatostatin receptor scintigraphy (SRS) is a nuclear medicine imaging modality that uses ^{111}In-labeled diethylenetriamine penta-acetic acid octreotide (DTPA-D-Phe^{1}-octreotide) to visualize tumors expressing somatostatin receptors 2 and 5. It is obtained as a full-body scan at 4, 24, and potentially 48 to 72 hours after radionuclide injection and is used for detection of distant metastases. It has a sensitivity of 85% and specificity of 95% for primary GEP-NETs. It has been shown to detect metastases missed by conventional imaging in 30% of cases, but it may miss 17.5% of hepatic metastases otherwise detected by CT or MRI.[40,43]

The development of a positron-emitting ^{68}Ga-labeled radioligand conjugated to SSAs has enhanced the sensitivity (97%) of somatostatin imaging. The PET scan can be fused with CT or MRI, enhancing its anatomic specificity (Fig. 34–2).[44] These studies have improved the detection rate of NETs of the small intestine, including endoluminal tumors as small as 1 cm. False-negative studies are more common with tumors in the head of the pancreas because the uncinate demonstrates a moderate amount of physiologic uptake. As well, subcentimeter multifocal tumors in the small intestine, found in 15% to 30% of patients who are surgically explored, may still be below the limit of resolution.

Fluorodeoxyglucose Positron Emission Tomography

18-Fluorodeoxyglucose PET (FDG-PET) is used for detection of distant metastases in NEC. It has limited utility for staging well-differentiated, low- or intermediate-grade GEP-NETs because these tumors are metabolically inert and thus fail to take up ^{18}FDG well.[45] In high-grade NECs, maximum standardized uptake values (SUV_{max}) exceeding 4.5 are associated with shorter OS and progression-free survival (PFS) compared with GEP-NETs that are not detected.[46]

Other Nuclear Scintigraphy Techniques

Metaiodobenzylguanidine (MIBG) is taken up by some NET cells. ^{131}Iodine-labeled MIBG (^{131}I-MIBG) has an overall sensitivity of 55% to 70% in detecting NETs.[47] Although ^{131}I-MIBG is less sensitive than SRS, it may be used in patients receiving long-acting octreotide, which competitively inhibits uptake of radiolabeled SSAs or for patients whose tumors lack somatostatin receptors.

Clinical Staging

GEP-NETs are staged using the American Joint Committee on Cancer (AJCC) tumor, node, metastasis (TNM) system (Table 34–3 and Table 34-4).[48] The

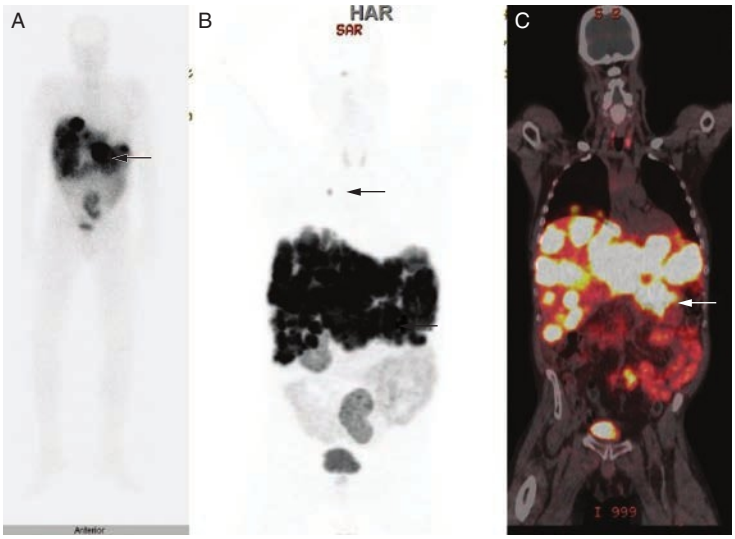

FIGURE 34–2 Somatostatin receptor imaging. All images are of the same patient. Image in **A** was obtained in 2015. Images in **B** and **C** were obtained in 2020. **A.** Octreoscan demonstrating a large pancreatic primary tumor (*arrow*) located in the tail of the pancreas and multiple hepatic lesions. **B.** ^{68}Ga-DOTATATE planar image. This more sensitive imaging technique demonstrates an increased number of hepatic metastases, a pulmonary nodule (*arrow*) and progression of the pancreatic primary tumor. **C.** Fused computed tomography and DOTATATE, coronal image. All images show physiologic uptake in the pituitary, thyroid, uncinate process, spleen, kidneys, and bladder. Note that the patient has a left pelvic kidney.

TABLE 34–3 TNM Staging System for G1/G2 (and rare G3) Well-Differentiated Extrapancreatic Gastrointestinal Neuroendocrine Tumors[a]

		Stomach	Duodenum or Ampulla	Jejunum or Ileum	Appendix	Colon or Rectum
T	TX	Tumor cannot be evaluated				
	T0	No evidence of tumor				
	T1	≤1 cm and extends into lamina propria or submucosa	≤1 cm and only involves mucosa or sphincter of Oddi	≤1 cm and extends into lamina propria or submucosa	≤2 cm	T1a: <1 cm and invades lamina propria or submucosa
						T1b: 1–2 cm and invades lamina propria or submucosa
	T2	>1 cm or extends into the muscularis propria	>1 cm or extends into the muscularis propria	>1 cm or extends into the muscularis propria	>2 cm but ≤4 cm	>2 cm with invasion of the lamina propria or submucosa or invades the muscularis propria
	T3	Invades into but not through subserosa	Invades the pancreas or peripancreatic adipose tissue	Invades into but not through subserosa	>4 cm or with subserosal invasion, or involvement of mesoappendix	Invades into but not through subserosa
	T4	Tumor extends beyond serosa or invades nearby organs

[a]For any T, add (m) for multiple tumors. For multiple tumors with different Ts, use the highest. Per World Health Organization/American Joint Committee on Cancer guidelines, poorly-differentiated neuroendocrine carcinomas (Ki-67 > 20%) are staged using the staging classifications for adenocarcinomas at the individual primary tumor sites, not as well-differentiated neuroendocrine tumors.
Data from Edge SB, Byrd DR, Byrd DR, et al: AJCC Cancer Staging Manual, 8th ed. New York, NY: Springer; 2017.

system is primary site specific and applies to grade 1 and 2 NETs. This staging is prognostic but not predictive of the benefit with any therapy. At least two staging systems are in use for PNETs. The AJCC TNM PNET staging system derives from the exocrine pancreas adenocarcinoma staging system and describes T stage in terms of resectability. In contrast, the ENETS staging system defines T stage by size and extent of invasion. Regardless of the system used, prognosis and stage maintain an inverse association.[49] High grade NEC are described with a TNM stage according to guidelines for carcinomas of the primary site but are summarized as limited-stage or extensive-stage disease, defined by the ability of the cancer to be treated in a single radiation port, based on the staging of the biologically analogous small cell lung cancer.[47]

CLINICAL FEATURES OF GASTROINTESTINAL NEUROENDOCRINE TUMORS

Gastric Neuroendocrine Tumors

There are three types of gastric NETs. Types I and II arise in response to hypergastrinemia, and type III tumors are sporadic.[50] Type I NETs are most common (75%) and are typically located in the gastric body

TABLE 34–4 Staging System for G1/G2 (and Rare G3) Well-Differentiated Pancreatic Neuroendocrine Tumors[a]

American Joint Committee on Cancer Tumor (T), Node (N), Metastasis (M) Staging System (8th ed, 2017) for G1/G2 (and Rare G3) Well-Differentiated Pancreatic Neuroendocrine Tumors[a] T	TX	Tumor	**Stage I**	**Stage II**	**Stage III**		**Stage IV**
	T1	Limited to the pancreas, <2 cm	T1				
	T2	Limited to the pancreas, 2–4 cm		T2			
	T3	Limited to the pancreas, >4 cm or invading the duodenum or common bile duct		T3			
	T4	Invading adjacent organs or the wall of large vessels			T4	Any T	Any T
N	NX	Regional lymph nodes cannot be assessed					
	N0	No regional lymph node metastasis	N0	N0	N0		Any N
	N1	Regional lymph node metastasis				N1	
M	MX	Distant metastases cannot be assessed					
	M0	No distant metastases	M0	M0	M0		
	M1a	Metastases confined to the liver					M1
	M1b	Metastases in at least one extrahepatic site					
	M1c	Both hepatic and extrahepatic metastases					

[a]Limited to the pancreas means there is no invasion of adjacent organs (stomach, spleen, colon, or adrenal gland) or the wall of large vessels (celiac axis or the superior mesenteric artery). Extension of the tumor into peripancreatic adipose is not a basis for staging. For any T, add (m) for multiple tumors. For multiple tumors with different Ts, use the highest. Per World Health Organization/American Joint Committee on Cancer guidelines, poorly-differentiated pancreas neuroendocrine carcinomas (Ki-67 >20%) are staged using the pancreatic adenocarcinoma guidelines, not as well-differentiated NETs.
Data from Edge SB, Byrd DR, Byrd DR, et al: AJCC Cancer Staging Manual, 8th ed. New York, NY: Springer; 2017.

or fundus. They are associated with chronic atrophic gastritis or pernicious anemia, are frequently subcentimeter and multifocal, and rarely metastasize. The survival rate is estimated at approximately 100% when these tumors are discovered as submucosal lesions amenable to endoscopic resection.[51] Type II tumors arise in the context of pathological hypergastrinemia from Zollinger-Ellison syndrome (ZES; 5%–10%) and are most often (70%) found in patients with MEN1.[51] These are more aggressive than type I tumors because 10% to 30% will metastasize, though usually only to locoregional lymph nodes.[52] Analyzed together, type I and II gastric NETs are associated with an approximate 80% 5-year OS rate.[51] Type III tumors, which arise in a eugastrinemic context and are most similar to NETs arising elsewhere in the body are the most aggressive subtype, with 50% to 100% metastasizing distantly. SEER analysis reveals a median OS of 13 months for patients with metastatic gastric NETs.[53]

Small Intestinal Neuroendocrine Tumors

Sporadic duodenal tumors comprise approximately 3% of all NETs, according to the SEER registry between 1973 and 1999. The vast majority of duodenal tumors arise in D1 and D2, with approximately 20% occurring in the periampullary region. Sporadic duodenal tumors are typically small (<2 cm) single lesions. If multiple tumors are detected, a diagnosis of MEN1 should be considered.[54] Periampullary tumors are typically more aggressive, and these patients may present with obstructive jaundice or cholangitis. Liver metastases occur in fewer than 10% of patients.[51] The most common duodenal NETs are gastrinomas, somatostatinomas, and nonfunctional tumors. Gastrinomas cause symptoms of ZES either sporadically or in the context of MEN1. These patients develop reflux and are at risk for peptic ulcers, GI bleeding, or perforation because of high levels of hydrochloric acid.

NETs of the jejunum and ileum are colloquially referred to as *carcinoid tumors*. These tumors are most often 1 to 2 cm in size and are located within 100 cm of the ileocecal valve.[55] Approximately 41% of patients will have locoregional nodal involvement, and 30% will have distant metastases.[56] In patients who undergo surgical exploration, up to 45% are found to have multiple small-bowel tumors.[57] These tumors are typically subcentimeter and can be missed if patients undergo a minimally invasive operation because of the lack of haptic feedback. Given their small size, they may also be missed on SRS imaging. On CT, an endoluminal tumor may not be obvious, but a calcified mesenteric mass is often seen, which upon surgical exploration approximates the location of the largest primary within the bowel. Before developing distant metastases, patients are either asymptomatic

or describe vague GI symptoms unrelated to the presence or location of the primary tumor. Patients with distant metastases are more likely to present with symptoms related to hormone secretion or from high tumor burden, such as GI bleeding, jaundice, or bowel obstruction. Patients who present with a large mesenteric mass at the takeoff of the superior mesenteric artery may develop chronic mesenteric ischemia. The median survival time of patients with G1 or G2 small intestine NETs is 8.5 years.

Appendiceal Neuroendocrine Tumors

Appendiceal NETs are often discovered incidentally during an appendectomy. Fifty-four percent of patients present with appendicitis, but this is unlikely related to the primary tumor because only one third are located at the base of the appendix.[58] Median OS is more than 30 years when the disease is localized or locally advanced and 2.3 years with distant disease.[53] Still undetermined is whether the disease-specific prognosis is meaningfully different between pediatric and adult patients.

Rectal Neuroendocrine Tumors

Rectal NETs are often found during an evaluation for symptoms related to a benign condition (ie, bleeding, pain, change in bowel habits). Most tumors are 4 to 8 cm from the anal verge, and 80% are localized tumors less than 1 cm in size.[59] Only 4% of patients with rectal NETs present with distant metastases. These tumors appear as a yellow-grey submucosal nodule in the rectal wall. Local excision is adequate for small tumors without high-risk features. Pathologic characteristics that mandate consideration of more extensive surgical resection are perineural or lymphovascular invasion, invasion into the muscularis, or size larger than 2 cm. Tumors with high-risk features carry a 60% to 80% risk of distant metastasis.[59,60] Localized rectal NETs are associated with a median OS of 24.2 years, whereas prognosis for advanced rectal NETs is much poorer at 1.8 years.[53]

CLINICAL FEATURES OF PANCREATIC NEUROENDOCRINE TUMORS

Insulinoma

Insulinoma is the most common type of functional PNET and is characterized by the "Whipple triad" of (1) hypoglycemia; (2) neuroglycopenic symptoms of shakiness, confusion, or sweating; and (3) resolution of these symptoms with eating. These tumors are generally benign (90%), intrapancreatic, solitary, and smaller than 2 cm.[61] Approximately 5% are associated with MEN1; thus, a careful family history must be taken at diagnosis. Measurement of plasma glucose, insulin, C-peptide, and proinsulin during a monitored 72-hour fast confirms the diagnosis. Insulinomas can be difficult to localize in 40% of cases, but combinations of MRI, pancreas protocol CT, and EUS have a sensitivity of 90%. ^{69}Gallium PET imaging may detect lesions missed by other modalities.[62] Patients with lesions that fail to localize on imaging can be discovered intraoperatively using a combination of careful palpation and intraoperative ultrasound to identify the tumor, though this is becoming less common as imaging improves. Portal venous sampling and arterial calcium stimulation are primarily of historical interest.

Gastrinoma

Gastrinomas are located in the duodenum or pancreas in an area called the gastrinoma or Passaro's triangle, which is bound superiorly by the junction of the cystic and common bile ducts, inferiorly at the junction of D2 and D3, and medially by the neck of the pancreas.[63] These tumors cause ZES and patients develop multiple, recurrent peptic ulcers.[64] Twenty percent are found in association with MEN1. Approximately 50% of gastrinomas have distant metastases at diagnosis.[65] Diagnosis requires measurement of fasting serum gastrin and basal gastric acid levels. Duodenal gastrinomas are submucosal and often difficult to detect with EGD. ^{69}Gallium SRS PET can detect 68% of gastrinomas diagnosed biochemically or clinically but missed on conventional imaging.[66]

Glucagonoma

Glucagonoma is a rare but aggressive PNET that typically arises in the tail of the pancreas. Glucagonoma syndrome features necrolytic migratory erythema, diabetes mellitus, stomatitis, anemia, neuropsychiatric disturbances, or diarrhea. The majority of patients present with glucose intolerance, necrolytic migratory erythema, or both. The reddish-brown rash typically involves the face, abdomen, perineum, or extremities. Erythematous areas form bullae that eventually open and encrust. The median time between symptom onset and diagnosis is 39 months, and by this time, 80% of tumors have metastasized. Diagnosis is supported by serum glucagon levels exceeding 1000 pg/mL.[67]

Somatostatinoma

Somatostatinoma is an extremely rare (incidence, 1 in 40 million people) solitary tumor that is found in the pancreas or periampullary duodenum. Functional tumors can cause diabetes, cholestasis, or steatorrhea. Most tumors are malignant (78%), and patients typically present with metastatic disease (70%–92%). Duodenal somatostatinomas are associated with NF1 in approximately 50% of cases and are less likely to

have metastasized at presentation. The 5-year OS for patients with localized disease is 60% to 100%, whereas the 5-year OS for patients with metastatic disease is 15% to 60%.[68]

VIPoma

VIP-secreting tumors (VIPomas) are rare tumors that cause "pancreatic cholera." Confirmed in human participants infused with high concentrations of IV VIP for 10 hours,[69] elevated serum concentrations of VIP cause high-volume (>10–20 L/day) watery diarrhea that results in profound dehydration, hypokalemia, achlorhydria, and paradoxical acidosis. These tumors are located in the pancreatic tail and are typically slow growing with a median OS of 5.9 years. Five percent are seen in patients with MEN1.[70]

Pancreatic Polypeptide–Secreting Tumor

PNETs that hypersecrete PP (PPomas) are exceedingly rare (<1% NET), and although considered a functional PNET, they do not produce a specific clinical syndrome. Secretion of PP is associated with increased satiety, delayed gastric emptying, and inhibition of gallbladder contraction. Some reports suggest an association between PP hypersecretion and glucose intolerance. In patients who present with metastatic disease, this may be the presenting sign.[71–73]

Nonfunctional Pancreatic Neuroendocrine Tumors

Whether sporadic or in the context of MEN1, the majority of PNETs are nonfunctional. These tumors are asymptomatic at presentation unless tumor size or location creates mass effect within the foregut and biliary tree. Their asymptomatic nature contributes to a delay in diagnosis, and 60% to 80% present with metastases.[74] Prospective studies of patients with MEN1 suggest that at least 50% of patients will develop nonfunctional PNET and that these tumors increase in size and number over time, albeit very slowly.[75]

CARCINOID SYNDROME, CARCINOID HEART DISEASE, AND CARCINOID CRISIS

Carcinoid Syndrome

Carcinoid syndrome occurs when metastatic disease, primary tumor location, or tumor volume allows secreted amines to bypass or overwhelm the first-pass effect of the portal circulation. It is most common in extrapancreatic GI NETs, although some cases of "pancreatic carcinoid" have been reported. Common symptoms include flushing, diarrhea, abdominal cramping, and less frequently, wheezing, right-sided heart failure or dysfunction, and pellagra. Symptoms are thought to be caused by circulating serotonin metabolites, kinins, and prostaglandins.

A recent population-based study identified the clinicopathologic factors associated with the presence of carcinoid syndrome at diagnosis. Regionally advanced (22%) and distant metastatic (24.9%) NETs were associated with carcinoid syndrome more frequently than localized NETs (11.9%). Small intestine (32.4%) and cecal (32.2%) NETs were most commonly associated with carcinoid syndrome at diagnosis.[76]

Carcinoid Heart Disease

Carcinoid heart disease is the result of valvular thickening and fibrous plaque formation on the tricuspid and pulmonic valves that results in tricuspid regurgitation and pulmonic valve stenosis. Right ventricular dysfunction or failure suggests long-standing, late-stage disease.[77] A result of sustained release of serotonin, tachykinins, histamine, and prostaglandins, carcinoid heart disease develops in 40% to 70% of patients with carcinoid syndrome.[56,78–80] Patients may be asymptomatic but may also present with exercise intolerance. Florid right heart failure is uncommon. Physical examination and echocardiography aid in diagnosis. Current National Comprehensive Cancer Network guidelines suggest echocardiographic screening for patients with carcinoid syndrome every 2 to 3 years.[81] Screening should also be considered in patients preparing for surgical resection or debulking.[79]

Carcinoid Crisis

Carcinoid crisis is a hemodynamic phenomenon that is the subject of recent controversy. Lacking a consensus definition, it is generally described as a prolonged episode of hemodynamic instability occurring during or in close proximity to an invasive procedure that cannot be ascribed to (peri-) procedural factors such as hypovolemia, medication, hemorrhage, or decreased venous return. Similar to an episode of carcinoid syndrome, patients may develop cutaneous flushing and diarrhea during an event. In part because of the lack of definition, the true prevalence of crisis is unknown but reported between 0% and 35% in patients undergoing surgical resection.[82–86] An episode of crisis is thought to be caused by a massive release of bioactive amines into the systemic circulation, though one recent prospective study did not find elevated levels of serotonin, histamine, kallikrein, or bradykinin during intraoperative crises.[86] Generally recommended treatment consists of bolus injection of 500 to 1000 ug of octreotide

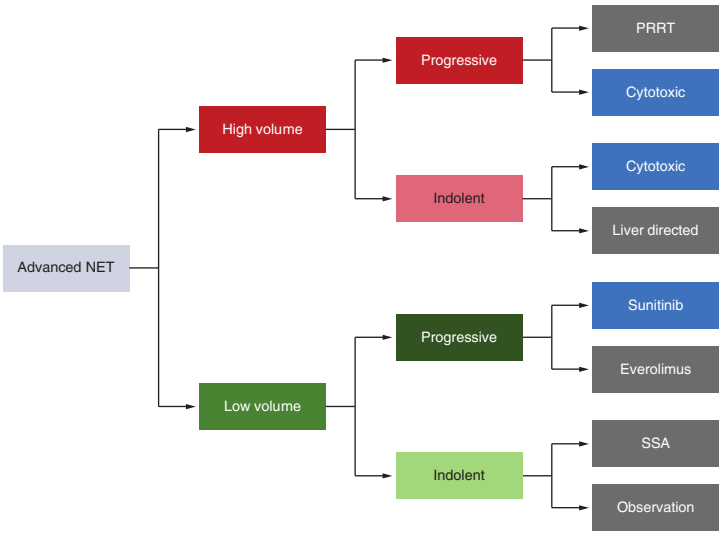

FIGURE 34–3 **Approach to therapy for advanced neuroendocrine tumors. Examples of low-volume metastatic disease are metastases isolated to a single organ or less than 20% liver replacement. PRRT, peptide receptor radionuclide therapy; SSA, somatostatin analogue.**

or a continuous infusion of 50 to 100 μg/hour in addition to standard management with antihypertensives or vasopressors. Patients with high-volume metastatic disease or a history of carcinoid syndrome undergoing invasive procedures may be premedicated with bolus injections of octreotide. An intraprocedural continuous infusion of octreotide can be administered as prophylaxis against periprocedural carcinoid crisis. This infusion is tapered over the next 8 to 24 hours. The use of periprocedural SSAs for these purposes is inconsistent among centers and practitioners. Both retrospective and prospective studies question the efficacy of SSA in this context.[83,85] Multi-institutional, prospective studies are required to resolve these issues.

GENERAL APPROACH TO TREATMENT

The dual nature of GEP-NETs—indolent but often discovered after metastatic spread—lies at the core of the challenges that arise during the care of these patients. Considered, deliberate ordering of a variety of treatment modalities is often necessary, which requires that patients obtain treatment at centers equipped to provide specialized, multidisciplinary care. Primary tumor location, stage, and grade dictate management. Regardless of primary site, surgical resection is recommended for G1 and G2 GEP-NETs when clearance of all gross disease can be achieved. Regional therapies for G1 and G2 GEP-NETs are also similar across primary sites, but systemic therapies diverge for pancreatic and extrapancreatic NETs (Fig. 34–3).

Treatment of Resectable Neuroendocrine Tumors

Surgical resection of locoregional disease offers the only chance for cure in patients with GEP-NETs. Appropriate patient selection considers primary site, tumor histology, the extent of detectable disease, and clinical presentation.

Endoscopic resection of types I and II gastric NET is appropriate when tumors are less than 2 cm in size and relatively few in number.[87] If histopathologic analysis reveals high-risk features such as positive resection margins, invasion into the muscularis or lymphovascular invasion, partial gastrectomy and regional lymphadenectomy must be considered. Tumors larger than 3 cm and type III gastric NETs also necessitate consideration of gastrectomy (partial or total, depending on location).[88–90] Endoscopic resection is not appropriate for type III gastric NETs of any size because of their propensity to behave similarly to gastric adenocarcinomas.[91]

Treatment of localized PNETs is dictated primarily by location within the pancreas but also by histology because functional tumors and those diagnosed in the context of MEN1 are often multifocal and theoretically amenable to repeat surgical treatment with parenchymal-sparing techniques. Sporadic tumors located in the head of the pancreas are treated with pancreaticoduodenectomy (Whipple procedure). Tumors in the body or tail can be resected with a distal pancreatectomy. In sporadic, nonfunctional PNETs surgical resection is associated with superior OS (14.3 years vs 3 years),[92]

although tumors smaller than 1 cm can be observed over time because of their low malignant potential. Patients with functional, multifocal tumors present a unique problem because R0 surgical resection may require total pancreatectomy, which is a morbid procedure condemning the patient to brittle diabetes and exocrine insufficiency. Alternatively, patients may be treated with surgical enucleation. This spares parenchyma but increases the risk of pancreatic fistula.[18] Novel technologies such as irreversible electroporation are under investigation for these tumors.[93]

Management of patients with pancreas VIPomas can be especially challenging because the clinical syndrome is commonly associated with advanced disease. Typically, management requires a multimodal approach. Surgical resection of the primary tumor and all metastases is ideal but rarely achieved. Surgical cytoreduction is attempted in some centers to decrease the amount of secreted VIP. Medical therapies may aid in symptom control and in severe cases, infusions of SSAs or glucocorticoid can be helpful to decrease the volume of diarrhea.

Duodenal NETs remote from the ampulla can be resected endoscopically (<2 cm), via transduodenal resection, or with a short-segment resection and anastomosis. Periampullary tumors require a Whipple procedure.[54,89,90] Localized NETs of the jejunum and ileum are treated with segmental resection and regional lymphadenectomy.[94] Regardless of imaging or gross inspection of the bowel intraoperatively, careful palpation of the entire bowel—from the ligament of Treitz to the terminal ileum—is required to ensure identification and resection of all primary tumors because up to 45% of patients have multifocal disease.[57]

For appendiceal NETs, simple appendectomy is appropriate treatment for tumors 1 cm or smaller, with invasion up to the subserosa or with mesoappendiceal invasion 3 mm or less and clear surgical margins. In adult patients, right hemicolectomy is recommended for tumors larger than 2 cm, tumors with deep mesoappendiceal invasion or positive margins, and tumors located at the base of the appendix, although studies have not clearly demonstrated a survival benefit with more extensive surgery.[28]

Colonic NETs are treated via endoscopic snare or partial colectomy and regional mesenteric lymphadenectomy. Small (~1–2 cm) intraluminal tumors that do not invade the muscularis can be excised endoscopically. Attempting removal of larger tumors with these procedures risks piecemeal removal, thus complicating pathologic analysis and increasing the risk of positive margins. Small, submucosal rectal NETs may be treated with local excision. Tumors that invade the muscularis, have high-risk features, or are associated with locoregional spread are treated with segmental resection. Choice of operation in this context parallels that of rectal adenocarcinoma, in which low anterior resection or abdominoperineal resection are options.

Poorly-differentiated grade 3 NEC seldom benefit from surgical resection in isolation because survival is poor regardless of the treatment modality selected. These patients are usually treated with chemotherapy, with radiation added for patients with limited-stage disease and surgical consolidation considered in selected cases.

Treatment of Advanced Neuroendocrine Tumors

The goal of treatment of patients with advanced GEP-NETs is improvement of quality of life and survival. At this stage, treatment is multimodal and can include SSAs, surgery, hepatic metastasis embolization, systemic PRRT, chemotherapy, and systemic targeted therapy. The literature is limited on specific recommendations for the order in which these modalities should be applied, emphasizing the need for specialized, multidisciplinary care.

Somatostatin Analogues

SSAs such as octreotide and lanreotide control symptoms of hormonally active NETs and demonstrate antiproliferative activity for NETs regardless of secretory behavior. These agents are the mainstay of therapy in carcinoid syndrome. Octreotide is an intermediate-acting SSA that can be self-administered subcutaneously every 6 to 12 hours as acute symptoms demand. It provides complete or partial relief of flushing or diarrhea in approximately 85% of patients with carcinoid syndrome and produces a biochemical response rate of up to 72%.[95,96] The dose of octreotide varies from 50 to 500 μg.

Long-acting SSAs have eliminated the need for multiple daily injections in most patients. Depot octreotide (10, 20, or 30 mg) is administered intramuscularly once per month. An intermediate-acting SSA can be used to supplement long-acting agents until steady state is reached. Lanreotide is another SSA in extended-release form, which can be administered subcutaneously monthly in doses of 60, 90, or 120 mg. In 2016, the phase III, randomized ELECT trial showed that treatment with 120 mg of lanreotide every 4 weeks decreased the percentage of days that patients required rescue doses of octreotide[97] and improved control of flushing and diarrhea in these patients.[98]

SSAs have a favorable side effect profile. These drugs can cause sinus bradycardia or cardiac conduction abnormalities; thus, caution is advised in patients with cardiac disease. More commonly, cholestasis and cholelithiasis can result from long-term use,[99] so cholecystectomy should be considered in patients who

undergo resection for their GEP-NETs.[94] Hypoglycemia, or more commonly, hyperglycemia may occur, especially among patients with brittle diabetes. Steatorrhea may also occur but can be managed with pancreatic enzymes taken with food.

SSAs also have anticancer activity. Interim analysis of the phase III randomized trial of depot octreotide 30 mg monthly in untreated metastatic midgut NET (PROMID) demonstrated a significantly longer time to progression with octreotide compared with placebo (PFS hazard ratio [HR], 0.34; P <.001).[100] An international double-blind placebo-controlled phase III trial of lanreotide (120 mg every 28 days) in treatment-naïve patients with nonfunctioning GEP-NET (CLARINET) also demonstrated significantly improved PFS with lanreotide compared with placebo (PFS HR, 0.47; P <.001).[101]

Surgical Resection in the Setting of Advanced Disease

Surgical treatment of advanced GEP-NETs is acceptable either for palliation of symptoms or survival benefit. These operations must be considered carefully and are best performed at high-volume NET centers by experienced surgeons because achieving an R0 resection is only possible in a minority of cases.[102] The risk of surgery must be carefully weighed and expected outcome clearly articulated because surgical complications can impact the survival and quality of life in a group of patients who may otherwise survive many years with their disease left in situ.

Palliative resection of the primary GEP-NET is recommended for patients with functional tumors causing debilitating secretory symptoms or in the setting of obstruction or bleeding. It is unknown whether resection of a nonfunctional tumor is beneficial. A meta-analysis of six studies examining this issue suggested that patients with advanced jejunal, ileal, or pancreatic NETs in the setting of unresectable distant metastatic disease may have a survival benefit with palliative resection of their primary tumors.[103] Studies using propensity matching are mixed. Daskalakis et al[104] compared patients who underwent early "logoregional" surgery for their stage IV small intestinal NETs with those who had surgery at least 6 months after their initial diagnosis. They found no survival difference between groups, but details on the conduct of the operations are not reported; thus, the extent of surgery is unknown. A single-institution series from Frankfurt, Germany, compared patients who had surgery as part of their treatment for hepatic metastases with those who had only nonsurgical interventions. This propensity-matched study showed that there was no survival advantage to incorporating surgery in the matched analysis. The 10-year mortality rate was associated with leaving the primary in situ.[105] Such propensity-matched analyses help minimize selection bias from the retrospective analyses but are not definitive evidence of lack of benefit from early surgical intervention. For now, consideration of surgery in patients with low overall tumor burdens and good functional status is reasonable and offered at the majority of high-volume NET centers.

Metastasectomy is most often performed to treat hepatic metastases and more rarely done for extrahepatic tumor debulking. In the liver, clearance of all hepatic metastases is ideal, although cytoreduction with a goal of clearing a minimum of 70%, and optimally 90% of disease, is considered reasonable in some centers. Anatomic surgical resection or parenchymal-sparing methods such as ablation are acceptable, although recurrence with either strategy is nearly universal. Patients undergoing liver-directed surgery experience superior PFS, OS, symptom control, and have a low postoperative complication rate when carefully selected.[94,106–109] Orthotopic liver transplantation is another investigational surgical approach for treating hepatic metastases and is also associated with OS at 5 and 10 years that is superior to unselected patients.[110] The extent to which this represents an effect of the surgery as opposed to an effect of the selection of patients fit for these interventions is as yet undetermined.

Hepatic Arterial Embolization and Chemoembolization

Liver metastases from NETs receive more than 80% of their blood supply from the hepatic arterial circulation, in contrast to normal liver parenchyma, which receives approximately 70% of its supply from the portal venous system. Thus, embolizing the hepatic artery targets tumor metastases while leaving normal parenchyma relatively unharmed. Three distinct techniques exist for liver-directed embolotherapy, but all rely on selective ischemia of the metastasis for effect. Bland embolization uses embolic particles (Gelfoam powder, polyvinyl alcohol particles, or microembospheres) to cut off the tumor blood supply.[111] The addition of an ethiodized oil emulsion of a chemotherapeutic agent to the embolic material, known as transcatheter arterial chemoembolization (cTACE), or drugs loaded onto embolic microspheres (drug-eluting bead transarterial chemoembolization [DEB-TACE]), allows delivery of relatively larger doses of agents to the tumor, combining local cytotoxicity and ischemia. The most frequently used chemotherapeutic agents for cTACE and DEB-TACE are doxorubicin, epirubicin, cisplatin, gemcitabine, 5-FU, and streptozocin.[112–116]

Benefits of this treatment include symptom relief, slowing progression, and reducing tumor burden before attempting surgical resection or tumor ablation. Many retrospective studies in markedly heterogeneous

populations have shown that these three techniques control symptoms and are associated with favorable PFS and OS. No study has clearly demonstrated one technique to be superior in patients with GEP-NETs, although a randomized trial comparing all three techniques is currently recruiting patients. It should be noted that the DEB-TACE arm of this study closed early because of reports of unacceptable toxicity.[114]

The primary risk of hepatic artery embolization is postembolization syndrome, which is typically self-limited and characterized by pain, GI distress, fever, leukocytosis, and transaminitis. Major complications such as renal failure, gallbladder perforation, cholangitis, peptic ulcer hemorrhage, and abscess formation are rare.[117] Liver necrosis is also uncommon postprocedurally but is associated with previous bile duct dilation and portal vein thrombosis.[118] Embolization has been associated with carcinoid crisis.[119]

In patients with extensive liver tumor burden, multiple embolization sessions may be required, starting with the hepatic lobe with the greatest tumor burden. Embolization of the whole liver in one session runs the risk of prolonged postembolization syndrome or liver failure. The timing of subsequent embolizations is determined primarily by symptoms, tumor behavior, and patient tolerance.

The ordering of hepatic arterial embolization with other regional and systemic therapies in the disease course remains a topic of debate, and specific guidelines from NANETS on this issue do not exist.[18,120] Although some investigators advocate early embolization to reduce tumor burden before initiating systemic therapy, late embolization can also be effective. In a randomized study, patients with NET treated with initial liver embolization followed by interferon therapy had a higher objective response rate after 1 year (86%) than patients who received interferon only (42%), without demonstrating altered survival.[121] In contrast, when embolization or chemoembolization are performed at a median of 37 months after diagnosis, the median survival time after embolization was 80 months, leading the investigators to conclude that later embolization is still effective.[122]

Selective Internal Radiation Therapy

Intra-arterial radioembolization with yttrium-90 (^{90}Y) microspheres is a technique used to treat unresectable liver metastases.[18,120] ^{90}Y is a pure β emitter with a mean soft tissue penetration of 2.5 mm and a maximal depth of 1.1 cm. Great care must be taken with ^{90}Y radioembolization to avoid nontarget delivery of radioactive microspheres to organs such as the lungs and stomach, making an angiogram with selective embolization of all extrahepatic arteries essential before treatment, as well as assessment of lung shunt fraction.

Radioembolization of hepatic metastases has been studied retrospectively as well as prospectively. The study cohorts are heterogeneous, but ^{90}Y radioembolization has been shown to improve symptoms, induce radiographic complete and partial responses, and decrease tumor marker levels and be associated with favorable PFS and OS.[117,123–125] There are no studies that show improved survival benefit with radioembolization compared with other hepatic arterial embolization techniques. This procedure has a favorable safety profile compared with hepatic arterial embolization techniques, with low rates of postembolization syndrome and carcinoid crisis, allowing it to be performed as an outpatient procedure.[119,126] The risk of hepatic cirrhosis is low with this technique but has been reported.[127]

Peptide Receptor Radionuclide Therapy

Radiolabeled SSAs have also been developed, and ^{177}Lu-DOTATATE was approved by the Food and Drug Administration (FDA) in 2018 for use in patients with metastatic GEP-NETs. DOTATATE is a SSA that can be conjugated to the β- and γ-emitter ^{177}lutetium (^{177}Lu).[128] In 2017, the results of the phase 3 trial of ^{177}Lu-DOTATATE for midgut neuroendocrine tumors (NETTER-1) were reported. The trial included 229 patients with well-differentiated, metastatic midgut NETs who were randomized to receive either ^{177}Lu-DOTATATE every 8 weeks or high-dose (60-mg) octreotide LAR. PFS was improved by 79% in the PRRT arm compared with the octreotide arm. The response rate in the ^{177}Lu-DOTATATE group was 18% versus 3% in the octreotide group (P <.001). A preliminary analysis suggested an OS advantage to PRRT, with 14 deaths in the ^{177}Lu-DOTATATE group compared with 26 deaths in the octreotide group (P = .004),[129] but more events are required to confirm this early result. Grade 3 and 4 side effects were rare. The most common in the ^{177}Lu-DOTATATE group were lymphopenia (9%) and thrombocytopenia (2%). A separate report detailed the results of patient quality of life outcomes as assessed with two different quality of life questionnaires administered at baseline and every 12 weeks until tumor progression. Patients treated on the ^{177}Lu-DOTATATE arm had significantly longer time to deterioration for global health status (28.2 months vs 6.1 month) and physical functioning (25.2 months vs 11.5 months).

Chemotherapy

Selection of chemotherapy regimen depends on grade and histology. Well-differentiated extrapancreatic NETs respond poorly to cytotoxic chemotherapy. PNETs respond better. Early randomized studies of streptozocin-based chemotherapy regimens demonstrated biochemical responses and improvements in survival.[130,131] Building on the progress of Moertel et al, a study from

MD Anderson Cancer Center noted radiographic response rates of 39% in a series of 84 patients with PNET using a regimen of 5-FU, doxorubicin, and streptozocin (FAS). The median PFS was an estimated 18 months, with a median OS of 37 months.[132] Temozolomide, an alkylating agent, is an alternative to FAS and has the advantage of being an oral formulation. A randomized trial comparing temozolomide and capecitabine to temozolomide alone in PNET patients demonstrated improved PFS (22.7 vs 14.4 months) and OS (not reached vs 38 months). Poorly-differentiated high-grade NECs are responsive to platinum-based chemotherapy.[133]

Targeted Therapy

The use of targeted therapies in GEP-NETs has greatly expanded in recent years. Building on the observation that increased vascular endothelial growth factor (VEGF) portends poor survival in patients with NET, the VEGF receptor inhibitor sunitinib was tested in a phase III study of 154 patients with PNET with advanced and progressive disease. An interim analysis demonstrated an HR for progression or death of 0.42 favoring sunitinib over placebo (P <.001).[134] This resulted in regulatory approval of sunitinib for the indication. Simultaneously, the mTOR inhibitor everolimus was studied in RADIANT-3. This randomized phase III trial compared everolimus versus placebo in 410 patients with advanced, progressive PNETs. The HR for progression or death was 0.35 (P <.001) favoring everolimus over placebo.[135]

Less progress has been made with targeted agents in extrapancreatic GI NETs. The phase II study of sunitinib showed limited evidence of benefit.[136] The RADIANT-2 study of everolimus in patients with extrapancreatic NET, although limited by randomization imbalance and informative censoring in central radiology review, also failed to demonstrate statistically significant benefit.[137] RADIANT-4, a randomized phase III trial of patients with advanced, progressive, well-differentiated, nonfunctional NETs of the lung or GI tract were assigned to everolimus or placebo in a 2:1 ratio. Everolimus was associated with a 52% decrease in the estimated risk of progression or death (P <.00001).[138] The FDA approved everolimus for well-differentiated, nonfunctional, advanced NETs in 2016.

Surufatinib is the newest targeted agent to be trialed in NETs. This agent targets the VEGF receptor, fibroblast growth factor receptor 1, and colony-stimulating factor 1 receptor. In the phase I/IIb trial, 42 patients with PNET and 39 patients with extrapancreatic NET were treated with 300 mg of oral surufatinib once daily until progression. Radiographic objective response rates were observed in 19% of PNETs and 15% of extrapancreatic NETs. Disease control rates were 91% and 92%, with associated median PFS of 21.2 months and 13.4 months in PNETs and extrapancreatic NETs, respectively.[139] The subsequent phase III trial in advanced extrapancreatic NETs randomized 198 patients (2:1) to 300 mg of surufatinib or placebo. This study was terminated at an interim analysis by the data safety monitoring board because of unequivocal evidence of benefit, with surufatinib significantly prolonging PFS compared with best supportive care (HR, 0.334; 95% confidence interval, 0.223–0.499; P <.0001). The most common severe adverse events were proteinuria (19.4%) and hypertension (36.4%). The disease control rates were 86.5% in the surufatinib group and 65.6% in the placebo group (P = .0022). A phase III trial investigating surufatinib in PNET is ongoing.[140]

Immunotherapy

Currently, there are no checkpoint or immunotherapies approved for use in GEP-NETs. Pembrolizumab, a programmed cell death protein 1 (PD-1) checkpoint inhibitor, may have a role in the treatment of patients with poorly-differentiated NEC because one study showed expression of PD-1 in 16% of GEP NECs.[141]

Additional Symptom Control Methods

Carcinoid symptoms can be exacerbated by epinephrine, exercise, emotions, eating tryptophan-rich foods, and ethanol and may be controlled through modulating these factors or supplementing dietary nicotinamide. Medical management of carcinoid symptoms can include a bronchodilator for bronchospasm and diuretics for fluid overload secondary to valvular dysfunction. A proton pump inhibitor (but not an H2 blocker) can manage gastric hypersecretion in gastrinoma patients. Malignant hypoglycemia in patients with insulinomas can be managed with everolimus.[142]

Elevated levels of serotonin are associated with diarrhea and are not always optimally managed with an SSA. Telotristat ethyl inhibits tryptophan hydroxylase—the rate-limiting step in serotonin synthesis. As such, it has been tested prospectively to determine its efficacy in reducing the frequency of NET-associated diarrhea. In the phase 3 TELESTAR study, patients had a reduction (-2.1 bowel movements per day compared with baseline but only -0.81 bowel movement per day compared with placebo) of the number of bowel movements per day as well as a significant decrease in their u5-HIAA levels.[143] The results of the TELECAST study paralleled those of TELESTAR and showed that telotristat was safe and resulted in a decreased number of bowel movements per day, as well as decreased u5-HIAA levels.[144] Telotristat ethyl is FDA approved for use at a dosage of 250 mg three times per day in patients with NET-related diarrhea that is inadequately controlled by SSA.

CONCLUSION

Multidisciplinary diagnosis and management of patients with GEP-NETs is essential. For localized disease, early and clear communication between the surgeon and the pathologist is required for appropriate prognostication and treatment. Advanced NETs present different challenges, and surgeons, interventional radiologists, medical oncologists, and endocrinologists may all play roles in improving quality and quantity of life for the patient. Despite recent advances in targeted therapy for GEP-NETs, these tumors remain challenging to treat and remain life limiting for many patients. Ongoing studies of targeted agents, PRRT, and immunotherapy will hopefully continue to advance our understanding of the biology of these diverse diseases while bringing needed therapies to this growing patient population.

MD ANDERSON PRACTICE TIPS

- A thin-slice, multiphasic CT scan is required for PNETs being considered for surgical resection.
- Jejunal and ileal NETs are resected using an open approach to allow for careful palpation of the entire small bowel because small, multifocal tumors are common.
- Hepatic metastases are commonly treated with resection when all visible tumors can be safely resected.
- NET growth over time is best gauged with imaging over longer time intervals since the last progression event, such as 6 to 12 months. It is common for studies read with limited comparison to underestimate or overestimate NET growth.
- NEC is fundamentally distinct from NET and requires very different management, principally aggressive chemotherapy.
- With the wide variety of systemic and locoregional treatment options for patients with advanced disease, it is always helpful to ask if the intensity of a proposed approach is appropriate for the pace, volume, and biology of disease.

35 Early-Stage and Locally Advanced Breast Cancer

Demetria Smith-Graziani
Mariana Chavez-MacGregor

KEY CONCEPTS

- A multidisciplinary approach is of upmost importance, especially with regard to planning and coordinating multimodality therapy. It is important to involve surgical and radiation oncology colleagues early to determine the best treatment plan.
- Choice of systemic therapy is ultimately guided by biomarker status of the patient's tumor.
- Whereas patients with hormone receptor–positive cancers should receive endocrine therapy, those with human epidermal growth factor receptor 2 (HER2)–positive cancers should receive anti-HER2 targeted therapy.
- Genomic assays can help assess the benefit of adjuvant chemotherapy in patients with hormone receptor–positive/HER2-negative breast cancer.
- All women with node-positive disease and a significant percentage of women with node-negative tumors that are hormone receptor negative or larger than 1 cm in size benefit from chemotherapy. Those with HER2-positive breast cancer need to receive anti-Her2 therapy
- Chemotherapy is the cornerstone of treatment for patients with triple-negative breast cancer (TNBC).
- Preoperative or neoadjuvant chemotherapy should be administered in most patients with HER2-positive or TNBC. The presence of a pathological complete response or residual disease has important prognostic implications but now allows us to identify patients that will benefit from additional adjuvant treatment.

EPIDEMIOLOGY

Incidence

Breast cancer is the second most common cause of death for U.S. women with an age-adjusted death rate of 20.3 per 100,000. In 2020, it is estimated that 276,480 American women will be diagnosed with breast cancer and that 42,170 will die from this disease, making breast cancer the third most common cause of cancer-related morality for all people in the United States, with lung cancer being the most common.[1]

In the early 1980s, the rates of breast cancer diagnosis rose sharply, likely related to increased mammographic screening, because it was the incidence of stage 0 and I carcinomas that rose most sharply. Data from the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute demonstrate that although the incidence of breast cancer later stabilized by the end of the 1980s, there has been an increase in the percentage of breast cancers that are hormone receptor positive. This is thought to be caused by either changes in receptor assays or an increased use of hormone replacement therapy by women.[2,3] The incidence of primary breast cancer then decreased around 2003, shortly after the publication of the Women's Health Initiative (WHI) results, which prompted many healthy postmenopausal women to stop using hormone replacement therapy.[4]

Breast cancer incidence has long varied in different regions of the world. Its incidence is highest in Northern Europe and North America and lowest in Asia and Africa. Data suggest that this variability is caused not only by environmental factors but also to lifestyle. This is supported by the observation that breast cancer incidence is higher in second-generation Asian immigrants in the United States.[5]

Mortality

Breast cancer overall mortality rates had been stable for more than 50 years before 1989. Starting in the 1990s, there has been a steady decrease in breast cancer deaths every year. Mortality rates declined by 1.4% per year from 1989 to 1995 and by 3.2% per year thereafter. This is thought to be due in part to increased use of mammography, resulting in earlier diagnosis, and the use of more effective treatments. Mortality rates continue to be higher for African American women. This is due in part to disparities in health care access that exist both for diagnosis as well as treatment.[6]

RISK FACTORS

The two most important risk factors for breast cancer are female gender and increasing age.[7] However, many additional patient characteristics increase one's risk of breast cancer (Table 35–1).

Hereditary

Family History

Although it is known that family history is an important risk factor for breast cancer, only 15% to 25% of newly diagnosed patients have a positive family history. The Gail model was the first to incorporate the number of first-degree relatives into a comprehensive model of breast cancer risk assessment.[8] Claus et al[9] then assessed the estimated risk of breast cancer based on the number of familial cases and their ages of diagnosis. It is now well known that the risk for each patient with a positive family history is affected by the age of the family member at diagnosis, the total number of first-degree relatives affected, and the patient's age. Based on data from a large meta-analysis, the risk of breast cancer for a patient with one affected first-degree relative increased 1.8-fold; if there were two affected first-degree relatives, that risk increased 2.93-fold. This risk was then further modified by the age of the patient, such that a woman's risk of breast cancer before age 40 years was increased to 5.7-fold if one relative was diagnosed before age 40 years.[10]

Genetic Mutations

The overall prevalence of specific genetic mutations accounting for breast cancer is rare (5%–10% of all cases). Risk can be further subdivided based on a patient's history. The most commonly studied mutations are on the *BRCA1* and *BRCA2* genes, although multiple other mutations exist on genes such as *p53*, *ATM*, *CHEK2*, *PTEN*, *MLH1*, *MSH2*, and *PALB2*.[11] In a study that analyzed 10,000 individuals, excluding those with Ashkenazi ancestry, the prevalence of *BRCA1* and *BRCA2* mutations varied, with a low of 2.9% if the patient and all first- or second-degree relatives had no prior history of breast cancer or ovarian cancer at younger than 50 years of age. A maximum prevalence of 81.3% was noted if the patient and any first- or second-degree relative had breast cancer diagnosed at younger than 50 years of age and ovarian cancer at any age.[12] Because genetic testing often leads to important medical decisions both for the patient and other family members, it is important to determine whom it is most appropriate to screen by taking into account population-dependent positive and negative predictive values of the test, using statistical models, and following current guidelines.

Conditions of the Breast

Ductal Carcinoma in Situ and Lobular Carcinoma in Situ

There has been a rapid increase in the literature concerning the epidemiology, natural history, and treatment of ductal carcinoma in situ (DCIS) and lobular carcinoma in situ (LCIS). (See detailed information in Chapter 38.)

With DCIS, the 10-year risk of invasive breast cancer is 5% in the contralateral breast. LCIS has been regarded as a risk factor for ipsilateral and contralateral breast cancer. Recent research supports that LCIS is a direct nonobligatory precursor of both invasive lobular and ductal carcinoma. For patients diagnosed with

Table 35-1 Risk factors for breast cancer. DCIS, ductal carcinoma in situ; LCIS, lobular carcinoma in situ.

Hereditary	Conditions of the breast	Natural hormonal factors	Exogenous hormonal use	Other risk factors
• Family history • Genetic mutations	• DCIS • LCIS	• Age at menarche • Age at first pregnancy • Age at menopause • Pregnancy	• Oral contraceptives • Hormone replacement therapy	• Alcohol consumption • Obesity

LCIS, the risk of developing breast cancer in either breast is 1% a year.[13]

Natural Hormonal Factors

Age at Menarche

A later age of menarche is protective. One study has reported that for every 2-year delay in menarche, there was a 10% reduction in breast cancer risk.[14]

Age at First Pregnancy

There is a favorable risk reduction associated with earlier age of pregnancy. Women who give birth for the first time at age 35 years have a 1.6-fold higher risk of breast cancer compared with women who were 26 to 27 years of age at the time of first birth. Women who are older than age 30 years at the time of first birth are at higher risk than nulliparous women.[15]

Age at Menopause

Late menopause is associated with a higher risk of breast cancer. Oophorectomy before age 40 years decreases the lifetime risk of breast cancer by 50%.[16]

Pregnancy

Breast cancer is the most common cancer associated with pregnancy, with its incidence being 1 in 3000. The incidence of pregnancy-associated breast cancer is likely related to the delay of childbirth until after age 30 years. There are controversial data from two reports suggesting that pregnancy might cause a transient rise in breast cancer risk. However, a clearly documented decreased risk of breast cancer occurs 10 to 15 years after childbirth.[17] (See detailed information in Chapter 38.)

Exogenous Hormonal Use

Oral Contraceptives

Most studies have not shown an increased risk of breast cancer with oral contraceptive use.[18,19] However, a meta-analysis showed a significant but small increase in relative risk of breast cancer.[20] A concern about the meta-analysis is that follow-up was limited.

Hormone Replacement Therapy

The WHI showed that the relative risk of breast cancer was increased to 1.26 for women who took combined treatment with estrogen and progesterone for a mean of 5.2 years compared with placebo.[21] Although long-term hormone replacement therapy was associated with a higher risk of breast cancer, short-term use did not seem to significantly increase the risk of breast cancer.

Other Risk Factors

The risk of breast cancer increases with the amount of alcohol consumed. Compared with women who do not drink any alcohol, consuming one alcoholic drink per day increases breast cancer risk by 7% to 10%. Consuming two or three alcoholic beverages per day is associated with a 20% increase in breast cancer risk.[7]

Obesity has also been linked to breast cancer risk. In postmenopausal women, obesity is more strongly associated with an increased risk of hormone receptor–positive breast cancer. However, weight gain in premenopausal women may increase the risk of triple-negative breast cancer (TNBC).[7]

STAGING OF BREAST CANCER

2017 Tumor, Node, Metastasis Revisions

The 2017 eighth edition of the *Cancer Staging Manual* published by the American Joint Committee on Cancer (AJCC) was modified from the prior staging criteria, published in 2010 (Tables 35–2 and 35–3).[22]

Anatomic Staging

Anatomic stage group should be used only when biomarker analysis is not available. It is based only on the anatomic extent of cancer as defined by the tumor (T), node (N), and metastasis (M) categories.[22]

Prognostic Staging

Prognostic staging is preferred for patient care and should be used for all patients in the United States. When biomarker analysis is available, clinicians should use clinical and pathological prognostic stage groups. The AJCC also recommends that all specimens have a histologic tumor grade and description of estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor 2 (HER2) status. Pathologic staging was updated to include genomic profiling to better refine prognostication. Approximately one third of patients' staging is reassigned after pathologic data are obtained. There are currently 122 different staging categories. Please refer to the AJCC eighth edition for more details regarding staging.

PROGNOSTIC FACTORS

There is interest in the assessment of prognostic factors in breast cancer. About 30% of patients with node-negative disease die from a breast cancer–related cause. Thus, there is a great thrust of research to

TABLE 35–2 Tumor, Node, Metastasis Staging System for Breast Cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ (DCIS)
Tis (Paget)	Paget disease of the nipple with no tumor[a]
T1	Tumor ≤20 mm in greatest dimension
T1mi	Microinvasion ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to
	(a) Chest wall or
	(b) Skin, only as described below
T4a	Extension to chest wall, not including pectoralis muscle adherence or invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma with typical skin changes involving one third or more of the skin of the breast
Regional Lymph Nodes—Clinical (cN)	
cNX	Regional lymph nodes cannot be assessed (eg, previously removed)
cN0	No regional lymph node metastases (by imaging or clinical examination)
cN1	Metastases to movable ipsilateral axillary level I, II axillary lymph node(s)
cN1mi	Micrometastases (~200 cells, >0.2 mm but none >2.0 mm)
cN2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in clinically detected ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastases
cN2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
cN2b	Metastases only in clinically detected ipsilateral internal mammary nodes and in the absence of clinically evident level I, II axillary lymph node metastases
cN3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected[b] ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastases in ipsilateral infraclavicular lymph node(s)
N3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastases in ipsilateral supraclavicular lymph node(s)
Regional Lymph Nodes—Pathological (pN)	
pNX	Regional lymph nodes cannot be assessed (eg, previously removed or not removed for pathologic study)
pN0	No regional lymph node metastasis identified or isolated tumor cell clusters (ITCs) only[c]
pN0(i+)	Malignant cells in regional lymph node(s) not > 0.2 mm (detected by H&E or IHC, including ITC)
pN0(mol+)	Positive molecular findings by RT-PCR; no ITCs
pN1	Micrometastases; or metastases in 1–3 axillary lymph nodes; and/or in internal mammary nodes with metastases detected by SLNB but not clinically detected

TABLE 35–2 Tumor, Node, Metastasis Staging System for Breast Cancer (*Cont.*)

pN1mi	Micrometastases (>0.2 mm and/or >200 cells but none >2.0 mm)
pN1a	Metastases in 1–3 axillary lymph nodes; at least one metastasis >2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastases or macrometastases detected by SLNB but not clinically detected[b]
pN1c	Metastases in 1–3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected
pN2	Metastases in 4–9 axillary lymph nodes or in clinically detected[d] internal mammary lymph nodes in the absence of axillary lymph node metastases
pN2a	Metastases in 4–9 axillary lymph nodes (at least one tumor deposit >2.0 mm)
pN2b	Metastases in clinically detected[d] internal mammary lymph nodes in the absence of axillary lymph node metastases
pN3	Metastases in ≥10 axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive level I, II axillary lymph nodes; or in >3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected or in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in ≥10 axillary lymph nodes (at least one tumor deposit >2.0 mm); or metastases to the infraclavicular (level III axillary lymph) nodes
pN3b	Metastases in clinically detected[d] ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in >3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by SLNB but not clinically detected
pN3c	Metastases in ipsilateral supraclavicular lymph nodes
Distant Metastases (M)	
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
cM1	Distant detectable metastases as determined by clinical and radiographic means
pM1	Any histologically proven metastases in distant organs; or if in nonregional nodes, metastases >0.2 mm

[a]Paget disease associated with a tumor is classified according to the size of the tumor.
[b]Not clinically detected is defined as not detected by imaging studies (excluding lymphoscintigraphy) or not detected by clinical examination.
ITCs are defined as small clusters of cells not >0.2 mm, single tumor cells, or a cluster of <200 cells in a single histologic cross-section. ITCs may be detected by routine histology or by immunohistochemistry (IHC) methods.
[d]*Clinically detected* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.
H&E, hematoxylin and eosin; RT-PCR, reverse transcription polymerase chain reaction; SLNB, sentinel lymph node biopsy.

determine markers that could further identify which patients would benefit most from available adjuvant treatment.

Predictive versus Prognostic Factors

With the growing array of articles in this field, it is important to distinguish predictive from prognostic factors. A predictive factor is one that can provide information on the likelihood of response to a given therapeutic intervention. A prognostic factor is one that can provide information on outcome at the time of diagnosis, independent of treatment.[23] Lymph node status is an example of a prognostic factor; ER and HER2 status are examples of a prognostic and predictive factor.

Pathologic Factors

Prognosis is still determined in large part by histopathology. Multiple studies showed that the most powerful prognostic factor is the extent of disease in the axillary lymph nodes.[24,25] Other important pathologic factors are hormone receptor status, HER2 status, histologic grade, tumor type, and lymphovascular invasion.

Axillary Lymph Nodes

More than 30 years ago, it was established that the number of involved lymph nodes could be used to predict disease-free survival (DFS) and overall survival (OS). In the absence of effective systemic therapy, the

TABLE 35–3 Tumor, Node, Metastasis Anatomic Stage Grouping for Breast Cancer

5-year DFSs were 62% with 1 to 3 positive axillary lymph nodes, 58% for 4 to 9 positive lymph nodes, and 29% for 10 or more positive lymph nodes.[25]

Nuclear Grade

Nuclear or histologic grade describes the degree of tumor differentiation and is based on a pathologist's assessment of nuclear size and shape, number of mitoses, and degree of tubule formation. Although a nuclear grade of 1 (most differentiated) to 3 (least differentiated) is reported with every breast cancer pathology report, its use in predicting outcome is still debated.[26] This is in part secondary to interobserver variation in the classification of differentiation. The Nottingham combined grading system seems to be most useful because of its semiquantitative approach and is currently recommended by the College of American Pathologists (CAP).

Hormone Receptor Status

ER and PR positivity correlate with favorable prognosis during the first 3 to 5 years after diagnosis. Immunohistochemical assays have now become the favored approach because they can be used with a variety of specimens. A "positive" specimen is defined as at least 1% of positive cells. The updated American Society of Clinical Oncology (ASCO)/CAP guidelines define cancers with 1% to 10% ER-positive cells as "ER low positive."[27]

Proliferative Rate

This can be evaluated by a variety of methods, including mitotic figure count, S-phase fraction (the fraction of cells synthesizing DNA) as determined by flow cytometry, thymidine labeling index, and monoclonal antibodies to antigens in proliferating cells. A high S-phase fraction is usually associated with poor differentiation and lack of ER positivity. Antibodies to Ki-67 can be used to determine a proliferative rate that corresponds with the S-phase fraction. A recent meta-analysis showed a positive correlation between high Ki-67 and poor prognosis.[28]

HER2/neu Overexpression

The *HER2/neu* oncogene codes for a 185-kDa transmembrane glycoprotein that has intracellular tyrosine kinase activity and is a member of the family of epidermal growth factor receptors. This group of receptors has an important role in the activation of epidermal signal transduction pathways controlling for epithelial growth and differentiation. Overexpression of the *HER2/neu* oncogene is present in up to 30% of invasive breast cancers.

The current standard is to perform either fluorescence in situ hybridization (FISH) by single or dual probe and immunohistochemistry (IHC). The ASCO/CAP guidelines for HER2 testing were updated in 2018. Breast cancer is defined as HER2-positive if IHC is noted to be 3+ or single probe FISH average HER2 copy number is 6.0 or more signals per cell. By dual-probe FISH, the *HER2*/CEP17 ratio should be 2.0 or greater, or the *HER2* copy number should be 6.0 or greater signals per cell regardless of *HER2-to-*CEP17 ratio. Equivocal results include IHC 2+ or dual probe FISH *HER2*/CEP17 ratio less than 2.0 and an *HER2* copy number between 4.0 and 6.0 signals per cell. Equivocal results should be confirmed with the other approved diagnostic tests. If results continue to be equivocal, repeat testing or a new biopsy should be considered.[29]

Before introduction of HER2-targeted therapy, overexpression of *HER2/neu* was associated with shorter DFS and OS.[30] A large single-institution study reviewed all women with T1a and T1b disease diagnosed between 1990 and 2002. Multivariate analysis of 965 patients showed that patients with HER2-positive tumors had 5.09 times the rate of recurrence and 7.81 times the rate of distant recurrence at 5 years compared

with patients with hormone receptor–positive, HER2-negative tumors.[31] The predictive response with HER2 has been demonstrated in prospective randomized controlled trials (discussed later in the Systemic Therapy for HER2-Positive Breast Cancer section).[32,33]

Genomic Assays

A number of gene expression assays are now commercially available that can help clinicians determine the patient's individual prognosis and the benefit of the addition of adjuvant chemotherapy to adjuvant endocrine therapy in hormone receptor–positive breast cancer (Table 35–4).

PRINCIPLES OF TREATMENT

At MD Anderson Cancer Center (MDACC), every effort is made to integrate clinical information with imaging, pathologic staging, and molecular characteristics to optimize treatment efficacy and, whenever possible, perform breast-conserving surgery (BCS). A multidisciplinary approach is of upmost importance, especially with regard to planning and combined-modality therapy. It is important to involve surgical and radiation oncology colleagues early to determine the best treatment plan. All patients at MDACC (including those with DCIS) undergo receptor testing for hormone receptor status for ER and PR. In addition, patients with invasive cancers are tested for *HER2/neu* status.

Surgery

Breast-Conserving Therapy

BCS, or segmental resection, has revolutionized patient care for breast cancer over the past three decades. Most women are able to preserve their breasts without a negative effect on survival. Breast-conserving therapy involves the surgical removal of tumor with negative margins followed by radiation therapy to the breast. Multiple studies have shown that patients with

stage I breast cancer treated with BCS have DFS and OS rates similar to patients treated with modified radical mastectomies.[34]

There are only a few true absolute contraindications to BCS, including persistently positive resection margins, multicentric disease, diffuse malignant-appearing microcalcifications, inflammatory breast cancer, a history of prior radiation to the breast or mantle region (for Hodgkin disease), and pregnancy, although it might be possible to perform BCS in the third trimester. Relative contraindications include a history of connective tissue disease suggesting that radiation would be poorly tolerated, centrally located tumors involving the nipple–areolar complex, and a large tumor in a small breast that might lead to a poor cosmetic result. Although the final decision about whether to offer BCS is left to the discretion of surgical colleagues, most patients who do not meet one of the absolute or relative contraindications are offered this surgical approach.

Risk Factors for Ipsilateral Recurrence with Breast-Conserving Surgery

The risk of ipsilateral tumor recurrence ranges from 0.5% to 2.0% per year. Risk factors include age younger than 35 years, an extensive intraductal component, major lymphocytic stromal reaction, peritumoral invasion, positive margins of resection, and presence of tumor necrosis.

Axillary Lymph Node Dissection

Sentinel lymph node biopsy (SLNB) is the standard of care for patients with clinically negative axilla. In accordance with the American College of Surgeons Oncology Group (ACOSOG) Z0011 trial, patients undergoing BCS with T1 or T2 tumors with fewer than three positive sentinel nodes can forgo complete axillary dissection if they are treated with whole-breast irradiation. Otherwise, if a positive sentinel node is identified, complete axillary node dissection should be performed.[35]

Mastectomy

As with stage I disease, multiple studies of patients with T2 tumors treated with either BCS or modified radical mastectomy have documented similar long-term outcomes. Patients with tumors larger than 4 to 5 cm are often not considered to be ideal candidates for BCS because of the potential for residual tumor and poor cosmetic result. These patients are usually treated with neoadjuvant systemic therapy but may still require mastectomy depending on response to treatment.

The historical surgical procedure for locally advanced disease is mastectomy. Clinical trials using neoadjuvant chemotherapy have noted that 50% or more of women with locally advanced breast cancer can be treated with BCS after neoadjuvant therapy.[36] One concern is that women who need to be downstaged with preoperative chemotherapy to be eligible for segmental mastectomy have a higher local failure rate.[37] This can be improved through accurate localization of the tumor using a radiopaque clip, so that the appropriate area of tumor involvement can be resected, even if a complete or near-complete response is achieved with neoadjuvant therapy. Shared decision making is encouraged in which patients understand the outcomes, potential for additional treatment (radiation therapy), and cosmetic implications of each option. Clearly, plastic-reconstructive surgeons are key of the multidisciplinary team, and their early involvement is recommended.

Radiation Therapy

After Breast-Conserving Surgery

Radiation of the breast after this form of surgery is similar in terms of area treated and dose given to the treatment of stage I. Regional nodal irradiation to negative axillary lymph nodes is not routinely given. Some groups recommend irradiation of the supraclavicular fossa or internal mammary chain for those with positive lymph nodes. The American Society of Radiation Oncology (ASTRO) also states that accelerated partial breast irradiation (APBI) may be suitable in carefully selected patients who meet criteria based on age, tumor pathology, and surgical margins.[38]

After Mastectomy

Postmastectomy irradiation should be considered for patients with positive postmastectomy margins, primary tumors larger than 5 cm, or four or more positive lymph nodes. The ASCO clinical care guidelines recommend the routine use of postmastectomy radiation for women with stage III or T3 disease or those with four or more positive lymph nodes.[39] Treatment of the axilla in the absence of gross residual disease, even for patients with multiple positive lymph nodes, is not routinely recommended. At MDACC, high-risk patients who do not fill the postmastectomy radiation criteria are discussed as individual cases in a radiation oncology planning conference to determine the benefit of this approach.

Nodal Disease

Radiation treatment guidelines recommend that patients with locally advanced disease and residual disease in the primary tumor and/or axillary lymph nodes, whether they undergo lumpectomy or mastectomy,

receive comprehensive radiation to the breast and/or chest wall, as well as the internal mammary, axillary apical, and supraclavicular lymph nodes to a total dose of 50 to 60 Gy. Patients who achieve a complete pathological response in the primary tumor and lymph nodes usually receive radiation therapy based on the tumor size and lymph node involvement at presentation; however, given the good outcomes seen in these patients, clinical trials are ongoing to determine the possibility of de-escalation and omitting radiation. The results are eagerly awaited and can be practice changing.

Systemic Therapy

The use of chemotherapy, hormonal therapy, and targeted therapy before or after definitive local therapy has had a significant effect on the management and outcomes of breast cancers. Systemic therapy reduces risk of recurrence and potentially eliminates micrometastatic disease. All women with node-positive disease and a significant percentage of women with node-negative tumors that are hormone receptor negative or larger than 1 cm in size benefit from chemotherapy. The choice of agents to be used for chemotherapy and hormonal therapy should be guided by the patient's age, concomitant medical issues, positive or negative axillary lymph node involvement, and status of the hormone receptors and HER2. Whereas patients with hormone receptor–positive cancers should receive endocrine therapy, those with HER2-positive cancers should receive anti–HER2-targeted therapy. The details of systemic therapy by subtype are discussed later in this chapter.

Selecting the Initial Treatment Strategy

Small node-negative tumors are often treated with upfront surgery followed by adjuvant radiation therapy and/or systemic therapy as indicated. Patients with larger or node-positive tumors often benefit from neoadjuvant systemic therapy.

The concept of giving chemotherapy in the preoperative setting was first evaluated more than 40 years ago for the treatment of patients with locally advanced and inoperable breast cancer. There are multiple possible benefits. One is the ability to downstage a tumor, which would result in making an unresectable tumor operable or enable BCS or segmental mastectomies to be offered to a greater number of patients with operable breast cancer. In addition, there are biological advantages, such as the ability to assess response or resistance to chemotherapy early, delivering the chemotherapy before surgical alterations to the vasculature, and using molecular profiling in conjunction with pathologic response to predict outcomes for patients.

A 1976 study of patients with inflammatory breast cancer showed that two thirds responded to neoadjuvant 5-fluorouracil, doxorubicin, and cyclophosphamide (FAC).[40] In 1978, another study was published addressing the benefit for patients with inoperable breast cancer treated with neoadjuvant chemotherapy. A total of 110 patients were enrolled and were treated with doxorubicin and vincristine. Complete response was seen in 16% of patients, and partial response was seen in 55% of patients. The 36-month survival rates were 53% for the study group and 41% for the historical controls. The positive results of this study led to other trials that confirmed the benefits of the neoadjuvant approach.[41]

The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-18 trial was the largest to date to investigate neoadjuvant chemotherapy. A total of 1523 patients with T1 to T3 and N0 to N1 disease were randomized to receive preoperative versus postoperative Adriamycin and Cyclophosphamide (AC) for four cycles.[42] Results showed a significant increase in lumpectomies in the neoadjuvant group. Final comparison of the two groups showed no difference in DFS or OS at 5 years. This was true for all groups including tumors larger than 5 cm. In a trial that investigated downstaging of axillary nodal metastases after primary chemotherapy,[43] Cox regression analysis showed that one of the parameters associated with poor distant DFS was persistent nodal involvement after neoadjuvant therapy. Thus, it was concluded that the response of the axillary nodes to neoadjuvant chemotherapy was a better predictor than the response of the primary tumor.

In general, neoadjuvant therapy with either anthracycline- or taxane-containing regimens has been shown in multiple trials to result in an increase in the number of women able to undergo BCS.[44] These responses have been well correlated to DFS and OS, making response to preoperative chemotherapy an important prognostic factor in the treatment of patients with early and locally advanced breast cancer. At this time, the majority of neoadjuvant studies have not yet shown an increase in OS for patients treated with this approach compared with the administration of the same systemic therapy postoperatively.

As part of the initial evaluation at MDACC, a radiopaque marker is placed in the breast before the initiation of systemic therapy. Clinical response is documented by serial physical examinations, mammograms, and ultrasounds of the breast and nodal regions. Overall, the response to neoadjuvant therapy regimens depends on the patient's tumors characteristics and the treatment. The tumor effect on the axillary lymph nodes, rather than the response of the primary tumor itself, may be more important in predicting long-term outcome.[45]

Clinical endpoints have been shown to improve with neoadjuvant therapy involving a combined-modality

approach. Patients who are treated with a multimodality treatment approach can achieve excellent long-term survival rates. However, it is clear that those who do not respond to neoadjuvant therapy have poorer outcomes. Women who fail to respond to neoadjuvant anthracycline-based therapy remain free of distant disease in only 30% of cases.[46] The 2014 Collaborative Trials in Neoadjuvant Breast Cancer (CTNeoBC) meta-analysis found that pathological complete response (pCR), defined as ypT0 ypN0 or ypT0(is) ypN0, is associated with improved survival and that this correlation is strongest among patients with TNBC (OS hazard ratio [HR], 0.16; 95% confidence interval [CI], 0.11–0.25) and hormone receptor–negative/HER2+ tumors (OS HR, 0.08 ; 95% CI, 0.03–0.22).[47]

SYSTEMIC THERAPY FOR HORMONE RECEPTOR–POSITIVE/ HER2-NEGATIVE BREAST CANCER

Node Negative

Multigene assays can help quantify a patient's risk of breast cancer recurrence.[48] Onco*type* DX is a commercially available, validated laboratory test performed on a tumor specimen that analyzes 21 genes associated with receptor expression, proliferation, invasion, and other factors. Calculations based on the expression of these 21 genes result in a recurrence score that relays the likelihood of breast cancer recurrence in the first 10 years after diagnosis if the patient receives 5 years of tamoxifen.[49] These studies found that patients with recurrence scores less than 11 have an excellent prognosis and do not benefit from chemotherapy, but those with high recurrence scores (>25) are likely to benefit from chemotherapy. For women with intermediate recurrence scores, the benefit of chemotherapy was initially uncertain. To elucidate the benefit of systemic cytotoxic therapy for this middle group, the Eastern Cooperative Oncology Group (ECOG) designed a trial known as TAILORx (Trial Assigning Individualized Options for Treatment).[50] This study randomly assigned women with node-negative, HER2-negative, hormone receptor–positive early breast cancer with a midrange recurrence score[11–25] to treatment with either hormonal therapy or chemotherapy followed by hormonal therapy. Among women with intermediate recurrence scores, endocrine therapy was noninferior to chemotherapy followed by endocrine therapy. However, a subgroup analysis showed evidence of some benefit in women 50 years of age or younger with recurrence scores of 16 to 25.[51] An update to TAILORx published in 2019 also incorporated clinical risk as defined by tumor size and histologic grade to guide adjuvant therapy selection. Investigators found no benefit from chemotherapy for women aged 50 or younger with a recurrence score of 16 to 20 and low clinical risk. However, there was a chemotherapy benefit for premenopausal women aged 46 to 50 years and a trend toward benefit in women aged 41 to 45 years. This benefit was thought by some to be due to the -induced menopause; however, the trial was not designed to test this hypothesis.[52] The MammaPrint assay, discussed in more detail later, can also be used to assess risk of recurrence.

Node Positive

Recently, investigators have attempted to use genomic assays to guide adjuvant systemic therapy in patients with limited nodal disease. A comprehensive review of evidence regarding use of Oncotype DX in node-positive hormone receptor–positive, HER2-negative breast cancer found that the testing consistently identifies patients at low risk for recurrence in whom chemotherapy can be avoided without negatively affecting outcomes.[53] In the Microarray in Node-Negative and 1-3 Positive Lymph Node Disease May Avoid Chemotherapy (MINDACT) trial, a randomized phase III study of women with node-negative and node-positive (up to three positive axillary nodes) early-stage breast cancer, the 70-gene signature assay MammaPrint was used in combination with clinical risk to guide adjuvant treatment. Patients with discordant genomic and clinical risk results were randomized to receive chemotherapy or no chemotherapy. Among women with high clinical risk and low genomic risk for recurrence who received chemotherapy, 5-year survival without distant metastasis was 1.5% higher than the 5-year survival among women with a similar risk profile who did not receive chemotherapy.[54] Clinicians should discuss the potential risk and benefits of chemotherapy with patients who fall into this category.

Chemotherapy

Neoadjuvant

As mentioned previously, neoadjuvant chemotherapy in appropriately selected patients can improve surgical outcomes and provide information regarding response to therapy that can be used to assess risk of recurrence. The same chemotherapy regimens used in the adjuvant setting (outlined later) can be used in the neoadjuvant setting. However, the response rates to neoadjuvant chemotherapy are lower among patients with hormone receptor–positive tumors.[47]

Adjuvant

The choice of agents to be used for chemotherapy should be guided by the patient's age, concomitant medical issues, and positive or negative axillary lymph

node involvement. Estimation of risk of recurrence and death should be assessed. As noted in the previous section, Oncotype DX, MammaPrint, and other assays can help stratify risk for hormone receptor–positive patients.[48]

Historical Perspective

Studies in the 1960s and 1970s evaluated whether single-agent chemotherapy after local therapy had any benefit compared with observation alone. Most reports documented that single agents have modest or no effect on DFS. Subsequently, the focus shifted to polychemotherapy, with most trials evaluating variations of the three-drug regimen of cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) or similar anthracycline-containing regimens.[55,56]

These polychemotherapy regimens clearly showed a greater benefit in DFS and OS, but it was often unclear to clinicians which regimens were superior or equivalent. The Oxford Overview in 1998 helped clarity this issue by reviewing data from about 18,000 women in 47 trials that compared polychemotherapy or no chemotherapy, about 6000 women in 11 trials that compared longer versus shorter polychemotherapy, and about 6000 women in 11 trials of anthracycline-containing regimens versus CMF.[57] The final interpretation concluded that adjuvant polychemotherapy was more effective than monotherapy, and anthracycline-based regimens reduced risk of recurrence by 12% compared with CMF. Data from the Oxford Overview in subsequent years also demonstrated that the addition of taxanes adds the efficacy of anthracycline-based regimens. However, sequential administration of anthracycline and taxane are better tolerated than concurrent administration.

The ECOG E1199 trial attempted to define the more effective adjuvant taxane and the optimal schedule of administration.[58] All patients received a standard dose and schedule of AC and were randomized to receive paclitaxel (175 mg/m^2) every 3 weeks for four cycles, paclitaxel (80 mg/m^2) every week for 12 doses, docetaxel (100 mg/m^2) every 3 weeks for four cycles, or docetaxel (35 mg/m^2) every week for 12 doses. Weekly paclitaxel compared with every 3 weeks was better, with an odds ratio of 1.27 for DFS (P =.006) and 1.32 for OS (P =.01). No significant difference existed between paclitaxel and docetaxel. Paclitaxel every 3 weeks was no longer recommended after this trial (Fig. 35–1).

The US09735 trial was a randomized study that compared four cycles of standard-dose AC with four cycles of docetaxel (75 mg/m^2) and cyclophosphamide (TC) (600 mg/m^2). Most patients (84.3%) were younger than 65 years old, and 48% had node-negative disease. At a median follow-up of 7 years, there

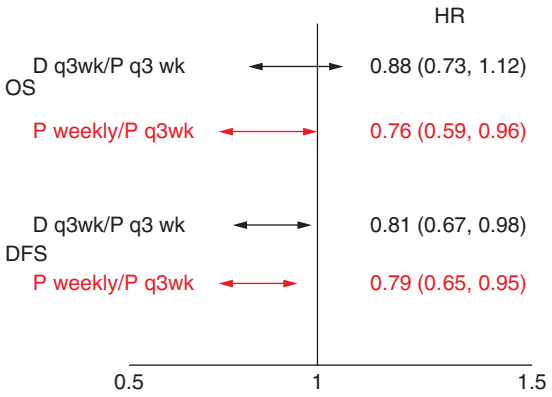

FIGURE 35-1 Results of Eastern Cooperative Oncology Group E1199: optimal adjuvant taxane and optimal schedule of administration. D, docetaxel; DFS, disease-free survival; HR, hazard ratio; OS, overall survival; q, every; P, paclitaxel. (Data from Sparano JA, Wang M, Martino S, et al: Weekly paclitaxel in the adjuvant treatment of breast cancer, *N Engl J Med* 2008 Apr 17;358(16):1663-1671.)

was a significant difference in DFS between TC and AC (81% vs 75%; HR, 0.74). Additionally, there was a significant difference in OS (87% vs 82%). Febrile neutropenia in older patients was 8% with TC and 4% with AC.[59] The Anthracyclines in Early Breast Cancer (ABC) Trials were a series of three trials of women randomized to six cycles of TC or a taxane in addition to AC. Data from these trials showed 88.2% 4-year invasive DFS for women who received TC and 90.7% invasive DFS for those received paclitaxel and AC. Subgroup analysis shows that TC may have more similar efficacy to AC and paclitaxel among patients with hormone receptor–positive tumors. However, there is a definite benefit to AC and paclitaxel among patients with hormone receptor–negative tumors.[60]

Dose Density

One approach to increase response rate to chemotherapy is dose density. This term refers to the administration of chemotherapeutic agents with a shortened interval between treatments based on the knowledge that a given dose always kills a particular fraction of cancer cells. More frequent administration of cytotoxic therapy may thus be more efficacious than dose escalation to reduce tumor burden. Several trials have explored dose-density regimens. The Cancer and Leukemia Group B (CALGB) 9741 trial explored the possible superiority of dose-dense over conventional scheduling of adjuvant chemotherapy for node-positive breast cancer.[61] Patients were randomly assigned to receive AC and paclitaxel (175 mg/m^2) either in 2- or 3-week schedules, with growth factor support provided to the dose-dense schedule. At a median follow-up period of 36 months, dose-dense treatment

improved DFS from 75% in the 3-week arm to 82% in the dose-dense arm (P =.01). OS was also improved (92% with every 2 weeks vs 90% with every 3 weeks; P =.013).

As noted in the Historical Perspective section, E1199 demonstrated a significant improvement of weekly paclitaxel over paclitaxel every 3 weeks.[58] It is not clear whether the benefit demonstrated in CALGB 9741 is from the dose-dense nature of the anthracycline or the taxane schedule. Additionally, NSABP B-38 found no significant difference in outcomes between TAC for six cycles and dose-dense AC with weekly paclitaxel.[62] Last, the SWOG SO0221 trial compared weekly paclitaxel (80 mg/m^2) versus dose-dense paclitaxel (175 mg/m^2) in patients with node-positive breast cancer who had already received AC.[63] The results showed equivalent 5-year PFS between the weekly (82%) and biweekly regimens (81%). The weekly schedule was less toxic and did not require growth factor supplementation.

Endocrine Therapy

The correlation between the endocrine system and breast cancer was first recognized more than 100 years ago. Beatson[64] first described bilateral oophorectomy in treating inoperable cases of breast cancer. However, the true understanding of the biological mechanisms that cause estrogen to stimulate the growth of hormone receptor–positive tumors is more recent. Jensen first identified the ER and led subsequent cloning of ER and PR.[65] This knowledge has enabled the development of multiple therapies. Many of these therapies have varying mechanisms of action. Selective estrogen receptor modulators compete with estrogen for binding ER. Selective estrogen receptor downregulators cause degradation of ER upon binding. Aromatase inhibitors (AIs) inhibit conversion of androgens to estrogens. Ovarian ablation and suppression result in estrogen deprivation. However, all endocrine therapies have the common goal of decreasing estrogen availability for hormone receptor–positive tumors. When selecting an appropriate endocrine therapy for a patient, it is important to know the patient's menopausal status.

Tamoxifen

In the late 1970s, tamoxifen was shown to be effective for the treatment of patients with metastatic breast cancer. This form of treatment was well received because data from trials showed that patients experienced fewer side effects than they did with traditional chemotherapy or with old-fashioned endocrine therapy (high-dose estrogens, androgens, adrenalectomy, or hypophysectomy). The proven efficacy of tamoxifen in the metastatic setting enabled its study for adjuvant use.

Tamoxifen was the first targeted drug to be used as an endocrine treatment for patients with early breast cancer. An early placebo-controlled trial Nolvadex Adjuvant Trial Organization (NATO) of tamoxifen as adjuvant therapy for patients with early breast cancer, NATO, showed that 2 years of tamoxifen treatment reduced treatment failure at 21 months compared with control (14.2% vs 20.5%, respectively).[66] Since then, the efficacy of tamoxifen in the adjuvant treatment of patients with primary breast cancer has been demonstrated repeatedly.

Since tamoxifen became available more than 40 years ago, a large number of trials have investigated its efficacy and tolerability in the treatment of patients with primary breast cancer. Although some individual trials are too small to justify firm conclusions, a meta-analysis has increased confidence in the effectiveness of tamoxifen in improving DFS and OS. Additionally, large cooperative group (NSABP B-14) and international randomized trials (Stockholm and Scottish trials) of tamoxifen versus placebo have demonstrated a clear benefit in DFS and OS.[67–69]

An overview of 55 trials studying adjuvant tamoxifen for 1, 2, or 5 years versus no treatment in patients with primary breast cancer showed that tamoxifen treatment produced highly significant benefits in terms of both recurrence of first events and mortality in the hormone receptor–positive population. The reductions in recurrence were 21%, 28%, and 50%, and the reductions in death rate were 14%, 18%, and 28% for 1, 2, and 5 years of tamoxifen treatment, respectively (P <.00001 for each). Tamoxifen treatment for 1, 2, and 5 years also reduced the incidence of contralateral breast cancer by 13%, 26%, and 47%, respectively.[70] The benefits occurred almost exclusively in the hormone receptor–positive population. Tamoxifen improves the 10-year survival rate of women who have ER-positive or ER-unknown tumors.

As noted in the Chemotherapy section, the addition of chemotherapy in intermediate- or high-risk groups is recommended. It was not until recently that the appropriate sequence of chemotherapy and hormonal therapy was definitively documented. One difficulty was that evidence had existed in experimental systems that tamoxifen could antagonize the cytotoxic effects of particular chemotherapeutic agents.

One particular study was designed to address the specific timing of tamoxifen therapy.[55] Patients were divided among three groups: tamoxifen alone, FAC chemotherapy followed by tamoxifen, and concomitant FAC and tamoxifen. Patients were followed up for a median of 8.5 years. The estimated DFS was 67% in the sequential treatment group compared with 62% in the concurrent treatment group.

Aromatase Inhibitors

First Line

Although tamoxifen has proven efficacy for the treatment of patients with hormone receptor–positive breast cancer both alone and in combination with chemotherapy, its usefulness is in part curtailed by its partial estrogen agonist activity. The documented negative secondary effects of tamoxifen include an increased incidence of endometrial cancer, uterine sarcoma, and thromboembolic disease. Thus, there is great interest in exploring other endocrine therapies.

In women whose ovarian function has ceased, the primary remaining estrogen source is the conversion of adrenal androgens to estrogens in peripheral tissues by the cytochrome P450 enzyme aromatase. AIs reduce the availability of estrogen by inhibiting the aromatase enzyme and are indicated for the treatment of breast cancer in postmenopausal women whose ovarian function has ceased.[71] Selective AIs, including anastrozole, letrozole, and exemestane, are now available for the treatment of metastatic breast cancer and in the adjuvant setting. Common side effects of all AIs include hot flashes, osteoporosis, arthritis, and joint and muscle pains.

Based on the antitumor activity of the third-generation AIs in the setting of metastatic disease, these drugs were evaluated in the adjuvant setting. The ATAC (Arimidex [anastrozole], Tamoxifen, Alone or in Combination) trial was a double-blind, multicenter study of postmenopausal women with invasive operable breast cancer who had completed primary therapy and were eligible for adjuvant treatment. They were randomized to tamoxifen, anastrozole, or a combination of the two.[72] Time to recurrence was significantly longer with anastrozole versus tamoxifen in the overall population, with a larger benefit seen in the hormone receptor–positive population. A reduction in the incidence of contralateral breast cancers favored anastrozole, with statistical significance in the hormone receptor–positive population. The DFS estimates at 4 years were 86.9% and 84.5% for anastrozole and tamoxifen, respectively.[73]

Anastrozole was associated with significantly fewer withdrawals from treatment than tamoxifen (21.9% vs 26.0%; P =.0002) and significantly fewer withdrawals because of adverse events (7.8% vs 11.1%; P <.0001). Anastrozole also resulted in a lower incidence of hot flashes, vaginal discharge, and vaginal bleeding (P <.0001 for each); of ischemic cerebrovascular events and thromboembolic events (P =.0006 for each), including deep venous thrombosis (P =.02); and of endometrial cancer (P =.02). Tamoxifen resulted in a lower incidence of musculoskeletal disorders (including myalgias and arthralgias) and fractures (P <.0001 for both). The tolerability results in the updated analysis showed no major difference from those seen in the first analysis.[74]

A meta-analysis published in 2010 reviewed the use of AIs versus tamoxifen in postmenopausal women with ER-positive tumors. This review compared AIs as initial monotherapy with tamoxifen monotherapy or as a hormone switch after 2 to 3 years of tamoxifen for a total of 5 years. The conclusion was that AI therapy was associated with a lower rate of recurrence when used as an initial monotherapy or after 2 to 3 years of tamoxifen compared with tamoxifen monotherapy.[75]

Sequential

It is postulated that tamoxifen might stop being effective because breast cancer cells develop resistance to tamoxifen, dependence on tamoxifen, or great sensitivity to circulating estrogen. Consequently, the use AIs after tamoxifen was investigated. The MA-17 trial showed that the addition of letrozole after 5 years of tamoxifen resulted in a significant improvement in DFS.[76]

The Breast International Group (BIG) 1-98 trial compared letrozole with tamoxifen in postmenopausal hormone receptor–positive women and was later amended to include two sequential strategies using letrozole either before or after tamoxifen for a total of 5 years. The results showed that upfront AI reduced the risk of recurrence and improved DFS better than upfront tamoxifen and better than either switching strategy.[77,78]

Another double-blind randomized trial investigated the use of exemestane to complete the 5 years of adjuvant endocrine treatment after 2 to 3 years of tamoxifen in postmenopausal women with primary breast cancer.[79] Exemestane demonstrated an absolute benefit in DFS of 4.7%.

Duration of Therapy

In general, outcomes with antiestrogen therapies are hindered by noncompliance, with 20% to 50% nonadherence rates. This is the same difficulty faced in other disease states, and a cancer diagnosis does not necessarily command optimal compliance with oral therapy. Many barriers influence compliance, including medication cost, access to mail-order pharmacies, and a lack of understanding of the benefits of such medicine. A population-based study performed in British Columbia noted that adherence was still difficult even when these oral agents were given free of charge in a country with a national formulary system. Patients who are prescribed oral medication should be followed regularly, and compliance should be reinforced as highly important, as shown in multiple studies, even when drug cost is not a barrier.[80]

Further clarification of the optimal treatment duration of tamoxifen was investigated in two large trials: ATTOM (Adjuvant Tamoxifen Treatment Offers More) and ATLAS (Adjuvant Tamoxifen—Longer Against Shorter). The ATLAS trial enrolled women with early breast cancer who had completed 5 years of tamoxifen and randomly assigned the women to either continue tamoxifen for 10 years or stop at 5 years.[81] The risk of recurrence during years 5 to 14 was 21.4% versus 25.1% for women who continued tamoxifen versus those who did not. The breast cancer mortality rates during years 5 to 14 for women who continued tamoxifen versus the control group were 12.2% and 15.0%, respectively. Pulmonary embolus and endometrial cancer occurred significantly more frequently in the extended tamoxifen group (Fig. 35–2).

The ATTOM trial had a similar design to ATLAS.[82] Women randomized to continue tamoxifen, versus those who stopped tamoxifen, had significantly less breast cancer recurrence (580 of 3468 patients vs 672 of 3,85 patients; P =.003) and significantly decreased breast cancer mortality (392 of 3468 patients vs 443 of 3485 patients; P =.050). Combining the two trials strengthens the statistical significance of recurrence (P <.0001), breast cancer mortality (P =.002), and OS (P =.005).

The MA.17R trial compared extended AI therapy with placebo in 1918 women who had already received 5 years of AI therapy, including those who received prior tamoxifen. Although extended AI therapy was not associated with improved OS, it was significantly associated with improved 5-year DFS (95% vs 91%) and a lower annual incidence of contralateral breast cancer (0.21% vs 0.49%).[82] Current ASCO clinical practice guidelines recommend that women with node-positive breast cancer be offered extended adjuvant endocrine therapy, including an AI, for up to 10 years. These recommendations are based on six studies comparing extended AI treatment with placebo. Clinicians should consider the potential side effects of long-term endocrine therapy, such as decreased bone density, and how individual patients tolerate therapy when deciding whether to continue extended treatment.

Additionally, ASCO recommends that women with node-negative breast cancer should consider extended therapy based on their individual recurrence risk as determined by established prognostic factors.[84]

Ovarian Ablation and Suppression

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overviews in 1990 showed that chemotherapy in combination with tamoxifen had a beneficial effect in premenopausal women. The 1998 EBCTCG overview[70] showed that the benefits of chemotherapy combined with tamoxifen in patients with ER-positive disease occurred irrespective of age or menopausal status. The benefits of chemotherapy in terms of contralateral breast cancer and improved survival also occurred irrespective of age or menopausal status.

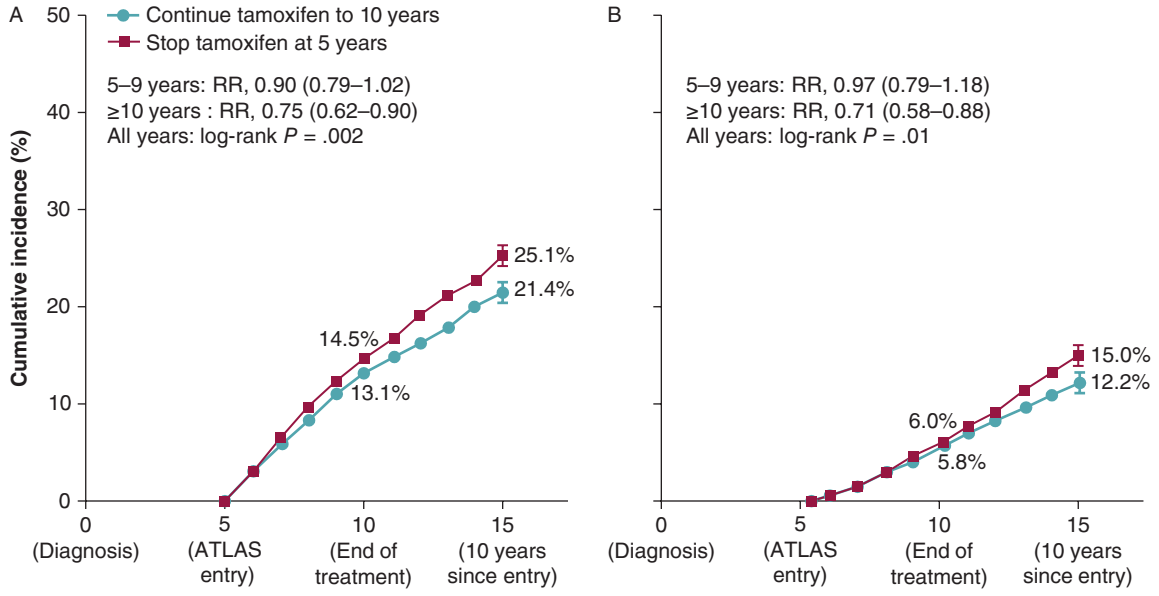

FIGURE 35-2 **ATLAS (Adjuvant Tamoxifen—Longer Against Shorter) trial studying 5 years versus 10 years of tamoxifen with respect to recurrence (A) and breast cancer mortality (B). RR, relative risk. (Reproduced with permission from Davies C, Pan H, Godwin J, et al. Long-term effects of continuing adjuvant tamoxifen to 10 years versus stopping at 5 years after diagnosis of oestrogen receptor-positive breast cancer: ATLAS, a randomised trial. *Lancet*. 2013 Mar 9;381(9869):805-816.)**

The 1996 meta-analysis by the EBCTCG demonstrated that for women younger than age 50 years, there was a distinct advantage in OS and DFS when they were treated with ovarian ablation versus no adjuvant therapy. In addition, the outcomes for these patients were similar to those who received the CMF regimen. The Zoladex Early Breast Cancer Research Association (ZEBRA) trial displayed similar results in hormone receptor–positive patients when comparing a luteinizing hormone–releasing hormone analog, goserelin, with CMF.[85]

The Supression of Ovarian Function Trial (SOFT) and Tamoxifen adn Exemestane Trial (TEXT) trials were designed to determine the value of the addition of adjuvant ovarian suppression to tamoxifen or exemestane in premenopausal patients with hormone receptor–positive breast cancer. The patients were randomized to receive tamoxifen, tamoxifen plus ovarian suppression, or exemestane plus ovarian suppression for 5 years (Table 35–5). In the total population, the addition of ovarian suppression to tamoxifen did not produce a significant benefit. However, in the high-risk cohort who received chemotherapy (most of whom had lymph node involvement), ovarian suppression plus tamoxifen improved 5-year DFS when compared with tamoxifen alone (HR, 0.78; 95% CI, 0.60–1.02). The combined analysis also showed that 5-year DFS with adjuvant endocrine therapy with exemestane was significantly more effective than tamoxifen when ovarian suppression was added (HR, 0.65; 95% CI, 0.49–0.87). The benefit of ovarian suppression was also more pronounced in patients who were younger than age 35 years. Longer follow-up is needed to evaluate survival data.[86,87] Given the results of the TEXT and SOFT trials, we recommend discussing ovarian suppression therapy with premenopausal patients, particularly high-risk patients. It is important to mention that ovarian suppression does come at significant costs because the adverse effects are not trivial. In these trials, women receiving ovarian suppression developed significant hot flashes, vaginal dryness, depression, sexual dysfunction, and possible long-term health implications such as hypertension, diabetes, and osteoporosis.

SYSTEMIC THERAPY FOR TRIPLE-NEGATIVE BREAST CANCER

Principles of Treatment

Cytotoxic chemotherapy remains the most effective systemic therapy for TNBC. Third-generation regimens including anthracyclines and taxanes are considered to be preferred and are associated with improved outcomes compared with anthracycline or taxane-only regimens. Current National Comprehensive Cancer Network (NCCN) guidelines recommend chemotherapy for all patients with TNBC with tumors larger than 1 cm.[88]

Neoadjuvant Therapy

As noted earlier in this chapter, neoadjuvant chemotherapy can improve surgical outcomes while also allowing clinicians to assess treatment response. The cornerstone of treatment of TNBC is chemotherapy, specifically, anthracycline- and taxane-based regimens. Two major studies sought to determine the efficacy of a platinum-containing neoadjuvant chemotherapy regimens in TNBC. The GeparSixto trial randomly assigned untreated patients with stage II and III TNBC to receive paclitaxel and liposomal doxorubicin with or without carboplatin. The pCR rate with carboplatin was 53.2% vs 36.9% without carboplatin.[89] The CALBG 40603 study compared outcomes in patients in with stage II and III untreated TNBC who received paclitaxel with or without carboplatin followed by dose-dense AC with or without bevacizumab. The addition of carboplatin increased the rate of pCR; however, the addition of carboplatin or bevacizumab did not improve long-term outcomes.[90] Although the routine use of platinum is not generally recommended by current guidelines, its use can be useful in high-risk patients in whom optimal local control is paramount. When making the individualized decision of using carboplatin in addition to an anthracycline and taxane-based regimen, consideration to side effects is crucial given the

increased side effects associated with the addition of carboplatin.

Although immunotherapy has not shown much activity across all breast cancer subtypes, trials of immunotherapy in TNBC have shown promise. The KEYNOTE-522 trial investigated the efficacy of the anti–PD-1 (programmed cell death protein 1) monoclonal antibody pembrolizumab in women with early-stage TNBC. Investigators randomized patients with untreated stage II and III TNBC to receive neoadjuvant therapy with either four cycles paclitaxel and carboplatin plus either pembrolizumab or placebo followed by an additional four cycles of pembrolizumab or placebo. Patients in both groups received either AC or Epirubicin and cyclophosphamide (EC). A total of 64.8% of patients who received pembrolizumab with chemotherapy achieved pCR compared with 51.2% of patients in the placebo–chemotherapy group. With a median follow-up period of 15.5 months, 7.4% of patients in the pembrolizumab–chemotherapy group and 11.8% of patients in the placebo–chemotherapy group had disease progression, local or distant recurrence, or second primary tumor or died from any cause.[91] Although immunotherapy is not currently approved by the Food and Drug Administration (FDA) for treatment of patients with early-stage TNBC, there is growing evidence of its potential to improve outcomes.

Adjuvant Therapy

The use of anthracycline and taxane-based regimens in the adjuvant setting has been well established. However, until recently, it was not known if any systemic therapy should be given to patients who received neoadjuvant therapy but did not achieve pCR by time of surgery. The Capecitabine for Residual Cancer as Adjuvant Therapy (CREATE-X) trial randomized patients with HER2-negative residual invasive breast cancer after neoadjuvant chemotherapy with an anthracycline and/or a taxane to receive standard postsurgical therapy with or without capecitabine (Fig. 35–3). DFS at 5 years was 74.1% versus 67.6% for capecitabine vs control group, respectively. In a subgroup analysis among patients with TNBC, DFS for the capecitabine group was 69.8% compared with 56.1% for the control group. OS was also improved in the capecitabine group (78.8% vs 70.3%)[92](Fig. 35–4). Additionally, a 2019 meta-analysis showed improved DFS and OS among patients with early-stage TNBC treated with

anthracyclines and taxanes who received adjuvant capecitabine.[93] The NCCN and ASCO guidelines recommend considering six to eight cycles of adjuvant capecitabine for patients with TNBC and residual disease after neoadjuvant chemotherapy.

SYSTEMIC THERAPY FOR HORMONE RECEPTOR–NEGATIVE AND HER2-POSITIVE BREAST CANCER

Principles of Treatment

The advent of anti-HER2 targeted therapy has significantly improved outcomes in patients with HER2-positive breast cancer and is now a backbone of treatment. Numerous trials have demonstrated that trastuzumab improves DFS and OS. The Herceptin Adjuvant (HERA) trial study team was designed to answer the question regarding the optimal duration of trastuzumab. Patients were assigned to observation or 1 or 2 years of trastuzumab. Patients were allowed a variety of standard neoadjuvant or adjuvant chemotherapies and had node-positive or high-risk node-negative disease. A recent update includes mature data from patients receiving trastuzumab for 2 years. Comparing 1 year of trastuzumab versus observation revealed an HR of 0.76 (95% CI, 0.67–0.86; P <.0001) for DFS and 0.76 (95% CI, 0.65–0.88; P =.0005) for OS despite significant (52%) crossover. No significant differences in DFS or OS were noted between the 1- and 2-year groups.[32]

The Protocol for Herceptin as Adjuvant therapy with Reduced Exposure (PHARE) trial and PERSEPHONE trials also attempted to answer the appropriate duration for trastuzumab by comparing 6 versus 12

months of adjuvant therapy. After a median follow-up period of 42.5 months in the PHARE trial, the 2-year DFS rate was 93.8% for the 12-month group versus 91.1% for the 6-month group, with an HR of 1.28 (95% CI, 1.05–1.56).[94] In the PERSEPHONE trial, DFS for 6 months of adjuvant trastuzumab was noninferior to 12 months (HR, 1.07; 95% CI, 0.93–1.24).[95] Currently, 1 year of trastuzumab remains standard of care.

Patients who have hormone receptor–positive and HER2-positive breast cancer should also receive adjuvant endocrine therapy as outlined earlier in this chapter.

Node-Positive Disease

Adjuvant Therapy

Trastuzumab is a high-affinity humanized monoclonal antibody that recognizes the *HER2/neu* receptor and is a targeted therapeutic for tumors that overexpress this growth factor receptor. Trastuzumab has been evaluated extensively in the *HER2/neu*-overexpressing metastatic setting and has been shown to be effective as a single agent both before[96] and after chemotherapy[97] and in combination with multiple agents.[98] One notable side effect has been a high rate of cardiotoxicity, particularly when trastuzumab is combined with anthracycline-based chemotherapy. This is partly because of overlapping toxicities and the long half-life of trastuzumab (up to 32 days). The toxicity rarely occurs in patients without a history of cardiac disease and not previously or simultaneously exposed to chemotherapy, especially anthracyclines.[99]

The NSABP B-31 and North Central Cancer Treatment Group (NCCTG) N9831 trials randomized patients to receive AC plus paclitaxel with the addition of trastuzumab versus placebo. The joint analysis of these trials showed an absolute difference in DFS of 12% at 3 years and a 33% reduction in the risk of death (P =.015).[100] An updated analysis with a mean time of 8.4 years in the study showed a 37% relative improvement in OS (95% CI, 0.54–0.73; P <.001) and an increase in 10-year OS from 75.2% to 84%.[101]

The Breast Cancer International Research Group (BCIRG) 006 trial was designed to evaluate the efficacy and safety of docetaxel and carboplatin plus 52 weeks of trastuzumab (TCH).[33] Patients were randomly assigned to standard doses of AC followed by docetaxel (100 mg/m^2) every 3 weeks (AC-T), the same regimen plus 52 weeks of trastuzumab (AC-TH), or docetaxel (75 mg/m^2) and carboplatin (area under the curve [AUC], 6 mg/mL/min) plus 52 weeks of trastuzumab (TCH). At a median follow-up period of 65 months, the 5-year estimated DFSs were 75% for patients receiving AC-T, 84% with AC-T, and 81% with TCH. Estimated rates of OS were 87%, 92%, and 91%, respectively. All trastuzumab regimens were statistically superior for DFS and OS to the nontrastuzumab regimen. The trial was not designed to evaluate differences in both DFS and OS between AC-TH and TCH. Rates of cardiac dysfunction were significantly higher with AC-TH compared with TCH (P =.001).

Neoadjuvant Therapy

The addition of trastuzumab to standard chemotherapy when given preoperatively has been shown to have improved pCR.[102] Additionally, neoadjuvant therapy has helped accelerate approval of promising drugs because clinical and pathologic responses can be quickly obtained. At MDACC, when we treat patients with TNBC and HER2-positive tumors, we favor the use of neoadjuvant chemotherapy.

Dual Therapy

A number of trials have investigated dual blockade of HER2 signaling. Pertuzumab is a monoclonal antibody that inhibits dimerization with other HER receptors, notably HER3, and binds to an independent domain from trastuzumab. With impressive results in the metastatic setting,[103] pertuzumab was studied in the neoadjuvant setting. The NeoSphere trial was designed to evaluate the safety and efficacy of pertuzumab along with trastuzumab in locally advanced, inflammatory, and early HER2-positive breast cancer.[104] The phase II study randomly assigned patients to four treatment groups: trastuzumab plus docetaxel (75 mg/m,^{2} escalating if tolerated to 100 mg/m,^{2} every 3 weeks), pertuzumab (loading dose of 840 mg followed by 420 mg every 3 weeks) and trastuzumab plus docetaxel, pertuzumab plus trastuzumab, or pertuzumab plus docetaxel. After completing this regimen, all patients underwent surgery and then received 5-fluorouracil (600 mg/m^2), epirubicin (90 mg/m^2), and cyclophosphamide 600 mg/m^2) (FEC) every 3 weeks. Patients receiving dual HER2-targeted therapy with docetaxel achieved a pCR of 45.8% compared with 29.0% among patients receiving trastuzumab and docetaxel alone (see Fig. 35–2).

The TRYPHAENA trial was a phase II study that explored the tolerability and efficiency of pertuzumab and trastuzumab given with three different chemotherapy regimens.[105] A total of 225 patients were randomized to receive one of the following regimens FEC (doses of 500 mg/m,^{2}100 mg/m,^{2}600 mg/m^2 respectively) with trastuzumab and pertuzumab followed by docetaxel (FEC + H + P × 3 → T + H + P × 3; arm A), FEC followed by docetaxel plus pertuzumab and trastuzumab all at same dose and schedule as (FEC → T+H+P × 3; arm B), or carboplatin (AUC, 6) and docetaxel plus pertuzumab and trastuzumab (TCHP × 6; arm C). Upon completion of chemotherapy, all

patients underwent surgery and then received adjuvant trastuzumab to complete 1 full year. pCR rates were 50.7%, 45.3%, and 51.9% in arms A, B, and C, respectively. Eleven patients experienced a decline in left ventricular ejection fraction to less than 50%, and diarrhea was the most common adverse event.

Given the results of these phase II trials, the FDA granted accelerated approval of pertuzumab in combination with docetaxel for neoadjuvant therapy for patients with tumors of at least 2 cm or node-positive, HER2-positive breast cancer.

The Adjuvant Pertuzumab and Herceptin in Initial Therapy in Breast Cancer (APHINITY) evaluated the impact of pertuzumab in the adjuvant setting, randomizing women with early HER2-positive breast cancer to receive trastuzumab-based chemotherapy in addition to either pertuzumab or placebo. Women who received pertuzumab showed improved 3-year DFS compared with women who received trastuzumab alone (94.1% vs 93.2%). This benefit was more evident among patients with nodal involvement in subgroup analysis (87.9% vs 83.4%).[105,106] Current ASCO guidelines state that adjuvant pertuzumab is preferred in patients with nodal disease and discouraged in patients with node-negative disease, with the exception of high-risk node-negative disease, such as T4N0.

Lapatinib, a dual tyrosine kinase inhibitor, improved progression-free survival when given with capecitabine in the metastatic setting.[108] In the Neoadjuvant Lapatiib and/or Trastuzumab Treatment Optimization Study (NeoALTTO) trial, trastuzumab and lapatinib (1000 mg orally daily) were investigated in the neoadjuvant setting. The pCR was significantly higher with both medications (51.3%) versus trastuzumab alone (29.5%; difference 21.1%, 9.1–34.2%; P =.0001).[109] The interest in lapatinib was blunted by the first results from the ALTTO trial.[110] The four-arm trial compared 1 year of lapatinib alone, trastuzumab alone, or both agents in sequence or in combination. After 4.5 years of follow-up, DFS was not significantly different between the patients receiving trastuzumab alone versus the patients receiving the combination. This was surprising given the doubling of the pCR rate seen in NeoALTTO. Lapatinib is not approved by the FDA to be use in the early-stage setting.

After Neoadjuvant Therapy

The KATHERINE trial sought to improve outcomes in patients with early HER2-positive breast cancer and residual disease after neoadjuvant therapy. Patients were randomly assigned to receive adjuvant trastuzumab emtansine (T-DM1) or trastuzumab for 14 cycles (Fig. 35–5). Invasive DFS was better among patients who received T-DM1 compared with those with trastuzumab (88.3% vs 77%), with an HR of 0.5 (95% CI, 0.39–0.64)110 (Fig. 35–6). T-DM1 is now FDA approved and has a category 1 recommendation for adjuvant treatment for residual disease in patients with HER2-positive breast cancer.

Extended Therapy

The Extended Adjuvant Treatment of Breast Cancer with Neratinib (ExteNET) trial demonstrated that treatment with 1 year of neratinib, a potent tyrosine kinase inhibitor, after completion of trastuzumab-based adjuvant therapy improved 2-year invasive DFS.

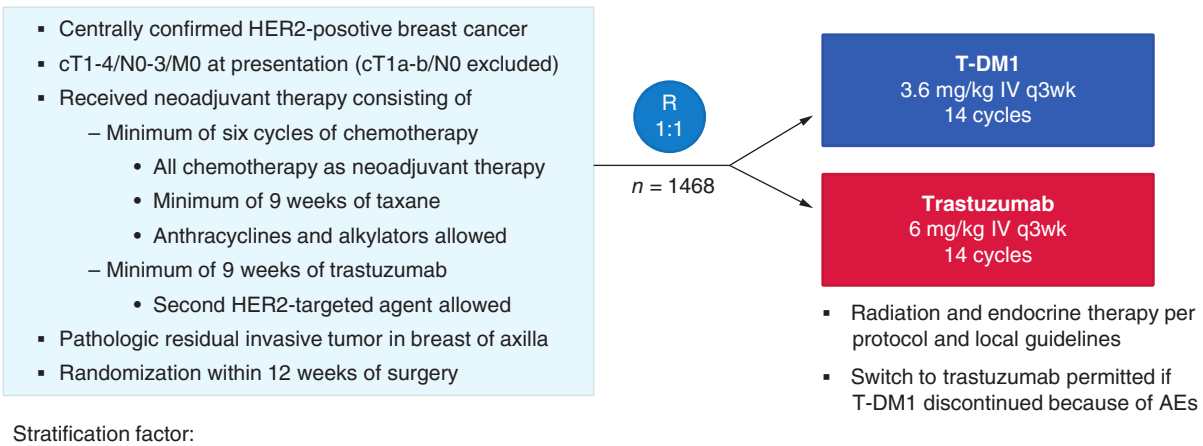

FIGURE 35-5 **KATHERINE trial design. AE, adverse event; ER, estrogen receptor; q, every; PR, progesterone receptor; T-DM1, trastuzumab emtansine.**

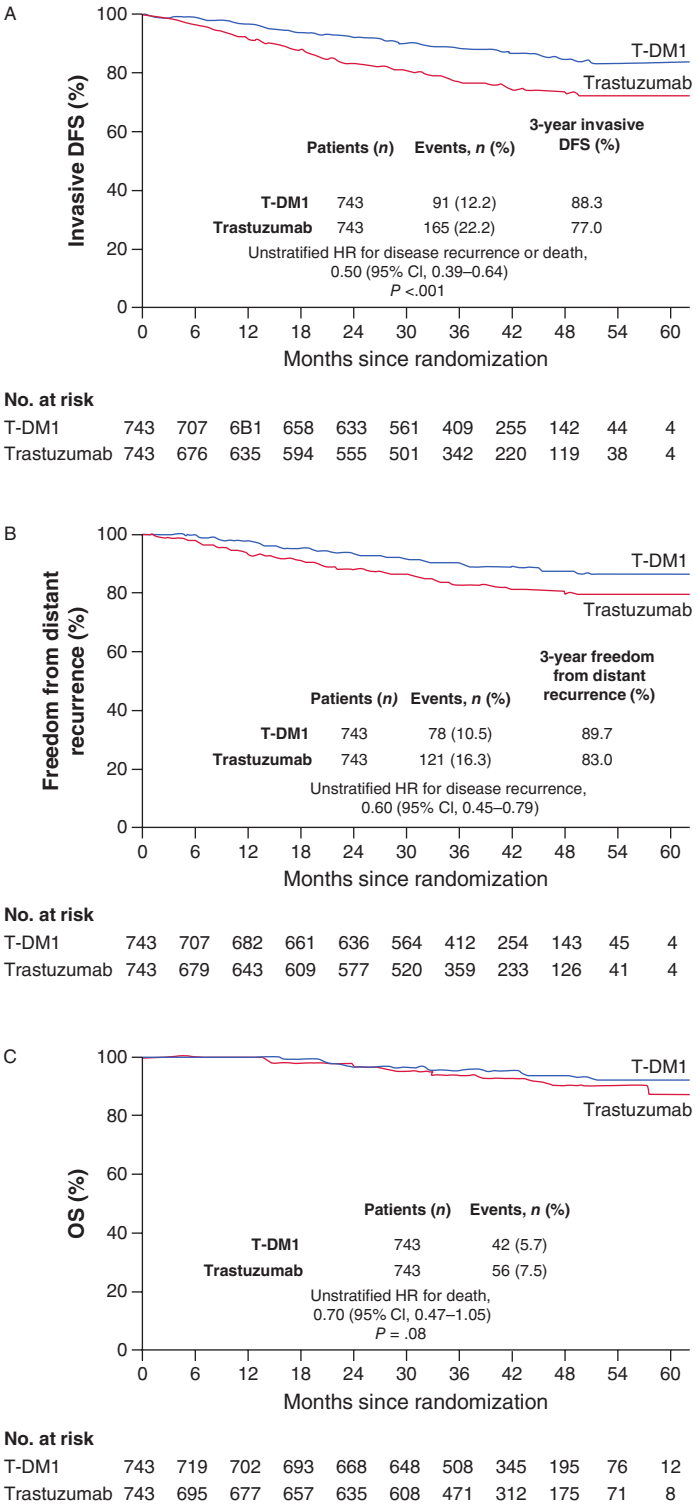

FIGURE 35-6 **KATHERINE results.CI, confidence interval; DFS, disease-free survival; HR, hazard ratio; OS, overall survival; T-DM1, trastuzumab emtansine. (Reproduced with permission from von Minckwitz G, Huang CS, Mano MS, et al: Trastuzumab Emtansine for Residual Invasive HER2-Positive Breast Cancer, *N Engl J Med* 2019 Feb 14;380(7):617-628.)**

An updated analysis at 5 years showed DFSs were 90.2% in the neratinib group and 87.7% in the control group. Of note, 40% patients who received neratinib experienced grade 3 diarrhea compared with 2% of patients who received placebo. Clinicians should take this significantly increased risk of an adverse event into account when considering extended therapy with neratinib.[112] Neratinib is approved by the FDA to be used after trastuzumab-based therapy has been completed; however, clinicians must be cognizant of the

toxicities associated with this regimen. ASCO guidelines preferentially recommend considering using it among patients with hormone receptor–positive disease based on the results of subgroup analysis. It important to mention that the impact in outcomes associated with neratinib among patients previously treated with pertuzumab or T-DM1 is unknown.

Node-Negative and Small Tumors

Patients with HER2-positive tumors smaller than 1 cm and no lymph node involvement can be treated with surgery alone without adjuvant systemic therapy. Particularly in T1a and T1b tumors, the benefit of anti-HER2 targeted therapy is uncertain. Clinicians should weigh risks associated with treatment, such as cardiac toxicity, with the potential benefits. The Adjuvant Paclitaxel and Trastuzumab trial was a phase II study of adjuvant paclitaxel and trastuzumab for 12 weeks followed by trastuzumab alone for 9 months in 410 patients with HER2-postitive breast cancer with tumors 3 cm or smaller and no nodal involvement. The 7-year DFS was 93%, and the 7-year OS was 97.5%.[113] At MDACC, most patients with node-negative disease, particularly those with tumors that are 1 cm or smaller in size, receive this regimen.

FOLLOW-UP

Although all treatment strategies are aimed at reducing the risk of recurrence, we still cannot predict which individual patients will experience a recurrence. Long-term follow-up in cancer survivors is essential to minimize the long-term side effects associated with systemic therapy. Among patients with hormone receptor–positive disease, long-term follow-up helps to ensure adherence to and management of side effects associated with endocrine therapy. Per NCCN guidelines, most patients at MDACC are evaluated every 3 to 4 months for the first 2 years, then every 6 months during years 3 to 5, and then yearly. Breast imaging is performed yearly in most patients but can be performed at shorter intervals if clinically indicated. Bone mineral density scans are performed before patients start endocrine therapy and periodically thereafter. The routine use of computed tomography, positron emission tomography, or tumor markers is not recommended, and any test should be driven by symptoms or clinical examination findings. Patients should be encouraged to maintain close communication with providers to evaluate any symptoms that could be associated with a recurrence in a timely manner.

CONCLUSION

Treatment of patients with breast cancer has evolved from single-agent therapies to more contemporary combinations. Combined-modality approaches with refinement in local therapies (surgery, irradiation) have resulted in progressive improvement in survival in this disease. This is reflected in the national trends in 5-year breast cancer survival as reported by the SEER Program (Fig. 35–7). A summary of approach to treatment can be seen in Table 35–6, and a list of common

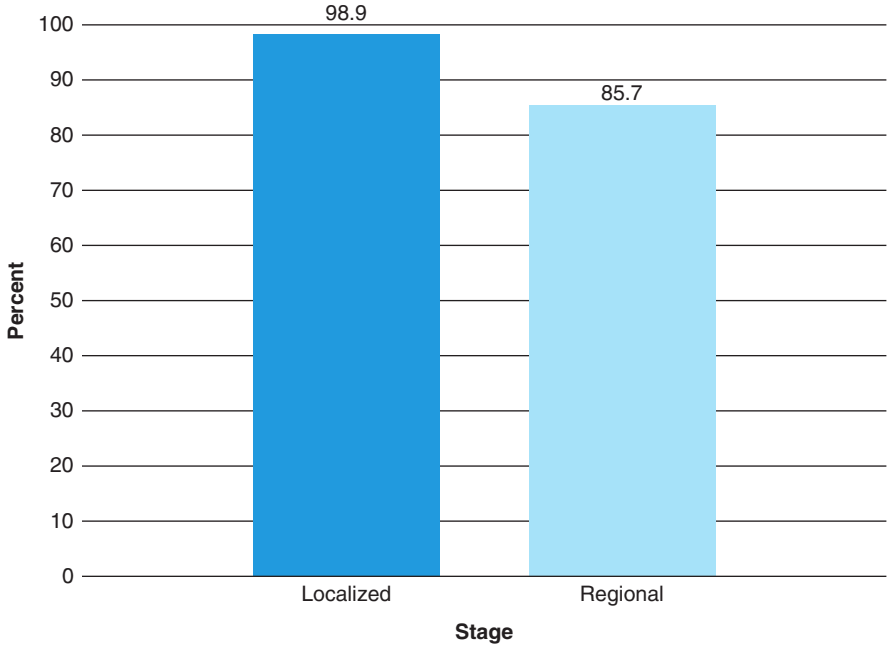

FIGURE 35-7 Five-year relative survival percent from 2010 to 2016 by stage. (Data from National Cancer Institute. SEER Cancer Stat Facts: Female Breast Cancer. Bethesda, MD: National Cancer Institute; 2020 https://seer.cancer.gov/statfacts/html/breast.html)

and serious side effects of various breast cancer therapies can be seen in Figure 35–8.

Over the past six decades, there have been significant advances in the care of patients with early-stage, locally advanced breast cancer. The use of optimal stage- and hormone receptor–specific therapy is of utmost importance and can significantly affect the risk of recurrence and death from breast cancer. Outcomes have improved with the addition of neoadjuvant therapy, taxanes, new hormonal therapy strategies, and HER2-targeted therapy. Coordinated and timely multidisciplinary therapy is of foremost importance to achieve optimal outcomes. At all times, treatment must be individualized, and clinical trial participation should be encouraged. Clinicians must take into account tumor and patients comorbidities as well as their preferences. There is strong interest among clinicians across all three cancer treatment modalities to deescalate therapy without compromising outcomes. For surgical oncology, this interest has resulted in a shift from radical mastectomy to BCS and from axillary dissection to SLNB even in some patients with nodal disease. For radiation oncology, this has led to more selective administration of radiation therapy,

Chemotherapy (anthracyclines, taxanes, platinums, capecitabine)	General: nausea, diarrhea, myelosuppression, alopecia, amenorrhea
	Anthracyclines: cardiotoxicity, secondary leukemia
	Taxanes: neuropathy, hypersensitivity reaction
	Platinums: neuropathy, hypersensitivity reaction, ototoxicity, nephrotoxicity
	Capecitabine: hand–foot syndrome, stomatitis
HER2-Targeted Therapy (trastuzumab, pertuzumab, T-DM1, neratinib)	General: diarrhea, cardiotoxicity
	T-DM1: thrombocytopenia, peripheral neuropathy, hyperbilirubinemia, transaminitis
Endocrine Therapy (SERMs, SERDs, aromatase inhibitors, ovarian suppression)	General: hot flashes, arthralgia, myalgia, nausea, headache, vaginal dryness, mood swings, weight gain, hair thinning
	Tamoxifen: endometrial cancer, venous thromboembolism, cataracts
	Aromatase inhibitors: decreased bone mineral density

FIGURE 35-8 Common and serious side effects of breast cancer therapies. SERD, selective estrogen receptor downregulator; SERM, selective estrogen receptor modulator; T-DM1, trastuzumab emtansine.

with some patients receiving APBI or hypofractionated therapy without affecting outcomes. Within medical oncology, we are now able to avoid chemotherapy in approximately half of HR-positive, HER2-negative patients using genomic prognostic assays, and we are reconsidering the need for 10 years of adjuvant endocrine therapy. Efforts to better identify patients that benefit from escalation and de-escalation strategies are ongoing and will in the future allow us to personalize treatment and avoid unnecessary toxicities.

MD ANDERSON PRACTICE TIPS

- Integrate clinical information with imaging, pathologic staging, and molecular characteristics to optimize treatment efficacy and, whenever possible, perform BCS.
- Involve surgical oncology and radiation oncology early in the treatment planning process to optimize a multidisciplinary approach. Other important team members include fertility specialists, nutritionist, plastic surgeons, and genetic counselors, among others.
- Prognostic staging is preferred for patient care when biomarker analysis is available.
- Neoadjuvant chemotherapy is preferred in patients with TNBC and HER2-positive breast cancer as well as patients with large primary tumors.
- We recommend treatment with trastuzumab and paclitaxel in most patients with node-negative disease, particularly those with tumors that are 1 cm or smaller in size.

36 Metastatic Breast Cancer

Haven R. Garber
Meghan S. Karuturi
Gabriel N. Hortobagyi

KEY CONCEPTS

- Metastatic breast cancer (MBC) most commonly arises from prior early-stage breast cancer and is incurable, with prognosis influenced by disease subtype (hormone receptor [HR] and HER2 receptor status).
- Treatment of MBC is increasingly guided by disease biology, and the armamentarium of treatments includes several targeted agents, antibodies and antibody-drug conjugates, and checkpoint inhibitors.
- Patients can live many years with MBC and preserving quality of life, minimizing toxicity, and shared patient-physician decision making are paramount in planning the best treatment strategy.
- Endocrine therapy remains the backbone of treatment for HR-positive MBC and now includes CDK4/6 inhibitors as standard frontline treatment.
- The clinical outcomes of patients with HER2-positive MBC continue to improve because of the efficacy of therapies that target the HER2 kinase pathway including pertuzumab, ado-trastuzumab emtansine, and tucatinib.
- Metastatic triple-negative breast cancer remains the breast cancer subtype with the worst prognosis. However, multiple clinical trials are underway that incorporate immunotherapy, antibody-drug conjugates, and targeted therapies in an effort to improve outcomes over those achieved with standard chemotherapy.

Breast cancer is the most common malignancy diagnosed in women in the United States and is a significant cause of morbidity and mortality. Approximately 268,600 new cases of invasive breast cancer occurred in the United States in 2019. Although lung cancer has surpassed breast cancer as the leading cause of cancer death among women, an estimated 41,760 deaths occurred from breast cancer in 2019.[1]

Since the 1970s, advances in combined-modality therapies have improved the outcomes of patients with early-stage breast cancer. Still, a significant proportion of patients with early-stage, localized breast cancer will have relapse with distant metastatic disease. The risk and timing of relapse varies widely among patients with breast cancer and is dependent on hormone receptor (HR) (estrogen receptor [ER] and progesterone receptor [PR]) and HER2/neu receptor (HER2) status as well as initial tumor (T) and nodal (N) staging. For example, among patients with ER-positive, stage T1 disease, the risk of distant recurrence at 20 years is 13% for patients without nodal involvement, 20% for 1 to 3 involved nodes, and 34% for 4 to 9 involved nodes, and the recurrence risk remains steady up to 20 years after diagnosis.[2] For patients with HER2-positive or triple-negative breast cancer (TNBC), the risk of recurrence after treatment of a primary breast tumor is highest within the first 5 years of diagnosis and depends not only on the initial TN staging, but also on the degree of sensitivity to HER2-targeted treatment and/or chemotherapy. For example, in the HER2-positive, neoadjuvant TRYPHAENA trial, 3-year disease-free survival was 87% to 90% regardless of regimen; however, patients achieving a pathologic complete response (pCR) were far more likely to be disease-free at 3 years (hazard ratio 0.27; 95% CI 0.11–0.64). Patients with TNBC with a pCR or minimal residual disease after neoadjuvant chemotherapy have an 80% to 90% chance of cure, whereas patients with significant residual disease have a more than 50% risk of relapse.[3,4]

Metastatic breast cancer (MBC) is diagnosed at the time of presentation, ie, de novo metastatic disease, in 6% to 10% of patients, depending on the series.[1,5] Bone is the most common site of distant metastasis in breast cancer; other common sites include lymph nodes, lung, liver, and, less frequently, brain. MBC is considered incurable, though there are reports of long-term durable remissions in around 2% of patients with MBC treated with anthracycline therapy and in a small subset of oligometastatic patients. The median overall survival (OS) of patients with MBC continues to improve owing to multiple new agents. For patients with HR-positive, HER2-negative MBC, the median OS in the pre-CDK4/6 inhibitor era was estimated at 57 months.[6] Analysis of more recent data that incorporate the widespread use of CDK4/6 inhibitors is ongoing. With respect to metastatic HER2-positive breast cancer, the CLEOPATRA trial reported a median OS of 56.5 months for patients in the experimental arm (vs 40.8 months in the control arm).[7] Metastatic TNBC remains the subtype with the poorest survival. The IMpassion130 trial for patients with metastatic TNBC reported an OS of 21 months in the experimental arm (vs 17.6 months in the control arm).[8] In general, patients with oligometastatic disease and/or bone-only disease live longer than patients with significant visceral involvement. Survival and response to therapy are affected by several factors, including performance status, number and sites of disease, and the disease-free interval (DFI) since prior treatment.

The therapeutic objectives for patients with MBC are distinct from those with early-stage disease. Improving survival, achieving disease control, and preventing/delaying serious complications remain important in MBC. However, because MBC is incurable and some patients can live for many years, preserving quality of life, minimizing toxicity, controlling symptoms, and shared patient-physician decision making are also paramount. Regular discussions regarding the goals of care are a key part of the treatment plan. Treatment for MBC includes endocrine therapy, chemotherapy, targeted therapy, and immunotherapy and is increasingly guided by disease biology. In select cases, there is a role for local therapy, including radiation and surgery. Patient performance status, comorbidities, organ function, prior therapies and response duration, and site(s)/extent of disease are important in each treatment decision.

Breast cancer is classified into three molecularly and clinically different subtypes: HR-positive/HER2-negative disease, HER2-positive/any HR breast cancer, and TNBC. Significant heterogeneity exists within each subtype and is the focus of many ongoing clinical trials. The breast cancer subtypes have different clinical courses, prognoses, metastatic patterns, and responses to available therapies. Although systemic treatment is not curative, it has been shown to prolong survival, palliate symptoms, and enhance or preserve quality of life. The OS of patients with MBC continues to improve because of increasingly effective therapies and supportive care. This chapter reviews standard care for patients with MBC and the current practice at MDACC.

DIAGNOSTIC WORKUP

Once metastatic disease is suspected, careful evaluation of the primary tumor disease history, current symptoms, and existing comorbid diseases is essential. A review of the initial presentation should include disease stage, histology, HR and HER2 status, and treatment modalities used. Knowledge of the initial tumor histology may yield clues about the sites of disease as well as its biology. For instance, infiltrating ductal carcinoma most commonly involves the bone, lungs, pleura, liver, and brain.[9] Infiltrating lobular carcinoma frequently recurs in unusual sites such as the bone marrow, meninges, peritoneum, and retroperitoneal structures, such as the ureters.[10]

A biopsy of the metastatic site is required to confirm histology and receptor status. Discordance in the receptor status from diagnosis to recurrence is common, and treatment is tailored to the receptor status of the relapsed disease.[11] Pathologic confirmation is also essential in patients with atypical presentations, including single-lesion metastasis, unusual metastatic sites, and long DFI. Solitary lesions should always be biopsied and may represent a benign process or a distinct tumor type. In rare cases, when biopsy of metastatic disease is infeasible or the results are uninterpretable, treatment is guided by the primary tumor histology/receptor subtype, though biopsy should be reattempted at the time of progression.

In addition to a comprehensive physical examination, basic laboratory evaluation should include a complete blood count with differential, renal and liver function tests including alkaline phosphatase, and serum calcium. Alkaline phosphatase is correlated with bone metastasis in patients with breast cancer but is neither sensitive nor specific.[12] In addition, the serum tumor markers CA 15-3, CA 27-29, and CEA are elevated in approximately 70% of patients with MBC and can be helpful in monitoring response to therapy; however, they are rarely used in isolation to determine disease response. Our baseline imaging consists of a computed tomography (CT) scan of the chest, abdomen, and pelvis, and a bone scan. In cases where baseline imaging is equivocal, positron emission tomography-CT scan or magnetic resonance imaging of the abdomen (eg for liver metastasis) can be informative. We reserve brain imaging for patients who report neurologic symptoms.

Several therapeutic agents have been approved in the past 3 years that require additional biomarker testing in blood or tumor tissue. These assays should be performed on tissue obtained from a metastatic site at the time of progression and not on the archived primary tumor sample. This is because molecular tumor evolution can occur over time, particularly in the context of adjuvant therapies. Patients with TNBC should have their tumors tested for programmed cell death–ligand 1 (PD-L1) expression on tumor-infiltrating immune cells to guide the appropriateness of therapy with checkpoint inhibitors.[8,13] Patients with HR-positive, HER2-negative MBC who have previously been treated with endocrine therapy are candidates for therapy with fulvestrant in combination with the PI3K inhibitor, alpelisib, which is effective only in patients with activating *PIK3CA* mutations and requires plasma or tumor polymerase chain reaction testing.[14] Germline testing for *BRCA1/2* mutations is also important for patients with MBC given the efficacy of talazoparib and olaparib for patients with HER2-negative MBC. Additional biomarker testing is relevant only for clinical trials or in rare MBC cases. For example, mismatch repair deficiency is rare in breast cancer (~1% of patients) and may be rational only for patients with Lynch syndrome, particularly given the number of other effective therapies in MBC.[15–17] Furthermore, clinical data regarding the activity of pembrolizumab in patients with mismatch repair–deficient MBC is limited. Similarly, tropomyosin receptor kinase fusions are uncommon in breast cancer (<1%) except in the very rare secretory subtype where fusions are highly prevalent. Moreover, secretory breast carcinomas rarely metastasize.[18] Finally, a priority at MDACC is to enroll patients with MBC into clinical trials and we use an institutional next-generation sequencing assay on tumor tissue to help guide selection of clinical trials for patients. We do not perform this assay in patients with MBC who are unable to participate in clinical trials.

TREATMENT

General Considerations

The decision to use endocrine therapy, targeted therapy, immunotherapy, and/or chemotherapy in the treatment of MBC is guided by several factors including hormone and HER2 receptor status and the presence or absence of visceral crisis. Regardless of receptor status, patients with visceral crisis but good performance status are often treated initially with chemotherapy, and sometimes combination chemotherapy, to try to achieve a significant and rapid tumor response. Patients with HR-positive, HER2-negative MBC, including those with symptomatic visceral disease, are treated with endocrine therapy paired with a CDK4/6 inhibitor, given the comparable response rates (RRs) to that of chemotherapy. For patients with HER2-positive MBC, novel therapies have transformed the treatment paradigm and have improved the prognosis for a disease that historically ranked among the most aggressive and lethal cancers. Patients with HER2-positive MBC are initially treated with anti-HER2 therapy in combination with chemotherapy, because this provides a significant survival advantage. The majority of patients with HER2-positive disease have breast cancer that also expresses hormone receptors. Because the HER2-positive component is more aggressive, anti-HER2 therapy is typically prioritized over endocrine therapy, which can be incorporated during periods when cytotoxic chemotherapy is omitted and patients are on anti-HER2 antibodies alone. Patients with TNBC are treated with chemotherapy, with or without immunotherapy.

Multiple agents are active against hormone-responsive tumors. Endocrine therapy is at least as effective as chemotherapy and is the initial preferred treatment option. Endocrine therapy is associated with fewer side effects and helps patients maintain a superior quality of life compared with cytotoxic chemotherapy. Many patients with HR-positive disease can be treated with multiple lines of sequential endocrine therapy. However, in the case of very rapid progression within the first few weeks of initial endocrine therapy or refractory disease after multiple lines of endocrine therapy, systemic chemotherapy is the best option.

A minority of patients with MBC (<5%) have a solitary metastasis or oligometastases, a unique subset of patients that have been a focus of research at MDACC. For patients with recurrent breast cancer and limited sites of metastasis (ie, not de novo metastatic disease), there are no phase 3 randomized data that support aggressive, multimodal local management of oligometastatic disease over systemic therapy, though multiple trials of stereotactic body radiation therapy/ablation and surgical resection are ongoing. Data from phase 1/2 trials suggest that combined-modality treatment with curative intent for patients with limited metastatic sites may improve survival and even yield MBC cures.[19,20] MDACC is participating in NRG-BR002, a phase 2R/3 trial of systemic therapy with or without local therapy for newly diagnosed oligometastatic breast cancer to help clarify this important clinical question.

Regarding patients with de novo metastatic disease and management of the primary breast tumor, the phase 3 E2108 study randomly assigned 256 patients with de novo MBC and no disease progression after 4 to 8 months of systemic therapy to either locoregional treatment for the intact primary breast tumor plus

systemic treatment or systemic treatment alone. The primary end point was OS and there was no significant difference in the 3-year OS (68.4% in the locoregional group vs 67.9% in the control group; hazard ratio 1.09; 95% CI 0.8–1.49), though the rate of locoregional recurrence/progression was expectedly higher in the control group (25.6% vs 10.2% at 3 years).[21]

At MDACC, we do offer combination systemic therapy and aggressive local therapy to a select group of patients with MBC who have few (≤4) small tumors in sites amenable to radiation or safe complete resection and to patients who have demonstrated a long DFI after prior treatments. Unfortunately, patients with TNBC are often excluded from this approach because of the aggressive nature of their disease.

Bone-Directed Agents

Bone is the most common site of distant metastasis in breast cancer and is the only site of disease in a subset of patients with HR-positive MBC. Bone metastases can cause significant debility and pain and are a treatment priority across MBC subtypes. The primary bone-targeting agents used at MDACC in patients with MBC are zoledronic acid, a bisphosphonate, and denosumab, an antibody against RANK ligand. Bone-targeting agents are palliative and no trials have shown an impact on survival. Bisphosphonates and denosumab are given in combination with other cancer-directed therapies. In addition, all patients should take the recommended daily amount of calcium (1200–1500 mg) and vitamin D (800 IU).

Bisphosphonates are pyrophosphate analogs that bind hydroxyapatite crystals and inhibit bone resorption by osteoclasts. They are used to prevent skeletal complications including pathologic fracture, pain requiring radiation and/or surgery, cord compression, and hypercalcemia.[22] Importantly, routine monitoring of renal function is required during bisphosphonate treatment because zoledronic acid can cause renal toxicity, requires dose reductions for chronic kidney disease, and is contraindicated in acute kidney injury. Physicians should also be aware of the risk of osteonecrosis of the jaw, a rare but serious complication of bisphosphonate therapy. Patients should have a dental exam before initiating a bone-targeting agent, and invasive dental procedures should be completed before starting or resuming bisphosphonates. Trials support the use of bisphosphonates for at least 2 years—benefit beyond 2 years is unproven. The OPTIMIZE-2 trial evaluated the frequency of zoledronic acid administration in 403 women with bone metastasis who had previously received at least nine doses of an intravenous (IV) bisphosphonate. The study demonstrated that administering zoledronic acid 4 mg IV every 3 months was as effective as giving it monthly. The rate of skeletal-related events was 22% in the monthly group versus 23.2% in the every-three-month group. The less frequent dosing also corresponded with lower rates of renal failure and osteonecrosis of the jaw.[23]

Denosumab is a monoclonal antibody that targets RANK ligand, a protein that activates osteoclasts via the RANK receptor. Denosumab is indicated for treatment of osteoporosis, therapy-induced bone loss, and bone metastases. A randomized controlled trial evaluated denosumab versus zoledronic acid in 2033 patients with MBC and bone metastases. Denosumab proved superior to zoledronic acid in delaying or preventing the first skeletal-related event (hazard ratio 0.82; 95% CI 0.71–0.95), supporting the use of monthly denosumab in the management of bone metastases.[24] Denosumab is administered subcutaneously, an advantage over zoledronic acid, which requires an IV line. A disadvantage is that administration is monthly and continuous. The optimal duration of denosumab therapy is unknown. The risk of osteonecrosis of the jaw with denosumab is similar to that of bisphosphonates, and patients with a creatinine clearance less than 30 mL/min are at an increased risk of development of hypocalcemia. At MDACC, all patients with MBC and bone metastases who do not have a contraindication to receive bone-targeting agents are treated with zoledronic acid or denosumab.

HORMONE RECEPTOR–POSITIVE, HER2-NEGATIVE BREAST CANCER

Patients with HR-positive, HER2-negative disease compose two-thirds of patients with MBC.[25] Breast cancers with 1% to 100% ER and/or PR positivity by immunohistochemistry are considered HR-positive and eligible for endocrine therapy. However, in practice, patients harboring tumors with 1% to 10% ER/PR expression are deemed HR low-positive and often have more aggressive disease. Depending on individual clinical features (presence/absence of visceral disease, number and volume of metastatic sites, biopsy site, initial primary tumor receptor status), a subset of patients with HR low-positive disease are treated initially with endocrine therapy, but with a low threshold to switch to cytotoxic chemotherapy in the event of rapid progression. Most other patients with adverse clinical features and HR low-positive disease are treated similarly to patients with TNBC with initial chemotherapy. A switch to endocrine therapy can then be tried later in the disease course for patients with excellent chemotherapy responses. Likewise, patients with ER-negative/PR-positive disease are a distinct group with unpredictable responses to endocrine therapy, and oncologists should have a low threshold to repeat a biopsy or switch to chemotherapy in the event of rapid progression.

Endocrine therapy, with or without a CDK4/6 inhibitor, is the standard frontline treatment for most patients with HR-positive, HER2-negative MBC, including for patients with de novo metastatic disease (Fig. 36–1). The optimal endocrine therapy varies for patients with recurrent disease and depends on whether the recurrence occurred while on endocrine therapy or within one year of stopping adjuvant endocrine therapy. For patients who have recurrrence while on or within one year of stopping an aromatase inhibitor (AI), a change in endocrine therapy is recommended, and the optimal regimen is fulvestrant in combination with a CDK4/6 inhibitor. Of note, CDK4/6 inhibitors are approved in women who are postmenopausal or in pre/perimenopausal women treated concurrently with a luteinizing hormone–releasing hormone (LHRH) agonist (eg, goserelin). The first CDK4/6 inhibitor received FDA approval in 2015 in combination with endocrine therapy, heralding a new class of drugs integral to the treatment of MBC. Because the CDK4/6 inhibitors are a new update to this edition, we will discuss the important clinical trials that led to their approval and will then review the principles of endocrine and chemotherapy in patients with HR-positive MBC.

CDK4/6 Inhibitors

In HR-positive breast cancer, estrogen drives accumulation of cyclin D1, which complexes with and activates the cyclin-dependent 4 and 6 kinases to hyperphosphorylate the retinoblastoma (Rb) tumor suppressor, leading to Rb inactivation. The end result is bypass of the G1/S cell-cycle checkpoint and unrestricted breast cancer cell proliferation. The CDK4/6 inhibitors (palbociclib, ribociclib, and abemaciclib) inhibit CDK4 and CDK6, thus preventing Rb hyperphosphorylation and reinstating the G1/S checkpoint in breast cancer cells.[26]

Palbociclib, in combination with an AI, received FDA approval in 2015 for the treatment of postmenopausal women with HR-positive/HER2-negative MBC. Approval was based on PALOMA-1, a randomized phase 2 study of palbociclib plus letrozole versus letrozole alone in the first-line treatment of patients with HR-positive, HER2-negative MBC (Table 36–1). A clear progression-free survival (PFS) advantage for the combination was seen in the initial cohort of 165 patients (20.2 months for the combination vs 10.2 months for letrozole alone).[27] The confirmatory study was PALOMA-2, a randomized, double-blind phase 3

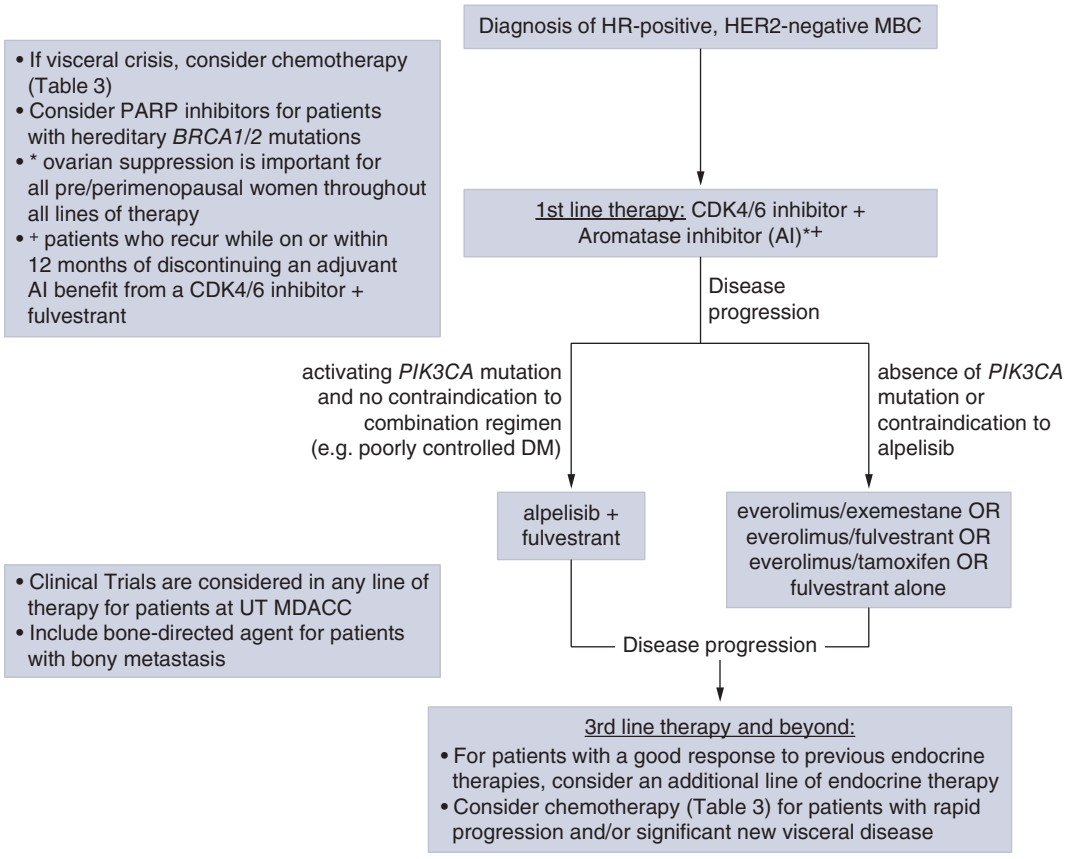

FIGURE 36–1 Concise algorithm for the treatment of patients with HR-positive, HER2-negative MBC at MDACC.

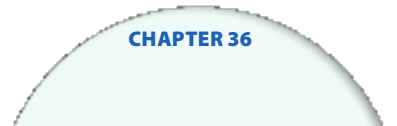
Table 36–1 CDK4/6 Inhibitors in HR-Positive, HER2-Negative MBC



Agent and Trial	n	Patients	Treatment	Outcomes	Notes
Palbociclib					
PALOMA-1[27]	165 (1:1)	Frontline treatment for MBC (~40% w/prior chemotx, 33% w/prior endocrine tx)	Palbociclib + letrozole vs letrozole	PFS (20.2 vs 10.2 mo, HR 0.49; 95% CI 0.32–0.75); ORR (55% vs 39%); CBR (81% vs 58%)	Accelerated FDA approval in 2015 for frontline treatment
PALOMA-2[28]	666 (2:1)	Frontline treatment for MBC (~50% w/prior chemotx, 56% w/prior endocrine tx)	Palbociclib + letrozole vs letrozole	PFS (24.8 vs 14.5 mo, HR 0.58; 95% CI 0.46–0.72); ORR (55% vs 44%); CBR (85% vs 70%)	Regular FDA approval in 2017 for frontline treatment; grade 3/4 neutropenia in 66.4% on combo arm
PALOMA-3[29]	521 (2:1)	Second-line treatment for MBC after progression on prior endocrine therapy	Palbociclib + fulvestrant vs fulvestrant	PFS (9.5 vs 4.6 mo, HR 0.46; 95% CI 0.36–0.59); ORR (25% vs 11%); CBR (67% vs 40%)	FDA approval in 2016 for treatment of patients with progression on previous endocrine therapy; OS benefit seen in patients with endocrine-sensitive disease
Ribociclib					
MONALEESA-2[31,32]	668 (1:1)	Frontline treatment for MBC (~43% w/prior chemotx, 52% w/prior endocrine tx)	Ribociclib + letrozole vs letrozole	PFS (25.3 vs 16 mo, HR 0.57; 95% CI 0.46–0.7); ORR (55% vs 39%); CBR (80% vs 73%)	FDA approval in 2017 for frontline treatment; grade 3/4 neutropenia in 59.3% on combo arm; QTc prolongation in ~3% of patients on combo arm
MONALEESA-3[33,34]	726 (2:1)	Second-line treatment for MBC after progression on prior endocrine tx (and first-line for ~20% of patients with de novo metastatic disease)	Ribociclib + fulvestrant vs fulvestrant	PFS (20.5 vs 12.8 mo, HR 0.59; 95% CI 0.48–0.83); ORR (40.9% vs 28.7%); CBR (70.2% vs 62.8%); OS at 42 mo (57.8% vs 45.9%, HR 0.72; 95% CI 0.57–0.92)	Led to an additional FDA indication for the frontline or subsequent line treatment of patients with MBC with progression on prior endocrine therapy
MONALEESA-7[35,36]	672 (1:1)	Frontline endocrine treatment for pre/perimenopausal women with MBC (~40% w/ prior endocrine tx; 55% w/ prior chemotx [14% for MBC])	Ribociclib + either tamoxifen or AI vs tamoxifen or AI (all w/ goserelin)	PFS (23.8 vs 13 mo, HR 0.55; 95% CI 0.44–0.69); ORR (41% vs 30%); CBR (79% vs 70%); OS at 42 mo (70.2% vs 46%, HR 0.71; 95% CI 0.54–0.95)	Median age 44 y (vs ~60 in most other CDK4/6 inhibitor trials); QTc prolongation was more pronounced in the ribociclib + tamoxifen group, which is not an FDA-approved regimen

Table 36–1 CDK4/6 Inhibitors in HR-Positive, HER2-Negative MBC (*Cont.*)

Agent and Trial	n	Patients	Treatment	Outcomes	Notes
Abemaciclib					
MONARCH 1[39]	132 (single arm)	Patients with pretreated MBC (median 3 prior lines), all had received prior chemotx for MBC	Abemaciclib monotherapy	ORR 19.7%, median PFS 6 mo; CBR 42.4%, OS 17.7 mo	FDA approval in 2017 as monotherapy after endocrine therapy and chemotherapy in the metastatic setting
MONARCH 2[38]	669 (2:1)	Second-line treatment for MBC after progression on prior endocrine therapy	Abemaciclib + fulvestrant vs fulvestrant	PFS (16.4 vs 9.3 mo, HR 0.55; 95% CI 0.45–0.68); ORR (48.1% vs 21.3%); CBR (72.2% vs 56.1%); OS (46.7 vs 37.3 mo, HR 0.76; 95% CI.61–.95)	Regular FDA approval in 2017; grade 3/4 diarrhea in 13.4% on combo arm (more than other CDK4/6i), grade 3/4 neutropenia in 26.5% on combo arm (less than other CDK4/6i)
MONARCH 3[37]	493 (2:1)	Frontline treatment for MBC (~40% w/prior chemotx, ~47% w/prior endocrine tx)	Abemaciclib + NSAI (physician's choice) vs NSAI	PFS (28.2 vs 14.8 mo, HR 0.54; 95% CI 0.42–0.7); ORR (61% vs 45.5%); CBR (78% vs 71.5%)	FDA approval in 2018 as frontline treatment;, grade 3/4 diarrhea in 9.5%, grade 3/4 neutropenia in 21.1%

AI, aromatase inhibitor; CBR, clinical benefit rate; HR, hazard ratio; MBC, metastatic breast cancer; NSAI, nonsteroidal aromatase inhibitor; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; tx, therapy.

trial. Patients (n = 666) with HR-positive, HER2-negative MBC and postmenopausal ovarian status, were randomly assigned 2:1 to frontline treatment with palbociclib and letrozole versus letrozole alone. The primary end point was PFS. Median PFS was 24.8 months in the palbociclib-letrozole group versus 14.5 months in the placebo-letrozole group (hazard ratio 0.58; 95% CI 0.46–0.72). The most common grade 3/4 adverse events (AEs) were neutropenia in 66% of patients, other cytopenias, and fatigue.[28] Of note, neutropenia and a rare risk of interstitial lung disease (ILD) are class effects of the CDK4/6 inhibitors.

Palbociclib received expanded approval in 2016 for use in combination with fulvestrant based on results from the PALOMA-3 trial. PALOMA-3 was a double-blind, placebo-controlled, randomized phase 3 study conducted in 521 patients with HR-positive, HER2-negative MBC whose disease had progressed on prior endocrine therapy. In the adjuvant setting, patients had to have relapsed while on or within 12 months of adjuvant therapy completion. Patients were randomly assigned 2:1 to fulvestrant and palbociclib versus fulvestrant and placebo. PFS was 9.5 months in the fulvestrant-palbociclib group versus 4.6 months in the fulvestrant-placebo group (hazard ratio 0.46; 95% CI 0.36–0.59).[29] There was an OS benefit for patients with sensitivity to previous endocrine therapy only, defined as clinical benefit from at least one prior endocrine therapy in the context of metastatic disease or the receipt of at least 24 months of endocrine therapy in the adjuvant setting before recurrence. In this group, OS was 39.7 months in the fulvestrant-palbociclib group compared with 29.7 months in the fulvestrant-placebo group (hazard ratio 0.58; 95% CI 0.47–0.73). Again, neutropenia was the most common grade 3/4 AE.[30] Importantly, palbociclib is also approved for the treatment of male breast cancer patients based on postmarketing data.

Ribociclib gained FDA approval in 2017 and has two indications for treatment of patients with HR-positive, HER2-negative MBC. First, as use in combination with an AI or fulvestrant for initial endocrine therapy and, second, as use in combination with fulvestrant for subsequent-line treatment of patients whose disease progressed on prior endocrine therapy. These approvals are based on the trials MONALEESA-2, 3, and 7. MONALEESA-2 trialed ribociclib with letrozole in 668 postmenopausal women with HR-positive, HER2-negative MBC as first-line therapy versus letrozole-placebo. PFS for ribociclib-letrozole was 25.3 months versus 16 months for placebo-letrozole (hazard ratio 0.57; 95% CI 0.46–0.70), with a RR of 54.5% versus 38.8%.[31,32] MONALEESA-3 evaluated the combination of ribociclib and fulvestrant versus placebo-fulvestrant in treatment-naïve patients and in patients treated with one prior endocrine therapy for metastatic disease. Approximately 20% of patients had untreated, de novo metastatic disease, representing a group of patients that were not included in PALOMA-3. The addition of ribociclib improved both median PFS (20.5 vs 12.8 months; hazard ratio 0.59; 95% CI 0.48–0.83) and survival, with an estimated OS at 42 months of 57.8% in the ribociclib group versus 45.9% in the placebo group (hazard ratio 0.72; 95% CI 0.57–0.92). Patients with de novo metastatic disease experienced a PFS of 33.6 months with ribociclib-fulvestrant compared with 19.2 months in the placebo-fulvestrant group.[33,34]

MONALEESA-7 tested ribociclib versus placebo in combination with goserelin and either tamoxifen or a nonsteroidal AI in 672 pre/perimenopausal women with HR-positive, HER2-negative MBC. This was the first and only CDK4/6 trial to include solely pre/perimenopausal women. Patients had not received prior endocrine therapy for metastatic disease, though approximately 40% had received adjuvant endocrine therapy and 14% had received chemotherapy for metastatic disease. Significant improvements in PFS and OS were observed with the addition of ribociclib.[35,36] Side effects of ribociclib are similar to palbociclib (neutropenia, other cytopenias, fatigue, nausea); however, ribociclib carries a warning for QT prolongation and requires routine electrocardiographic monitoring. Because tamoxifen was found to further prolong the QT interval, ribociclib is not approved in combination with tamoxifen.

Finally, for the CDK4/6 inhibitors, abemaciclib is the third approved agent with indications similar to palbociclib, with one important exception: abemaciclib is also approved as monotherapy for patients with HR-positive, HER2-negative MBC after disease progression on prior endocrine or chemotherapy. Approval was based on the MONARCH-1, 2, and 3 clinical trials. MONARCH 3 evaluated the combination of abemaciclib and a nonsteroidal AI (physician's choice) versus a nonsteroidal AI alone as frontline therapy for postmenopausal women with HR-positive, HER2-negative MBC. PFS was 28.2 months for the combination arm versus 14.8 months for AI monotherapy (hazard ratio 0.54; 95% CI 0.42–0.7).[37] Of note, the hazard ratios in PALOMA-2, MONALEESA-2, and MONARCH-3 are remarkably similar, suggesting comparable efficacy among the kinase inhibitors and a consistent benefit from the class. MONARCH-2 evaluated abemaciclib in combination with fulvestrant versus fulvestrant alone (2:1) in patients with disease that had progressed on one prior endocrine therapy. In the 669 women enrolled, PFS was 16.4 months versus 9.3 months (hazard ratio 0.55; 95% CI 0.45–0.68) and OS was improved by about 9.5 months.[38] Importantly, neutropenia occurred at one-third the rate seen with either palbociclib or ribociclib despite continuous dosing of abemaciclib. However, grade 3/4 diarrhea was

far more common with abemaciclib (9.5%) than with the other kinase inhibitors.

MONARCH-1 was a phase 2 trial with a unique design, focused on patients who had received multiple lines of prior therapy in the metastatic setting (median = 3). All patients had received previous endocrine and chemotherapy, including at least one line of chemotherapy for metastatic disease. Patients with prior CDK4/6 treatment were excluded. Patients (n = 132) were treated with abemaciclib monotherapy and the RR was 19.7% with a median PFS of 6 months, supporting its activity as a single agent.[39]

In practice, all three CDK4/6 inhibitors are used, and the agent is selected based on patient/physician preference, frequency of monitoring, ease of dose adjustment, patient comorbidities, and side effects. As of this writing, there are insufficient data to support continuing a CDK4/6 inhibitor after progression on a CDK4/6 inhibitor-containing regimen, either alone or in combination therapy, although this remains an active area of investigation.

Endocrine Therapy

Endocrine therapy has dramatically improved outcomes for patients with HR-positive breast cancer. Not only does endocrine therapy prolong survival, but the medicines can also palliate symptoms and improve quality of life. Manipulation of the endocrine system as a treatment for MBC was introduced in 1896, when Beatson demonstrated objective regression of breast cancer after oophorectomy. Today, a number of endocrine therapies are used in patients with hormone-sensitive MBC that reduce the synthesis of estrogen or block or downregulate ERs in hormone-dependent tumors.

Patients whose tumors express both estrogen and progesterone receptors have a 50% to 70% chance of clinical benefit from endocrine therapy, whereas patients with either ER- or PR-positive disease have around a 30% chance of benefit from endocrine therapy.[40] Importantly, patients with MBC who responded to prior endocrine therapy have a 30% to 50% chance of clinical benefit from a second hormonal regimen. Higher RRs to endocrine therapy are generally seen in patients with MBC with low-volume disease, bone-only disease, and good performance status. Importantly, though, patients with visceral metastases comprised more than half of patients accrued to the CDK4/6 trials and received substantial clinical benefit from combination endocrine therapy and kinase inhibition. The duration of first response with endocrine therapy alone is about 9 to 12 months, similar to that with chemotherapy. The selection of endocrine therapy depends on the menopausal status of the patient. Tamoxifen can be used regardless of menopausal status, whereas AIs and fulvestrant require ovarian suppression/ablation in pre/perimenopausal women. The side effect profile also guides use because the agents are similarly effective.[41] A substantial minority of patients with HR-positive MBC benefit from sequential, single-agent endocrine monotherapy, though this clinical situation is becoming rarer owing to CDK4/6 inhibitor use. Some patients benefit from 3 to 4 lines of endocrine therapy, and a subset will respond for many years. In addition, for patients whose tumors are unusually sensitive to endocrine therapy, repeat treatment with a previously effective agent may offer benefit if a long interval has elapsed since discontinuation.

Several types of endocrine therapy are used in MBC. These include ovarian ablation (oophorectomy, ovarian radiation) or functional suppression (LHRH agonists), tamoxifen, nonsteroidal and steroidal AIs, fulvestrant, progestins, androgens, and estrogens. For premenopausal women with HR-positive MBC, ovarian ablation/suppression is a critical and longitudinal part of endocrine therapy. Medical ovarian suppression is achieved with LHRH agonists, though many patients elect for laparoscopic surgical oophorectomy to eliminate the need for frequent injections. In postmenopausal women, the ovaries are naturally suppressed. There is no indication for adrenalectomy or hypophysectomy in MBC.

Tamoxifen, a selective estrogen receptor modulator (SERM) that competitively binds to estrogen receptors, was first approved to treat advanced breast cancer in postmenopausal women in 1977 and is still widely used, particularly in the adjuvant setting. Toremifene is another SERM that was approved in 1997 for the treatment of HR-positive MBC. In MBC, both AIs and fulvestrant have proven slightly more effective than tamoxifen, and because tamoxifen is not approved with CDK4/6 inhibition, it is often reserved for later lines of treatment or for patients with intolerable side effects on other endocrine treatments. An early publication of tamoxifen use in 46 postmenopausal women with advanced breast cancer showed near equivalence with androgens and estrogens, which were the standard treatments at the time.[42] In a meta-analysis of four randomized trials of LHRH agonists versus LHRH agonists plus tamoxifen in premenopausal patients with MBC, there was a significant PFS (hazard ratio 0.7) and OS (hazard ratio 0.78) benefit in favor of the combination treatment.[43]

The third-generation AIs that are currently in practice were approved in the mid-1990s. AIs inhibit the aromatase enzyme system, which is responsible for catalyzing the final step in the conversion of androgens to estrogens in ovarian and peripheral tissues and in breast tumors. AIs do not completely block ovarian estrogen production in premenopausal women, and the use of an AI in young patients can cause a reflexive

increase in gonadotropin levels and resultant ovarian hyperstimulation. For this reason, AIs are used in pre/perimenopausal women only in combination with ovarian ablation/suppression.

Anastrozole was compared with tamoxifen as first-line therapy in 353 postmenopausal patients with MBC in a 1:1 randomized, double-blind study. RRs for anastrozole and tamoxifen were 21% and 17%, respectively. Time to progression (TTP) was 11.1 months for anastrozole compared with 5.6 months for tamoxifen.[44,45] Letrozole, the other commonly used nonsteroidal AI, was also compared with tamoxifen as first-line treatment in 916 postmenopausal patients with MBC and showed improved RR (32% vs 21%) and improved PFS (9.4 vs 6 months).[46] Finally, exemestane is the only approved steroidal AI and is indicated for treatment of MBC after progression on tamoxifen. A randomized, phase 3 clinical trial compared exemestane with tamoxifen in the first-line treatment of 371 postmenopausal women with MBC. Patients treated with exemestane had improved RR (46% vs 31%) and early PFS (9.9 vs 5.8 months), though there was no long-term PFS or survival benefit.[47] In practice, the AIs demonstrate similar efficacy, and large meta-analyses have supported their near equivalence. Letrozole and anastrozole are used interchangeably in combination with CDK4/6 inhibitors. Exemestane was previously felt to offer significant benefit after progression on a nonsteroidal AI; however, a large, randomized trial showed little benefit from exemestane monotherapy post–nonsteroidal AI, though it did demonstrate a benefit in combination with everolimus (discussed below).[48]

Fulvestrant is a selective estrogen receptor downregulator (SERD) that binds and downregulates estrogen receptors on tumor and other cells and has no agonist effects. Fulvestrant gained initial FDA approval in 2002 and is approved as monotherapy in first- or subsequent-line treatment (after prior endocrine therapy) of patients with HR-positive MBC. It is also approved in combination with CDK4/6 inhibitors and the PIK3CA inhibitor, alpelisib (discussed below). The CONFIRM trial tested fulvestrant at doses of 500 mg versus 250 mg in 736 postmenopausal women with ER-positive MBC who had progressed after prior endocrine therapy. Both PFS (6.5 vs 5.5 months) and OS (26.4 vs 22.3 months) were longer with the 500-mg dose.[49] The FALCON trial compared fulvestrant (500 mg) with anastrozole in a phase 3, 1:1 randomized trial of 462 postmenopausal women with HR-positive MBC who had not received prior endocrine therapy. The clinical benefit rate was similar between the two arms; however, PFS was significantly longer in the fulvestrant arm compared with the anastrozole arm (16.6 vs 13.8 months; hazard ratio 0.80 ;95% CI 0.64–0.999). Survival data remain immature. Combination fulvestrant and anastrozole is also an acceptable first-line treatment for patients with de novo MBC who are naïve to endocrine therapy based on the phase 3 SWOG S0226 trial.[50] Fulvestrant is also effective in combination with several targeted agents in subsequent-line therapy, which is discussed below. In practice, fulvestrant is usually reserved for second or later lines of therapy because of the inconvenience and discomfort associated with monthly injections in both gluteal muscles.

Endocrine therapy causes fewer side effects than cytotoxic chemotherapy and remains the standard backbone in clinical trials of new agents for HR-positive MBC. However, there are several unique complications and side effects of endocrine therapy. SERMs and estrogens (but not AIs or fulvestrant) can cause flare, which is defined clinically by an abrupt, diffuse onset of musculoskeletal pain and/or increased size or erythema of skin lesions within the first month of endocrine therapy. Flare can also worsen the appearance of bone lesions on bone scan, which can complicate the assessment of response to endocrine therapy. The most serious manifestation of flare is hypercalcemia, which can occur in patients with bone metastases, and manifests within the first two weeks of starting therapy. The underlying mechanism is the predominating early agonist effect of SERMs and estrogens. Low-dose prednisone (10–30 mg/day) can abrogate the initial flare-related bone pain.

Other side effects of endocrine therapy include hot flashes and mood disturbances, which are related to estrogen deprivation and are common with tamoxifen, AIs, and fulvestrant. These side effects are most pronounced in young women who begin ovarian suppression, an abrupt and early menopause. Tamoxifen has estrogenic effects that are beneficial in some tissues—it lowers serum cholesterol and protects against bone loss and cardiovascular disease, but tamoxifen is also associated with an increased risk of endometrial cancer and thromboembolic events. Randomized trials of tamoxifen do not support an association with weight gain. Common side effects of the AIs include arthralgia, myalgia, and bone density loss.

Older endocrine therapies that are not commonly used in current practice include progestins, androgens, and estrogens. These agents are typically reserved for patients who have progressed on all other endocrine therapies and who are not candidates for either targeted therapy or chemotherapy. Progestins are synthetic derivatives of progesterone that have a progesterone-agonist effect. Progestins such as megestrol acetate and medroxyprogesterone acetate are active in treating MBC. These drugs have anti-estrogenic properties through their disruption of the pituitary-ovarian axis. Androgens (fluoxymesterone, danazol, etc) also have efficacy in MBC, including in patients treated with multiple endocrine therapies. Before the identification of hormone receptors and the development of SERMs, high-dose estrogens were commonly used to treat MBC. Their efficacy is similar to that of

tamoxifen, although high-dose estrogens (DES, ethinyl estradiol, etc) are associated with more severe side effects including nausea/vomiting, fluid retention, congestive heart failure, and thromboembolic disease.

At MDACC, our preferred first-line endocrine therapy for patients with HR-positive MBC is a CDK4/6 inhibitor combined with an AI (and a bone-targeting agent in the case of bone metastasis). For patients whose disease recurs while on an adjuvant AI or within 12 months of discontinuing an AI, we typically use a CDK4/6 inhibitor in combination with fulvestrant. The choice of treatment after progression on initial endocrine therapy and a CDK4/6 inhibitor is more nuanced and depends on several factors, including the duration of response to initial endocrine therapy, disease burden, performance status, comorbidities, and *PIK3CA* mutation status (see below). In general, for patients with a reasonable response to initial endocrine therapy in the metastatic setting, we continue endocrine therapy and change the endocrine therapy agent (eg, AI to fulvestrant). Patients who respond to initial endocrine therapy have a higher probability of response to second-line endocrine therapies. In cases where endocrine therapy agents (with or without targeted agents, see below) have been exhausted or there is rapid progression, we initiate single-agent chemotherapy. At MDACC, we also consider available clinical trials. The treatment algorithm used for treating patients with HR-positive MBC at MDACC is illustrated Fig. 36–1.

Intrinsic (de novo) resistance to endocrine therapy is an unfortunate reality for a subset of patients with HR-positive MBC and eventual acquired resistance to endocrine therapies is universal. There are multiple genetic and epigenetic mechanisms that underlie endocrine resistance, a subject that remains an intense area of investigation in breast cancer.[51–53] Fortunately, some of these mechanisms are targetable in the clinic, and we will discuss these approaches below.

Targeted Therapy

mTOR inhibition

Activation of the PI3K-Akt-mTOR pathway in breast cancer has been implicated as one mechanism of resistance to endocrine therapy. Everolimus is an inhibitor of mammalian target of rapamycin (mTOR) and was approved in 2012 in combination with exemestane for the treatment of HR-positive MBC after progression on nonsteroidal AI monotherapy. Everolimus in combination with either fulvestrant or tamoxifen has also proven effective, and these regimens are reasonable considerations after progression on an AI (Table 36–2).

Table 36–2 Summary of Targeted Therapies for MBC

Class and Agent	Disease Subtype	References from Text	Class and Agent	Disease Subtype	References from Text
CDK4/6 Inhibitors (see Table 36–1)			**Tyrosine Kinase Knhibitors**		
Palbociclib	HR+/HER2- negative MBC	See Table 36–1	Lapatinib	HER2-positive MBC	121–125, 129, 130
Ribociclib			Neratinib		
Abemaciclib			Tucatinib		
PARP Inhibitors			**Antibodies**		
Olaparib	Hereditary *BRCA1* or *BRCA2* mutations	56, 57	Trastuzumab	HER2-positive MBC	111–117
Talazoparib			Pertuzumab		
mTOR Inhibitor			**Antibody-Drug Conjugates**		
Everolimus	HR+/HER2- MBC	48, 54, 55	T-DM1	HER2-positive MBC	118, 119
PI3K Inhibitor			Trastuzumab Derutxtecan		122, 183
Alpelisib	HR+/HER2 MBC; w/an activating *PIK3CA* mutation	14	Sacituzumab govitecan-hziy	TNBC	159
			Checkpoint Inhibitor		
			Atezolizumab	TNBC	8, 157

Approval of combination everolimus and exemestane was based on the BOLERO-2 study, a randomized, phase 3 trial that assigned 724 patients with HR-positive MBC with recurrence or progression on a prior nonsteroidal AI, to receive exemestane alone or exemestane plus everolimus.[48] The combination resulted in improved PFS (10.6 vs 4.1 months; hazard ratio 0.36; 95% CI 0.27–0.47) but not improved OS. Common AEs of everolimus included stomatitis, infections, rash, fatigue, diarrhea, reduced appetite, and a 3% risk of pneumonitis.

The combination of everolimus and fulvestrant was trialed in a similar context, MBC patients with progression on prior AI therapy, in the phase 2 PrE0102 study. Patients (n = 131) were randomly assigned to receive fulvestrant (500 mg) versus everolimus and fulvestrant. Again, the combination demonstrated superior PFS (10.3 vs 5.1 months; hazard ratio 0.61; 95% CI 0.4–0.92).[54] Finally, the combination of tamoxifen and everolimus versus tamoxifen alone also showed benefit in patients with MBC with AI resistance. In a phase 2, open-label trial of 111 postmenopausal women, TTP was 8.6 months with tamoxifen-everolimus versus 4.5 months with tamoxifen alone (hazard ratio 0.54; 95% CI 0.36–0.81).[55]

Importantly, these trials were all conducted before the widespread use of CDK4/6 inhibitors and so their efficacy in breast cancer patients exposed to these agents is less certain. There are no data to support the use of everolimus after progression on an everolimus-containing regimen.

PI3K Inhibition

Approximately 40% of patients with HR-positive breast cancer have mutations in the gene *PIK3CA*, which encodes the alpha isoform (p110α) of phosphatidylinositol 3-kinase (PI3K). PI3K plays a critical role in breast tumor cell growth, and endocrine therapy is thought to select for *PIK3CA* activating mutations, conferring endocrine resistance. To test this hypothesis, the SOLAR-1 study evaluated the combination of fulvestrant and the PI3Kα inhibitor alpelisib versus fulvestrant alone in patients with HR-positive MBC who had received prior AI therapy. Two cohorts were enrolled and were stratified by the presence or absence of *PIK3CA* mutations in tumor tissue. In 2019, the FDA approved alpelisib based on a demonstrated PFS benefit for the 341 patients with *PIK3CA* mutations (11 months in the fulvestrant-alpelisib arm vs 5.7 months for fulvestrant alone; hazard ratio 0.65; 95% CI 0.5–0.85).[14] Of note, alpelisib did not significantly affect PFS in patients without *PIK3CA* activating mutations. A companion diagnostic was also approved to test for activating *PIK3CA* mutations in the plasma or tumor tissue, preferably obtained at the time of progression. Unfortunately, grade 3/4 hyperglycemia and rash were common, occurring in 36.6% and 9.9% of patients, respectively, and accounted for a 25% rate of discontinuation of the combination therapy. Importantly, only about 6% (n = 20 with a mutation) of patients in SOLAR-1 had received prior CDK4/6 inhibition and so the efficacy of alpelisib in patients with disease progressing on CDK4/6 agents is uncertain. The adoption of this regimen at our center and in the community will depend on the ease of managing its frequent toxicity.

Poly (ADP-Ribose) Polymerase Inhibition

Germline mutations in *BRCA1* and *BRCA2* (*gBRCA*) are present in 5% of breast cancer patients and account for 40% of hereditary breast cancer diagnoses. Poly (ADP-ribose) polymerase (PARP) inhibitors are particularly effective in patients with *gBRCA* because of the concept of synthetic lethality. PARP inhibitors prevent the repair of DNA single-strand breaks and, in BRCA1/2-deficient tumors that harbor an endogenous impairment in DNA double-strand break repair, this results in tumor cell death.

In 2018, the FDA approved the PARP inhibitors olaparib and talazoparib for the treatment of HER2-negative, *gBRCA*-associated MBC. The olaparib indication requires exposure to previous chemo- and endocrine therapy, whereas talazoparib does not. Talazoparib was approved based on the phase 3 EMBRACA trial, which randomly assigned (2:1) 431 patients with HER2-negative MBC to talazoparib monotherapy versus physician's choice chemotherapy (capecitabine, eribulin, gemcitabine, or vinorelbine). PFS was superior in the talazoparib arm (8.6 vs 5.6 months; hazard ratio 0.54; 95% CI 0.41–0.71). Impressively, the RR was also higher for talazoparib (62.6% vs 27.2%) as were patient-reported outcomes.[56] OLYMPIAD trialed (2:1) olaparib versus physician's choice chemotherapy (capecitabine, eribulin, or vinorelbine) in 302 *gBRCA* patients with HER2-negative MBC. Despite the majority of patients having received previous chemotherapy for metastatic disease, the PARP inhibitor again proved superior in terms of PFS (7 vs 4.2 months; hazard ratio 0.58; 95% CI 0.43–0.8) and RR (59.9% vs 28.8%).[57] The common side effects of PARP inhibitors include hematologic toxicity—primarily macrocytic anemia but also thrombocytopenia and neutropenia/leukopenia—as well as nausea and fatigue. Multiple clinical trials are underway that combine PARP inhibitors with other agents, including immunotherapies, in an effort to improve response duration.

Chemotherapy

In HR-positive MBC, chemotherapy is reserved for patients with endocrine resistance or for patients in

visceral crisis.[58] In TNBC and HER2-positive MBC, chemotherapy is used in the first line (discussed below).

There is no standard sequence for chemotherapy in HR-positive MBC. Consideration is given to previous therapies and response, comorbidities, organ function, dosing and monitoring frequency, and patient preference regarding side effects (eg, alopecia, neuropathy). In general, choosing successive agents from different mechanistic classes is preferable (Table 36–3). Many patients have received anthracyclines and taxanes in the early breast cancer setting, in which case they are reserved for later therapy lines, particularly if recurrence was within a few years of treatment.

The choice between sequential single-agent chemotherapy and combination chemotherapy is controversial. The principle of nonoverlapping mechanisms of action and resistance provides a rationale for combination chemotherapy. However, numerous randomized trials have evaluated single- versus multiagent regimens in MBC and have generally shown that combination chemotherapy achieves higher RRs and longer PFS, but OS is unchanged.[59] Combination chemotherapy is usually associated with increased toxicity, including neutropenia and nausea/vomiting. In two randomized trials of combination versus single-agent therapy in MBC, formal quality-of-life analyses favored the single-agent arms, even though RRs were slightly lower.[60,61]

At MDACC, we generally reserve combination chemotherapy for patients with visceral crisis and for fit patients with rapid progression or symptomatic, large-volume disease. MBC is unfortunately incurable, and single-agent chemotherapy is best suited to the goal of prolonging survival without compromising quality of life. This is in agreement with consensus recommendations from several oncologic societies.[62] Ultimately, the choice of sequential versus combination chemotherapy depends on a careful evaluation of the risks and benefits for each patient. One additional potential indication for combination therapy is oligometastatic disease before consolidation with surgery or radiation.

Several studies have compared continuous chemotherapy with intermittent therapy in MBC. One systematic review and meta-analysis of these data showed a statistically significant improvement in OS for patients receiving first-line chemotherapy for a preplanned longer versus shorter duration.[63] A European trial randomly assigned patients with MBC to intermittent (two sets of four cycles) versus continuous first- or second-line chemotherapy and found that the continuous schedule was better in terms of efficacy and quality of life.[64,65] Some chemotherapies, including anthracyclines, have inherent dose-limiting toxicities that prohibit prolonged use. Other agents, such as capecitabine, lend themselves to extended therapy. Most clinical trials are designed to treat patients until there is progression of disease or limiting toxicities. The practice at MDACC is to treat patients with MBC with continuous chemotherapy unless unacceptable toxicity arises and/or Eastern Cooperative Oncology Group performance status declines to 3 or higher. Within this framework, though, we are mindful of the importance of treatment breaks, including for significant life events.

Table 36–3 Chemotherapy Options for MBC

Class and Agent	References From Text			References From Text
Anthracyclines		**Platinum Salts**		
Doxorubicin	66–69	Carboplatin		101–103, 135, 174
Liposomal doxorubicin	71	Cisplatin		167, 168, 175
Taxanes		**Alkylating agent**		
Paclitaxel	72,73	Cyclophosphamide		80, 95
Docetaxel	74–76	**Combination Chemotherapy regimens**		
Nab-paclitaxel	77,78	Doxorubicin/cyclophosphamide (AC)		95, 96
Antimetabolites		Doxcetaxel/capecitabine		99
Capecitabine	79–82	Gemcitabine/paclitaxel		100
Gemcitabine	83–85	Carboplatin/paclitaxel		101–103
Non-taxane micotubule inhibitors		Gemcitabine/carboplatin		164
Eribulin	86–88	Capecitabine/methotrexate/fluorouracil (CMF)		80
Vinorelbine	89–91	Capecitabine/ixabepilone		106, 107
Ixabepilone	92–94	gemcitabine/capecitabine		109

Single-Agent Chemotherapy

Anthracyclines

The introduction of anthracyclines (doxorubicin and epirubicin) in the 1970s was a significant advance in treating MBC. Anthracyclines work by intercalating DNA and inhibiting topoisomerase II, inhibiting DNA repair. RRs to single-agent doxorubicin (25–75 mg/m^2 every 3 weeks) range from 25% to 50% for MBC and are heavily influenced by patient characteristics such as prior chemotherapy exposure, performance status, and extent and sites of disease.[66–69] At MDACC, doxorubicin-containing regimens are the initial chemotherapy of choice for patients with MBC with good cardiac function who have not received a prior anthracycline. Patients treated with a prior anthracycline occasionally benefit from repeat administration of doxorubicin (or liposomal doxorubicin) in later lines of therapy. However, given the increasing number of active agents in MBC, repeat anthracycline therapy should be reserved for patients in whom other treatments have failed, given the potential risk of heart failure.

Epirubicin is a doxorubicin analog that was shown to have similar efficacy and slightly less toxicity than doxorubicin at equimolar doses. A formal comparison of two different anthracyclines in combination regimens (FAC versus FEC) at equimolar doses found both regimens to be equally effective in terms of RR, TTP, and survival. The FEC regimen was associated with fewer gastrointestinal, hematologic, and cardiac toxicities.[70]

Efforts to improve the safety profile of doxorubicin led to the development of liposomal doxorubicin. In a phase 3 clinical trial, the efficacy and safety of pegylated liposomal doxorubicin was compared with that of conventional doxorubicin as first-line cytotoxic therapy in patients with MBC.[71] A total of 509 patients received pegylated liposomal doxorubicin (50 mg/m^2 once every 4 weeks) or conventional doxorubicin (60 mg/m^2 once every 3 weeks). The median PFS and OS were similar in both groups (6.9 vs 7.8 months and 20.1 vs 22.0 months, respectively). The incidence of alopecia, myelosuppression, and nausea/vomiting were lower with pegylated liposomal doxorubicin compared with conventional doxorubicin. Importantly, pegylated liposomal doxorubicin was associated with a significantly lower incidence of cardiotoxicity, even at higher cumulative doses (hazard ratio 3.16; 95% CI 1.58–6.31, $P < .001$).[71] One important dose-limiting toxicity of pegylated liposomal doxorubicin is palmar-plantar erythrodysesthesia (hand-foot syndrome), which is both dose- and duration-related. As with all liposomal drug delivery systems, there is a low incidence of hypersensitivity reactions.

Taxanes

Taxanes (paclitaxel, docetaxel, and nanoparticle albumin–bound paclitaxel [nab-paclitaxel]) are among the most active classes of cytotoxic drugs in breast cancer treatment. Taxanes stabilize microtubules during the mitotic phase, preventing cell division. They rival the anthracyclines in terms of RR and response duration. Taxanes are frequently used as first-line cytotoxic therapy in chemotherapy-naïve patients with MBC or as second-line chemotherapy after anthracyclines.

In the Intergroup E1193 study, similar RRs (36% for doxorubicin vs 34% for paclitaxel) and TTP (5.8 vs 6 months) were observed using either doxorubicin (60 mg/m^2 every 3 weeks) or paclitaxel (175 mg/m^2 every 3 weeks).[72] A meta-analysis compared paclitaxel 80 mg/m^2 given weekly with paclitaxel 175 mg/m^2 given every 3 weeks and found that weekly dosing resulted in better OS and a lower incidence of AEs, though the RR was slightly better for the every 3-week dosing schedule.[73] At MDACC, the most popular taxane regimen for MBC is weekly paclitaxel 80 mg/m,^{2} very commonly in a 3-weeks-on/1-week off or 2-weeks-on/1-week-off schedule.

Docetaxel is a semisynthetic taxane with several pharmacologic differences from paclitaxel. It is associated with a 37% to 57% RR in patients with anthracycline-resistant breast tumors and was initially FDA-approved for this indication at a dose of 60–100 mg/m^2 every 3 weeks. At these doses, hematologic toxicity is common, and the rates of neutropenia are similar to those observed with paclitaxel given every 3 weeks. In one clinical trial that aimed to establish the optimal docetaxel dose, 527 patients were randomly assigned to receive docetaxel 60, 75, or 100 mg/m^2 every 3 weeks. A positive relationship between increasing dose of docetaxel and RR was observed, but at the expense of greater toxicity.[74] One phase 3 trial of 449 patients with MBC directly compared docetaxel 100 mg/m2 every 3 weeks with paclitaxel 175 mg/m2 every 3 weeks. All patients had progressed after prior anthracycline-based chemotherapy. Docetaxel 100 mg/m^2 was associated with longer TTP (hazard ratio 1.64; 95% CI 1.33–2.02) and improved OS (hazard ratio 1.64; 95% CI 1.33–2.02) versus every-3-week paclitaxel, but also resulted in a greater incidence of treatment-related toxicity.[75] The most commonly used single-agent taxane regimens, paclitaxel 80 mg/m^2 weekly and docetaxel 75 mg/m^2 every 3 weeks, have not been directly compared. In patients who have received prior paclitaxel chemotherapy, subsequent treatment with docetaxel achieved RRs of 18% to 21%, demonstrating a partial lack of cross-resistance between the two agents.[76] Docetaxel administered every 3 weeks at doses between 75 and 100 mg/m^2 is an appropriate choice as first-line therapy for MBC; in most cases at MDACC, we use 75 mg/m.^{2} Moderate nail changes, cumulative neuropathy, and fatigue are commonly seen with paclitaxel and docetaxel treatment. Diarrhea, stomatitis, and

neutropenia are more common with docetaxel compared with weekly paclitaxel. There is the potential for fluid retention in patients who receive docetaxel at a cumulative dose greater than 300 mg/m^2, though premedication with steroids can mitigate this side effect. At MDACC, we routinely prescribe dexamethasone 4 mg orally twice daily for 3 days, beginning the day before starting docetaxel.

The last commonly used taxane is nab-paclitaxel, a nanoparticle albumin–bound formulation of paclitaxel. In several comparisons, nab-paclitaxel has proven as effective, and, in some cases, more effective than the other taxanes.[77,78] One distinct advantage of nab-paclitaxel over paclitaxel is that it does not require cremophor for solubility, and accordingly, nab-paclitaxel is associated with a much lower risk of hypersensitivity reactions. In a phase 3 study, 454 patients with MBC were randomly assigned to 3-week cycles of nab-paclitaxel 260 mg/m^2 or paclitaxel 175 mg/m.^{2} Nab-paclitaxel demonstrated significantly higher RRs compared with paclitaxel (33% vs 19%) and longer TTP (23.0 vs 16.9 weeks). Grade 3 sensory neuropathy was more common with nab-paclitaxel, the incidence of grade 4 neutropenia was significantly lower with nab-paclitaxel, and the rate of febrile neutropenia was similar in both groups.[78] A phase 2, four-arm study compared nab-paclitaxel (300 mg/m^2 every 3 weeks, 150 mg/m^2 weekly, or 100 mg/m^2 weekly) and docetaxel (100 mg/m^2 every 3 weeks). Weekly nab-paclitaxel at 150 mg/m^2 demonstrated longer PFS than docetaxel (12.9 vs 7.5 months). Grade 3/4 fatigue, neutropenia, and febrile neutropenia were less frequent in the nab-paclitaxel arms, but the rate and severity of peripheral neuropathy were similar across all groups.[77] At MDACC, nab-paclitaxel is frequently used as first- or second-line therapy administered in a weekly schedule (100 mg/m^2, typically 3 weeks on/1 week off), and it is the taxane of choice for patients with contraindications to steroid use. Nab-paclitaxel can be trialed in patients with hypersensitivity to either paclitaxel or docetaxel.

Antimetabolites

Capecitabine. Capecitabine is an oral fluoropyrimidine approved by the FDA in 1998 as single-agent therapy for the treatment of MBC resistant to anthracyclines and taxanes. In September 2001, capecitabine received an additional indication for use in combination with docetaxel in patients with MBC previously treated with an anthracycline. The first phase 2 study of capecitabine in MBC included 162 patients who had received prior treatment with paclitaxel for metastatic disease. Most patients had also received a prior anthracycline. Capecitabine was administered at 2510 mg/m^2 per day in two divided doses for 2 weeks on/1 week off. The RR was 20%, the median TTP was 93 days, the median duration of response was 8.1 months, and the median OS was 12.8 months.[79] In a separate phase 2 trial, O'Shaughnessy and colleagues randomly assigned (2:1) patients with MBC who had not received any prior cytotoxic therapy for metastatic disease to receive capecitabine or IV cyclophosphamide, methotrexate, and 5-fluorouracil (CMF). The trial was designed to accrue older patients in an effort to avoid anthracycline-related toxicity and the median age was 69 years. Capecitabine achieved an overall RR of 30% versus 16% for CMF; no differences in TTP (4.1 vs 3 months) or OS (19.6 vs 17.2 months) were seen. Similar levels of nausea, vomiting, and stomatitis were observed in both groups. More cases of grade 3/4 diarrhea (8%), fatigue (5%), and hand-foot syndrome (15%) were noted with capecitabine. In the capecitabine group, 34% of patients required treatment interruption and/or dose modification and 10 (16%) patients discontinued the medicine as a result of AEs.[80]

The FDA-approved dose and schedule for capecitabine are 2500 mg/m^2 per day given orally in two divided doses for 14 days, followed by one week of rest. Retrospective studies suggest that a lower starting dose (2000 mg/day) or a week on/week off schedule are better tolerated, with fewer dose reductions and preserved efficacy.[81,82] At MDACC, capecitabine is often used as first-line cytotoxic therapy for patients previously treated with anthracyclines and/or taxanes in the adjuvant or neoadjuvant setting, though there are several additional options. We prefer to start at 1800–2000 mg/m^2 per day (divided twice daily) for 2 weeks on/1 week off, but tolerance, patient age, and comorbidities (such as concomitant renal disease) factor importantly in each patient's dosing schedule.

Gemcitabine. Gemcitabine, a nucleoside analog, was approved in combination with paclitaxel by the FDA in April 2004 for the treatment of MBC. Gemcitabine is phosphorylated intracellularly to gemcitabine diphosphate and gemcitabine triphosphate, which are both active cytotoxins. The taxane combination regimen is discussed below; however, several small phase 2 trials of gemcitabine monotherapy were also conducted in patients with MBC. Single-agent RRs range from 14% to 37%.[83–85] The differing RRs are attributable to differences in dosing (800–1200 mg/m^2 in the referenced trials) and the extent of prior treatment. In general, chemotherapy-naïve patients tolerate doses of 800–1200 mg/m^2 per week on days 1, 8, and 15 every 28 days. Dose reductions and/or omission of the day 15 dose are frequently necessary to prevent cycle delays. Pretreated patients may require further dose reductions to limit thrombocytopenia and neutropenia. There is also a small risk of hemolytic uremic syndrome and pulmonary toxicity. As alluded to above, gemcitabine has been investigated in many doublet and triplet combinations. At MDACC, gemcitabine

is rarely used as monotherapy for first-line cytotoxic therapy in patients with HR-positive MBC because of its modest activity; however, it is a useful drug in patients with renal or hepatic impairment or in later lines of treatment.

Non-Taxane Microtubule Inhibitors

Eribulin. Eribulin mesylate is a non-taxane inhibitor of microtubule dynamics that works by inhibiting microtubule growth. Eribulin was approved for patients with MBC in 2011 based on the registration trial, EMBRACE. In this phase 3, open-label, randomized study, 762 patients who had received a median of four previous chemotherapy regimens were randomly assigned (2:1) to either eribulin 1.4 mg/m^2 on days 1 and 8 every 21 days versus physician's choice chemotherapy (primarily vinorelbine, gemcitabine, or capecitabine). Patients treated with eribulin had improved OS (13.1 vs 10.6 months; hazard ratio 0.81; 95% CI 0.66–0.99). Median PFS was 3.7 months with eribulin and the RR was 12% by independent review. Asthenia, fatigue, and neutropenia were the most common side effects associated with eribulin, and peripheral neuropathy led to discontinuation of treatment in 5% of patients in the eribulin arm.[86]

A phase 2 study then evaluated the efficacy of eribulin in the treatment of HER2-negative MBC in the first-line setting.[87] Fifty-six patients were treated, the majority having received anthracycline and/or taxane-containing chemotherapy in the adjuvant setting. The RR was 29%, the clinical benefit rate was 52%, and the median PFS was 6.8 months.

Finally, a second phase 3 randomized trial directly compared eribulin with capecitabine in patients with MBC who had previously received a taxane and an anthracycline. A total of 1102 patients were randomly assigned (1:1) to eribulin or capecitabine as first-, second-, or third-line cytotoxic therapy for MBC. Median OS was 15.9 months for eribulin versus 14.5 months for capecitabine (hazard ratio 0.88; 95% CI 0.77–1.00; P = .056), and PFS was similar at 4.1 vs 4.2 months; RR was 11% for eribulin and 11.5% for capecitabine.[88] Based on the evidence, MDACC oncologists use either eribulin or capecitabine for patients with HR-positive MBC who have received prior taxane and/or anthracycline treatment. Capecitabine is convenient as an oral regimen, though eribulin is also well tolerated and is infused over only 5 minutes. Capecitabine causes less alopecia.

Vinorelbine. Vinorelbine is a semisynthetic vinca alkaloid that interferes with microtubule assembly and is active in the treatment of MBC. Vinblastine and vincristine are other agents in the vinca alkaloid class that are widely used in other tumor types. Vinorelbine was FDA-approved in 1994 for the treatment of lung cancer. In an early phase 2 trial, 183 patients with MBC and prior anthracycline exposure were randomly assigned (2:1) to weekly vinorelbine 30 mg/m^2 versus melphalan. Vinorelbine demonstrated a 16% RR and time to treatment failure was significantly longer with vinorelbine than melphalan (12 vs 8 weeks).[89] A separate phase 2 trial evaluated vinorelbine 35 mg/m^2 weekly (with growth factor support) in patients with MBC treated with a prior anthracycline and taxane and reported a RR of 25% and TTP of 13 weeks. The dose-limiting toxicity was neutropenia despite growth factor support.

Vinorelbine has also been evaluated as first-line cytotoxic therapy in the metastatic setting. One-hundred fifty-seven patients with MBC, many with visceral disease, were treated with weekly vinorelbine 30 mg/m^2. The trial reported a RR of 41% and time to treatment failure of 6 months. Grade 3/4 neutropenia occurred in 72% of patients.[90] Finally, vinorelbine has been evaluated in multiple combinations. A phase 3 trial randomized 252 patients with MBC to either vinorelbine monotherapy 30 mg/m^2 on days 1 and 8 every 21 days versus combination vinorelbine and gemcitabine. All patients had received prior anthracycline and taxane chemotherapy and 75% of patients had visceral disease. RR (36% vs 26%) and PFS (6 vs 4 months; hazard ratio 0.66; 95% CI 0.5–0.88) were significantly improved with the combination; however, OS was similar between arms (15.9 vs 16.4 months). Hematologic toxicity was more significant in patients treated with the combination regimen.[91] Vinorelbine carries a black box warning for myelosuppression. Other adverse effects include neuropathy, flu-like symptoms, and gastrointestinal symptoms such as nausea and constipation. At MDACC, vinorelbine is used as third-line (or later) cytotoxic therapy for patients with MBC. We typically start vinorelbine at a dose of 25 mg/m^2 weekly on days 1, 8, and 15 of a 28-day cycle.

Ixabepilone. Ixabepilone is an epothilone B analog that stabilizes microtubules causing mitotic arrest. It was approved by the FDA in October 2007 and is approved in combination with capecitabine for patients with MBC whose disease has progressed after anthracycline and taxane treatment. Ixabepilone is also approved as monotherapy for patients with MBC who have received a prior anthracycline, taxane, and capecitabine.

Ixabepilone monotherapy was evaluated in a single-arm, phase 2 trial of 126 patients with MBC who had received a prior anthracycline, taxane, and capecitabine. Most patients (88%) had received at least two prior lines of therapy in the metastatic setting. The RR was 11.5%, the median response duration was 5.7 months, and the PFS was 3.1 months. Grade 3/4 neutropenia occurred in 54% of patients and grade 3/4 peripheral neuropathy in 14%.[92] When used as first-line cytotoxic therapy in 65 patients with MBC who had received previous adjuvant anthracycline treatment, the RR was 41.5% with a median duration of response of 8.2 months.[93] Finally, in a separate phase

2 trial, ixabepilone monotherapy was evaluated in 49 patients with MBC who had received prior anthracycline chemotherapy and who had experienced recent disease progression on taxane therapy. The trial mandated that taxanes had to be the most recent chemotherapy. In these patients, the RR was 12% with a median duration of response of 10.4 months. TTP was 2.2 months.[94] At MDACC, we sometimes use ixabepilone in patients who have received anthracyclines, taxanes, capecitabine, and, often, eribulin. Its use is more common in TNBC (see below). We typically start ixabepilone at 40 mg/m,^{2} but dose reductions to 32 mg/m^2 are common. Neuropathy is predominantly sensory-type and is largely reversible.

Combination Chemotherapy

As discussed above, sequential single-agent chemotherapy is preferred over combination chemotherapy for most patients with ER-positive MBC. Patients in visceral crisis or fit patients with rapidly progressing, endocrine-resistant disease are potential candidates for combination chemotherapy. There have been numerous trials of combination chemotherapy in MBC and an exhaustive list of these results is outside the scope of this chapter. However, we will outline the evidence for several combination therapies that we use at MDACC. We reserve anthracycline- or taxane-based combinations for patients who are naïve to these agents.

Anthracycline-Based Combination Regimens

The combination of doxorubicin and cyclophosphamide (AC) is a standard neoadjuvant/adjuvant regimen in early-stage breast cancer that remains effective in the metastatic setting for AC-naïve patients. Doxorubicin/paclitaxel was compared with standard AC as first-line chemotherapy in 275 patients with MBC in a randomized, phase 2 trial. The regimens were doxorubicin 60 mg/m^2 and paclitaxel 175 mg/m^2 every 3 weeks versus doxorubicin 60 mg/m^2 and cyclophosphamide 600 mg/m^2 every 3 weeks for a maximum of six cycles. Median PFS was 6 months in both arms and RR was 58% for doxorubicin/paclitaxel versus 54% for AC. Neutropenic fever was more common in the doxorubicin/paclitaxel arm (32%) compared with AC (9%) and compromised doxorubicin dose delivery in that group.[95]

Standard AC chemotherapy was also compared with another taxane-based regimen, doxorubicin and docetaxel (AT) as first-line chemotherapy in 429 patients with MBC. AT (doxorubicin 50 mg/m^2 and docetaxel 75 mg/m^2 every 3 weeks) modestly improved TTP (37.3 vs 31.9 weeks; P = .014) and overall RR (59% vs 47%; P = .008) compared with AC, but there was no difference in OS. The lack of survival benefit was partially attributable to patients in the AC arm crossing over to taxane chemotherapy during subsequent lines of therapy. Neutropenic fever and other infections were more frequent for AT (33%) than AC (10%). Grade 3/4 cardiac events were similar (3% for AT vs 4% for AC).[96] Based on this evidence, we prefer AC to either doxorubicin/paclitaxel or doxorubicin/docetaxel in patients with MBC.

The use of triple-combination therapy is far rarer than doublet chemotherapy in our current practice for MBC. However, for many years at MDACC, FAC (500/50/500 mg/m^2) was the standard regimen for patients with MBC. Nabholtz et al[97,98] compared the use of docetaxel/doxorubicin/cyclophosphamide (TAC 75/50/500 mg/m^2) with FAC as first-line therapy for MBC (n = 484). The RR was 55% for TAC versus 44% for FAC (hazard ratio 1.5; 95% CI 1.1–2.2; P = .02). There was no significant difference in TTP or OS between treatment arms. Febrile neutropenia occurred more frequently with TAC (29% vs 5%) but similar rates of infection were seen.

Taxane-Based Combination Regimens

The combination of docetaxel and capecitabine was approved by the FDA in 2001 for patients with MBC previously treated with an anthracycline. The registration trial was a phase 3, randomized study of docetaxel/capecitabine (75 mg/m^2 every 3 weeks, 1250 mg/m^2 twice daily on days 1–14 every 21 days) versus docetaxel alone (100 mg/m^2 every 3 weeks) in 511 anthracycline-refractory patients with MBC. The RRs for the single-agent and combination regimens were 30% and 42%, respectively. The TTP was 4.2 versus 6.1 months for the combination (hazard ratio 0.65; 95% CI 0.55–0.78). The OS was also superior for the combination, with a median OS of 11.5 months for docetaxel alone versus 14.5 months for docetaxel/capecitabine (hazard ratio 0.775; 95% CI 0.63–0.95). Approximately two-thirds of patients (65%) in the combination arm required dose reductions versus 36% in the docetaxel group. Grade 3 AEs were more common in the combination arm (71% vs 49% for docetaxel alone).[99]

Gemcitabine/paclitaxel (GT) was approved as combination therapy for MBC by the FDA in 2004. Approval was based on a randomized phase 3 trial of GT versus paclitaxel alone as frontline chemotherapy for patients who had received a prior adjuvant anthracycline. A total of 266 patients were randomly assigned to receive gemcitabine (1250 mg/m^2 on days 1 and 8) plus paclitaxel (175 mg/m^2 on day 1) every 21 days versus paclitaxel alone (175 mg/m^2 every 21 days). Median survival was 18.6 months for GT versus 15.8 months for paclitaxel monotherapy (hazard ratio 0.78; 95% CI 0.64–0.96) and RR was 41.4% for the combination versus 26.2% for paclitaxel alone. The TTP was longer for the combination (6.14 vs 3.98 months). Hematologic toxicity, primarily neutropenia, was more common in the GT arm.[100]

Briefly, there are also data for combination carboplatin/paclitaxel or carboplatin/docetaxel[101–103] and combination paclitaxel/bevacizumab[104,105] in ER-positive MBC. At our institution, platinum chemotherapy is used more commonly in TNBC and *gBRCA*-associated breast cancers. Bevacizumab was approved for use in combination with paclitaxel for MBC in 2008; however, the breast cancer indication was later removed in 2011 based on the absence of an OS benefit. At MDACC, bevacizumab is rarely used in treating MBC outside of clinical trials or metaplastic histology.

Capecitabine Combination Regimens

Capecitabine in combination with ixabepilone was approved to treat patients with MBC in 2007, supported by two similarly designed randomized, phase 3 trials. The first trial randomly assigned 752 patients with MBC to either ixabepilone 40 mg/m^2 plus capecitabine 2000 mg/m^2 on days 1 to 14 every 21 days or capecitabine 2500 mg/m^2 on the same schedule. All patients had received prior anthracycline and taxane therapy. The combination demonstrated improved PFS (5.8 vs 4.2 months; hazard ratio 0.75; 95% CI 0.64–0.88) and overall RR (35% vs 14%). Grade 3/4 toxicity was more pronounced in the combination arm, including peripheral neuropathy (21% vs 0%) and neutropenia (68% vs 11%). The rate of death was also increased with combination therapy (3% vs 1%). Patients with liver dysfunction are at higher risk of complications and should not be treated with this regimen.[106] The second trial included the same patient population and randomly assigned 1221 patients to the identical two regimens but evaluated OS rather than PFS as the primary end point. No difference in OS was detected (16.4 months for the combo vs 15.6 months for capecitabine alone; hazard ratio 0.9; 95% CI .08–1.03; P = .12), though improvements in PFS and RR again favored the combination.[107] Despite its toxicity, this combination represents a reasonable alternative for fit patients with resistant disease in whom a tumor response is critical.

The combination of gemcitabine and capecitabine has been evaluated in small, phase 2 trials. A total of 76 patients with MBC and prior anthracycline treatment were treated with gemcitabine 1000 mg/m^2 on days 1 and 8 plus capecitabine 830 mg/m^2 twice daily on days 1 to 14 every 21 days. Slightly more than half of the patients received this regimen as frontline cytotoxic therapy. The ORR was 55.2% with a TTP of 11.1 months. Grade 3/4 neutropenia occurred in 60% of patients, asymptomatic hepatotoxicity in 13.5%, and hand-foot syndrome in 16%.[108] The gemcitabine/capecitabine combination was tested against gemcitabine/cisplatin and gemcitabine/vinorelbine in a randomized trial in Germany and again demonstrated reasonable safety and efficacy. A total of 49 patients with MBC and prior anthracycline therapy were treated in the gemcitabine/capecitabine arm (identical gemcitabine dosing as the above study, but with a lower dose of capecitabine at 650 mg/m^2 twice daily on the same schedule). RR was 34.7% in the gemcitabine/capecitabine arm, with a PFS of 8.3 months and the regimen was well tolerated.[109]

Finally, at MDACC we infrequently utilize the CMF regimen (also discussed in the capecitabine section) in older patients who have received multiple previous treatments and who are unable to tolerate capecitabine.[80]

HER2-POSITIVE BREAST CANCER

HER-2 positive disease accounts for around 15% of all diagnosed breast cancers. Before the development of anti-HER2 monoclonal antibodies, HER2-positive breast cancer was among the most aggressive subtypes with a poor prognosis.[110,111] Multiple novel therapies have entered the clinic over the past two decades that improve the survival and quality of life of patients with HER2-positive MBC (Table 36–4). In this section, we will review the most relevant data associated with anti-HER2 treatment regimens, including the sequence we use at MDACC (Fig. 36–2).

Docetaxel/Trastuzumab/Pertuzumab—First-Line Therapy

The HER2/neu protein, a transmembrane receptor tyrosine kinase, plays a critical role in tumor development and progression when overexpressed in breast cancer. Trastuzumab is a murine-human chimeric monoclonal antibody that binds the extracellular domain of the HER2 protein and mediates antibody-dependent cellular toxicity. Trastuzumab was approved by the FDA in 1998 for the treatment of HER2-positive MBC after clinical trials demonstrated its efficacy as a single agent and in combination with chemotherapy.[111–113] Early trials reported an approximate 2.5% risk of cardiotoxicity related to trastuzumab that was usually reversible with discontinuation, with the potential for safe rechallenge.[114] Trastuzumab cardiotoxicity was exacerbated by concurrent anthracycline treatment and the combination is contraindicated. Combination taxane and trastuzumab therapy remained a standard of care regimen for many years until the development of a second anti-HER2 monoclonal antibody, pertuzumab.

Pertuzumab is a humanized anti-HER2 monoclonal antibody approved by the FDA in 2012 for the treatment of HER2-positive MBC. Pertuzumab binds to a different epitope of the HER2 extracellular domain than trastuzumab and prevents its heterodimerization with other HER family members, particularly HER3. The combination of pertuzumab, trastuzumab, and docetaxel (THP) was tested against trastuzumab and

Table 36–4 Recent Trials Relevant to the Management of HER2-Positive MBC and Metastatic TNBC

Trial	n	Patients	Treatment	Outcomes	Notes
HER2-positive MBC					
CLEOPATRA[7,115]	808 (1:1)	Frontline treatment for MBC (~46% had received prior chemotherapy and 10% had received previous trastuzumab)	THP (docetaxel, trastuzumab, pertuzumab) vs trastuzumab + docetaxel	PFS (18.5 vs 12.4 mo, HR 0.62; 95% CI 0.51–0.75); ORR (80.2% vs 69.3%); OS (57.1 vs 40.8 mo, HR 0.69; 95% CI 0.58–0.82)	Remains standard frontline tx; the median number of docetaxel cycles delivered in each arm was 8; 3.8% of patients in the THP arm (vs 6.6% in control arm) had LVEF decline of ≥10%; grade 3/4 diarrhea in ~8% in THP arm
EMILIA[118,119]	991 (1:1)	MBC patients with previous trastuzumab and taxane treatment (40% had received >1 chemotx for MBC, 84% had received trastuzumab for MBC)	T-DM1 vs lapatinib + capecitabine	PFS (9.6 vs 6.4 mo, HR 0.65; 95% CI 0.55–0.77); ORR (43.6% vs 30.8%); OS (29.9 vs 25.9 mo, HR 0.75; 95% CI 0.64–0.88)	Led to FDA approval in 2013 of T-DM1 as second-line tx for MBC; grade 3/4 thrombocytopenia in 12.9% on T-DM1 arm; grade 3/4 AST/ALT elevation in 7.2%
MARIANNE[120]	1095 (1:1:1)	Frontline treatment for MBC (~55% had received prior neoadjuvant/adjuvant therapy)	Trastuzumab + taxane vs T-DM1 vs T-DM1 + pertuzumab	PFS (13.7 vs 14.1 vs 15.2 mo); ORR (67.9% vs 59.7% vs 64.2%)	T-DM1 and T-DM1 + pertuzumab are noninferior but not superior to trastuzumab + taxane in terms of PFS, which further cements THP as the frontline regimen for HER2-positive MBC
HER2CLIMB[121]	612 (2:1)	Subsequent-line treatment for MBC (all patients had received previous pertuzumab, trastuzumab, and T-DM1)	Tucatinib + trastuzumab + capecitabine vs trastuzumab + capecitabine	PFS (7.8 vs 5.6 mo, HR 0.54; 95% CI 0.42–0.71); ORR (40.6% vs 22.8%); OS (21.9 vs 17.4 mo, HR 0.66; 95% CI 0.5–0.88)	FDA approval in 2020 after 1 or more prior anti-HER2 lines for MBC; among 219 patients with brain metastases, PFS at 1 year was 24.9% in the tucatinib arm vs 0% in the control arm; 81% of patients in the tucatinib arm experienced diarrhea and there was grade 3/4 AST/ALT elevation in 5%
DESTINY-Breast01[122]	184 (single arm)	Subsequent-line treatment for MBC (median 6 prior lines, all patients had received prior trastuzumab and T-DM1)	Trastuzumab deruxtecan	ORR 60.9% (median duration of response 14.8 mo); PFS 16.4 mo	FDA accelerated approval in 2019 after at least 2 prior anti-HER2 regimens for MBC; 13.6% of patients with ILD/pneumonitis (2.2% fatal); agent also had activity in low HER2-expression MBC
NALA[123]	662 (1:1)	Subsequent line treatment for MBC (patients had received at least 2 prior anti-HER2 therapies for metastatic disease)	Neratinib + capecitabine vs lapatinib + capecitabine	PFS (8.8 vs 6.6 mo, HR 0.76; 95% CI 0.63–0.93); ORR (32.8% vs 26.7%); OS at 1 year (72.5% vs 66.7%, HR 0.88; 95% CI 0.72–1.07)	FDA approval in 2020 after at least 2 prior anti-HER2 regimens for MBC; grade 3 diarrhea in 24%; neratinib combo also delayed the time to intervention for symptomatic CNS disease

Table 36–4 Recent Trials Relevant to the Management of HER2-Positive MBC and Metastatic TNBC (*Cont.*)

Trial	n	Patients	Treatment	Outcomes	Notes
Metastatic TNBC					
IMpassion130[8,157]	902 (1:1)	Frontline treatment for mTNBC (~50% had received prior taxane and/or anthracycline chemotx)	Atezolizumab + nab-paclitaxel vs nab-paclitaxel	For any PD-L1, PFS (7.2 vs 5.5 mo, HR 0.8; 95% CI 0.69–0.92); in the 40% of patients with PD-L1+ disease, PFS (7.5 vs 5 mo, HR 0.62; 95% CI 0.49–0.78); ORR (any PD-L1, 56% vs 45.9%)	FDA accelerated approval in 2019 for PD-L1+ mTNBC; no OS was demonstrated in the ITT population; however, in the PD-L1+ group OS (25 vs 18 mo, HR 0.71; 95% CI 0.54–0.93); hypothyroidism in 17.3% in the atezolizumab arm
IMMU-132-01[159]	108 (single arm)	Subsequent-line treatment for mTNBC (median 3 previous therapies)	Sacituzumab govitecan-hziy	RR 33.3% (3 CRs and 33 PRs); median duration of response 7.7 mo; CBR 45.4%; median PFS 5.5 mo	FDA accelerated approval in 2020 for patients with mTNBC after 2 lines of therapy for metastatic disease

CBR, clinical benefit rate; HR, hazard ratio; ITT, intention to treat; LVEF, left ventricular ejection fraction; MBC, metastatic breast cancer; ORR, overall response rate; OS, overall survival; PFS, progression-free survival; tx, therapy.

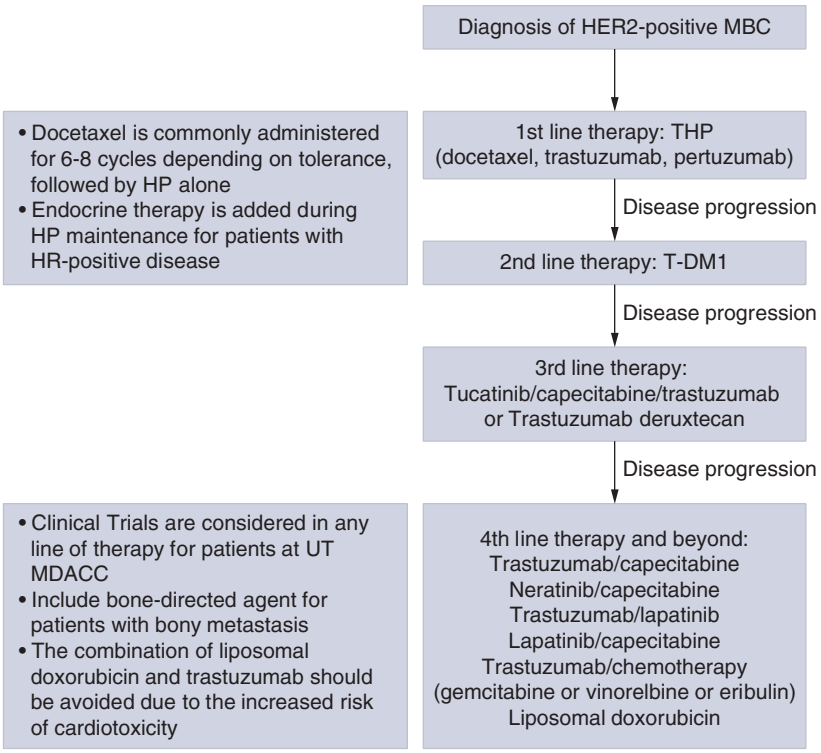

FIGURE 36–2 Concise algorithm for the treatment of patients with HER2-positive MBC at MDACC.

docetaxel in a landmark clinical trial, CLEOPATRA. About 10% of patients had received trastuzumab in either the neoadjuvant or adjuvant setting. A total of 808 patients with HER2-positive MBC were randomized and THP demonstrated remarkable efficacy versus docetaxel/trastuzumab. PFS was 18.5 months in the THP arm versus 12.4 months in the control group (hazard ratio 0.62; 95% CI 0.51–0.75). The rate of grade 3/4 neutropenic fever and diarrhea were higher in the THP arm, but cardiotoxicity was similar between groups.[115] The end-of-study results were recently published for CLEOPATRA. Median OS was 57.1 months for the THP arm versus 40.8 months for docetaxel/trastuzumab (hazard ratio 0.69; 95% CI 0.58–0.82). At 8 years, the OS in the THP group was 37% compared with 23% in the docetaxel/trastuzumab arm.[7] At MDACC, THP (or paclitaxel/trastuzumab/pertuzumab[116,117]) remains the standard first-line regimen for most patients with HER2-positive MBC. T-DM1 is a more appropriate first-line therapy for patients who experience distant metastatic recurrence within 6 months of receiving neoadjuvant or adjuvant chemotherapy and trastuzumab/pertuzumab.

T-DM1—Second-Line Therapy

Ado-trastuzumab emtansine (T-DM1) is a HER2-antibody drug conjugate, linking trastuzumab with the microtubule inhibitor, DM1 (a maytansine derivative). T-DM1 was approved by the FDA in 2013 for the treatment of patients with HER2-positive MBC, previously treated with trastuzumab and a taxane. The registration trial, EMILIA, was an open-label, randomized phase 3 study comparing T-DM1 versus capecitabine/lapatinib in 991 patients with HER2-positive MBC who had previously received trastuzumab and a taxane. A significant improvement in PFS was observed with T-DM1 (9.6 vs 6.4 months; hazard ratio 0.65; 95% CI 0.55–0.77).[118] Median OS was also improved with T-DM1 (29.9 vs 25.9 months; hazard ratio 0.75; 95% CI 0.64–0.88).[119] Rates of grade 3/4 toxicity were higher with capecitabine/lapatinib, though thrombocytopenia and elevated aspartate aminotransferase/alanine aminotransferase (AST/ALT) were more common with T-DM1. T-DM1 carries a warning label for risk of liver failure and requires routine liver function test monitoring. In addition, routine echocardiograms are recommended for patients on T-DM1 as with trastuzumab and pertuzumab. All HER2-specific therapies, including T-DM1, are contraindicated in pregnancy because of the risk of oligohydramnios.

The MARIANNE trial was a large, randomized, phase 3 trial of candidate frontline therapies for HER2-positive MBC. A total of 1095 patients were randomly assigned (1:1:1) to trastuzumab plus taxane versus T-DM1 versus T-DM1 plus pertuzumab. The T-DM1 regimens were noninferior to trastuzumab/taxane in terms of the primary PFS end point but did

not demonstrate superiority. PFS was 13.7 months for trastuzumab/taxane versus 14.1 months T-DM1 versus 15.2 months for T-DM1 plus pertuzumab. Peripheral neuropathy of any grade occurred in 28% of patients in the control arm, 13.3% on T-DM1, and 17.8% on T-DM1 plus pertuzumab.[120]

At MDACC, T-DM1 3.6 mg/kg every 21 days is standard second-line therapy for HER2-positive MBC. Dose reductions are common for thrombocytopenia. T-DM1 was recently approved for early-stage HER2-positive breast cancer in the setting of residual disease, and this will change the treatment paradigm for patients who experience distant recurrence within 6 to 12 months of completing adjuvant therapy. In that situation, we would consider one of the third-line therapies.

Tucatinib/Trastuzumab/Capecitabine or Trastuzumab Deruxtecan—Third-Line Therapies

Two different regimens received recent FDA approval for HER2-positive MBC. In the HER2CLIMB trial, 612 patients with HER2-positive MBC who had previously received trastuzumab, pertuzumab, and T-DM1 were randomly assigned (2:1) to either tucatinib plus trastuzumab plus capecitabine versus placebo/trastuzumab/capecitabine. Tucatinib is an oral tyrosine kinase inhibitor that is highly selective for the HER2 kinase domain. At 1 year, PFS was 33.1% in the tucatinib combination arm versus 12.3% in the control arm (hazard ratio 0.54; 95% CI 0.42–0.71), with a median PFS of 7.8 months compared with 5.6 months. OS at 2 years was 44.9% in the tucatinib group versus 26.6% in the control group (hazard ratio 0.66; 95% CI 0.5–0.88), with a median OS of 21.9 versus 17.4 months. Importantly, patients with treated or untreated brain metastases were eligible provided they did not require urgent local intervention. Among the 219 patients with brain metastases in the initial PFS analysis, PFS at 1 year was 24.9% in the tucatinib arm versus 0% in the control arm, and the median PFS was 7.6 months compared with 5.4 months (hazard ratio 0.48; 95% CI 0.34–0.69). The most common AEs in patients assigned to the tucatinib regimen were diarrhea (81% of patients) and hand-foot syndrome (63% of patients). Diarrhea was reportedly manageable in most patients with preventive medicines. Approximately 5% of patients in the tucatinib arm had grade 3/4 elevations in AST/ALT and the FDA has provided guidance on dose reductions for hepatic impairment.[121] The tucatinib/capecitabine/trastuzumab regimen was approved by the FDA in 2020 for treatment of patients with HER2-positive MBC after one or more prior anti-HER2–based regimens in the metastatic setting. MDACC participated in the HER2CLIMB trial, and we expect this regimen to be widely adopted, particularly in patients with brain metastasis.

The other novel agent that garnered recent accelerated FDA approval in 2019 is trastuzumab deruxtecan, an antibody-drug conjugate that links a humanized monoclonal antibody analogous to trastuzumab with the topoisomerase I inhibitor, DXd. The conjugate is internalized by tumor cells and DXd is released intracellularly, causing DNA damage and tumor cell death. Approval was based on an open-label, single-arm, phase 2 trial known as DESTINY-Breast01. A total of 184 patients with HER2-positive MBC and a median of six prior lines of therapy were treated with trastuzumab deruxtecan 5.4 mg/kg every 21 days. All patients had received prior T-DM1. The RR was 60.9% (6% CR, 55% PR) and the median PFS was 16.4 months (95% CI, 12.7–not reached). For context, the RR for the tucatinib arm in HER2 CLIMB was 40.6%. With trastuzumab deruxtecan, nausea/vomiting, neutropenia (~20% grade 3/4), and anemia were common AEs. By independent review, ILD developed from trastuzumab deruxtecan in 25 patients (13.6%), including four patients (2.2%) who ultimately died from ILD. Pneumonitis was treated with drug discontinuation and glucocorticoids in many patients.[122] The potency of trastuzumab deruxtecan will have to be carefully weighed against its risk of ILD. Two randomized trials are currently underway (vs T-DM1 and vs physician's choice treatment) that will help further clarify the toxicity and the role of trastuzumab deruxtecan in HER-2 positive MBC.

Other Regimens for HER2-Positive MBC

Previous second- and third-line therapies have now been relegated to later use in patients with HER2-positive MBC owing to the efficacy of the aforementioned novel agents. For example, neratinib was approved in 2020 in combination with capecitabine for the third-line treatment of patients with HER2-positive MBC, but most oncologists at MDACC prefer either the tucatinib combination or trastuzumab deruxtecan because of their apparent superior efficacy and side-effect profile, understanding that cross-trial comparisons are problematic. Neratinib was approved for MBC based on the NALA trial, a randomized, phase 3 trial of neratinib plus capecitabine versus lapatinib plus capecitabine in 662 patients with MBC who had received at least two prior HER2-directed regimens. Both neratinib and lapatinib are small-molecule, tyrosine kinase inhibitors that inhibit HER1 and HER2; however, neratinib inhibits HER4 and possesses other pharmacologic differences. The combination of neratinib/capecitabine proved superior in terms of PFS (8.8 months in the neratinib arm vs 6.6 months in the lapatinib arm), with 1-year PFS rates of 29% versus 15% (hazard ratio 0.76; P = .006). Grade 3 diarrhea was

more significant with neratinib (24% vs 13% for the lapatinib group).[123] Trials of neratinib in the early-stage and metastatic settings have consistently reported significant diarrhea, and daily antidiarrheal prophylaxis is recommended for all patients starting on neratinib. Notably, both neratinib and lapatinib have been shown to have modest activity against HER2-positive central nervous system disease.[124,125]

In general, HER2 pathway blockade is continued despite tumor progression on initial therapies. Typically, this is achieved with trastuzumab or a tyrosine kinase inhibitor once trastuzumab and pertuzumab have been used concurrently in any treatment line, because the benefit of their combined use beyond progression has not been proven. The optimal sequence of agents beyond the third line is unknown and the clinical trials that tested the regimens were conducted before the use of T-DM1, tucatinib, and trastuzumab deruxtecan. Combination regimens with activity in refractory, HER2-positive MBC include capecitabine/trastuzumab,[126–128] capecitabine/lapatinib,[129] trastuzumab/lapatinib,[130] and trastuzumab with chemotherapies, including eribulin,[131] vinorelbine[132,133] and gemcitabine.[134] Carboplatin also has activity in HER2-positive MBC; however, the data are in combination with taxanes, which are now used in early-stage or frontline metastatic treatment.[135] Anthracyclines are active in HER2-positive disease, but as discussed, the risk of cardiotoxicity precludes their use in combination with trastuzumab. The use of single-agent anthracycline treatment (eg, liposomal doxorubicin) is reasonable in later treatment lines for patients with refractory disease who are anthracycline-naïve.[111]

HER2-Positive, HR-Positive Breast Cancer

Nearly 70% of HER2-amplified breast tumors also express the ERs and/or PRs and are known as "triple-positive" tumors. HER2-positive/HR-positive breast cancers exhibit different biology than HER2-positive/HR-negative breast cancers. For example, HER2-positive/HR-negative early breast cancers have higher rates of pCR to neoadjuvant therapy than triple-positive tumors.[136,137] There is some evidence that in HR-positive tumors, the responsiveness to anti-HER2 therapies is positively correlated with the degree of HER2 amplification.[138,139] In addition, HER2-positive/HR-negative tumors are usually more aggressive, with a higher risk of relapse in the first 5 years since diagnosis; however, HER2-positive/HR-positive tumors are more likely to recur after 5 years, particularly in patients with node-positive disease.[140–142] Accordingly, the treatment of HER2-positive breast cancer varies based on HR expression. In both groups, anti-HER2 therapies are prioritized because the HER2-positive component harbors more aggressive biology; however, endocrine therapies can be added in HR-positive patients during treatment periods that do not contain chemotherapy. Chemotherapy targets both HR-positive and HER2-positive tumor cells but is generally not combined with endocrine therapy because of theoretical concerns that endocrine therapy, which is cytostatic, will limit the tumor cell division that chemotherapy exploits for its potency.

Trials in HER2-positive, HR-positive breast cancer have shown a PFS advantage for adding trastuzumab (with or without pertuzumab) to AI endocrine therapy.[143,144] A benefit in PFS was also demonstrated for adding lapatinib (with or without trastuzumab) to AI endocrine therapy for patients with triple-positive breast cancer.[145,146] There are limited data for tamoxifen or fulvestrant in combination with trastuzumab (or pertuzumab) in metastatic disease, though data from the adjuvant setting suggest the combinations are safe and possibly beneficial.[147,148] There is also rationale for integrating CDK4/6 inhibitors with endocrine therapy and anti-HER2 therapy in patients with triple-positive breast cancer and these clinical trials are ongoing.[149] At MDACC, we commonly begin AI endocrine therapy (with ovarian suppression in pre/perimenopausal women) when patients transition to maintenance trastuzumab and pertuzumab from frontline, induction THP after the docetaxel has been discontinued. Endocrine therapy is discontinued when patients proceed to second- and third-line therapies with T-DM1, trastuzumab deruxtecan, or tucatinib/capecitabine/trastuzumab. There is also a role for combined anti-HER2 and endocrine regimens for patients with triple-positive MBC who cannot tolerate cytotoxic therapies.

TRIPLE-NEGATIVE BREAST CANCER

TNBC accounts for about 15% of breast cancer cases diagnosed in the US and disproportionately affects young and non-White patients. The 5-year OS for patients who have metastatic TNBC (mTNBC) is 11.2%.[150] There is considerable intertumoral heterogeneity among HR-positive and HER2-positive breast tumors and the same is true for TNBC; however, the disease is uniformly characterized by aggressive biology and a lack of targetable hormone and HER2 receptors.[151] Until recently, cytotoxic chemotherapy was the only treatment option for patients with TNBC (Fig. 36–3). When checkpoint inhibitor immunotherapies arrived in the clinic, TNBC was a rational target because tumor-infiltrating lymphocytes were known to be prognostic.[152,153] Unfortunately, the RRs to single-agent checkpoint blockade were disappointing, with an ORR of about 5% in unselected patients and, at best, around 20% in the half of patients variably defined as having a favorable tumor microenvironment.[154–156]

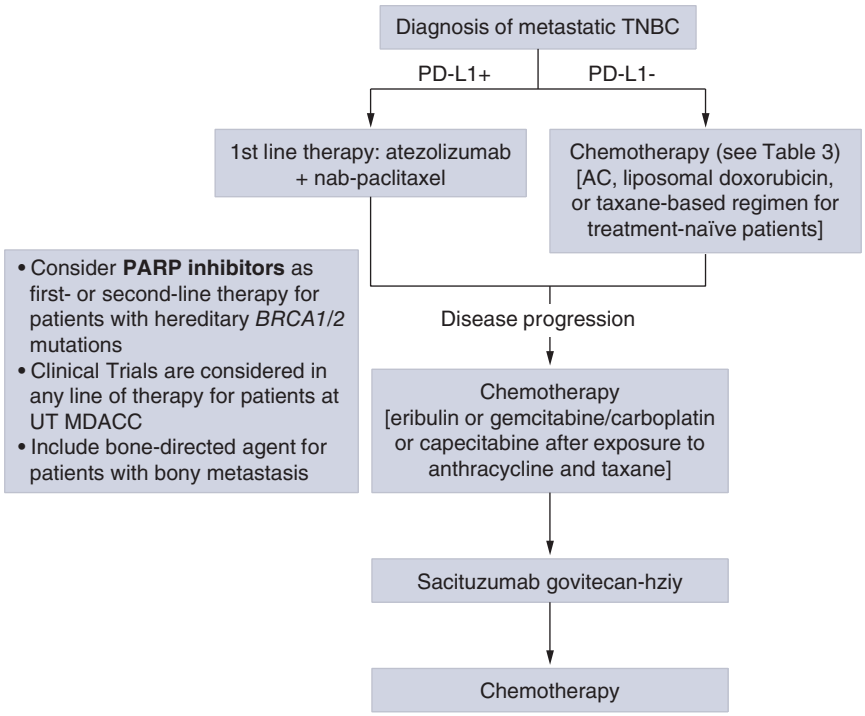

FIGURE 36–3 **Concise algorithm for the treatment of patients with metastatic TNBC at MDACC.**

New Agents—Atezolizumab and Sacituzumab Govitecan-Hziy

The trial that led to the accelerated approval of the first immunotherapy for breast cancer, atezolizumab, was IMpassion130. This was a phase 3, randomized, double-blind study that compared atezolizumab plus nab-paclitaxel versus nab-paclitaxel alone as frontline therapy for mTNBC. Approximately half of patients had received prior taxane and/or anthracycline chemotherapy. Each group included 451 patients, and PFS was 7.2 months for the combination versus 5.5 months for nab-paclitaxel alone (hazard ratio 0.8; 95% CI 0.69–0.92). There was no survival benefit for the overall population (21 vs 18.7 months). About 40% of patients had PD-L1–positive disease, defined as PD-L1 expression on tumor-infiltrating immune cells greater than or equal to 1%. In this subgroup, PFS was 7.5 months for atezolizumab/nab-paclitaxel versus 5 months for nab-paclitaxel alone and, in an exploratory analysis, improved OS was observed for the immunotherapy arm (25 vs 18 months). The most common grade 3/4 AEs were neutropenia and neuropathy.[8,157] There is now great interest in biomarkers apart from PD-L1 that might predict response to immunotherapy in breast cancer, including tumor mutational burden and specific molecular alterations.[158]

The second recently approved agent (under FDA accelerated approval) for mTNBC is sacituzumab govitecan-hziy, an antibody-drug conjugate composed of a humanized monoclonal antibody targeting trophoblast cell-surface antigen 2 (Trop 2) linked to the topoisomerase I inhibitor SN-38. Trop 2 is a transmembrane calcium signal transducer that is overexpressed in many epithelial cancers. The design was as a phase 1/2, single-group basket study in patients with pretreated, advanced epithelial cancers. A total of 108 patients with mTNBC who had received at least two prior chemotherapy lines for metastatic disease were treated with sacituzumab govitecan-hziy at 10 mg/kg on days 1 and 8 every 21 days. The median number of prior treatment lines was three and most patients had received a previous taxane and anthracycline. The RR was 33.3% with a duration of response of 7.7 months and a PFS of 5.5 months. The clinical benefit rate (which includes stable disease for at least 6 months) was 45.4%. Nausea and diarrhea were common AEs, and the most common grade 3/4 AEs were anemia and neutropenia.[159] We are hopeful that the ongoing randomized trials will confirm the remarkable efficacy of this drug and expect early adoption at MDACC given the modest activity of standard chemotherapy in pretreated disease. As of this writing, sacituzumab govitecan-hziy is approved after two prior lines of treatment for metastatic disease.

Cytotoxic Chemotherapy

For patients with mTNBC whose disease progresses on frontline atezolizumab and nab-paclitaxel or who

have PD-L1–negative disease, further treatment is with cytotoxic chemotherapy or in a clinical trial (Fig. 36–3). mTNBC patients with *gBRCA* are a special population that are discussed below. There is no standard sequence of chemotherapies for mTNBC and, similar to HR-positive disease, disease-specific and patient-specific factors should be considered. The chemotherapies used in mTNBC are nearly identical to those used for HR-positive MBC (see Chemotherapy section above), with several nuances that we will briefly review here. The strategy is also similar where successive chemotherapies are used until disease progression or limiting toxicities. Sequential single-agent chemotherapy is preferred, though there is a role for combination chemotherapy in mTNBC. Importantly, the majority of clinical trials that evaluated various chemotherapies included all breast cancer subtypes, though there have been recent trials focused exclusively on mTNBC.

The majority of patients with mTNBC received treatment with anthracycline and taxane chemotherapy in the neoadjuvant or adjuvant setting. For patients with de novo metastatic disease or who are anthracycline- and/or taxane–naïve, these agents are commonly used in the initial lines of treatment for metastatic disease.[160] Much of the efficacy data is extrapolated from the neoadjuvant and adjuvant settings where AC chemotherapy preceded or followed by taxane chemotherapy remains the standard of care with the highest rate of pCR (~40%–60%).[161–163] Either liposomal doxorubicin or conventional doxorubicin can be used. At MDACC, we commonly administer liposomal doxorubicin or AC chemotherapy for fit patients with de novo metastatic TNBC who are PD-L1–negative. We typically opt for combination chemotherapy in mTNBC patients with bulky disease, visceral crisis, or rapid progression provided they have a good performance status and organ function.

Taxanes can be used in mTNBC regimens as monotherapy or in combination with several different partners (eg, atezolizumab as discussed above, gemcitabine, or platinum chemotherapy). The tnAcity trial studied three different frontline chemotherapy combinations for mTNBC. A total of 191 patients were randomly assigned (1:1:1) to nab-paclitaxel plus carboplatin versus nab-paclitaxel plus gemcitabine versus gemcitabine plus carboplatin. A significantly longer PFS was demonstrated for nab-paclitaxel plus carboplatin than the other combinations (8.3 vs 6 months for gemcitabine/carboplatin vs 5.5 months for nab-paclitaxel/gemcitabine). RRs were 73%, 44%, and 39%, respectively.[164]

Platinum chemotherapy has been a particular focus in TNBC because of data suggesting a higher prevalence of homologous recombination deficiency in TNBC than in other breast cancer subtypes.[165] Platinum salts induce double-strand DNA breaks and are potent in patients with *BRCA* mutations with inherent homologous recombination deficiency. There have been numerous trials of platinum monotherapy and combinations in early and metastatic TNBC.[166–168] One study of particular interest was a phase 3 study that evaluated the combination of gemcitabine and carboplatin (GC) versus gemcitabine, carboplatin and iniparib (GCI). Iniparib was later shown not to be a true PARP inhibitor, and so the trial serves as a good measure of the efficacy of GC in patients with refractory mTNBC. A total of 519 patients were randomly assigned and PFS was 4.1 months for GC (5.1 months for GCI) with a RR of 33.7% for GC (33.7% for GCI). Approximately 90% of the patients had received a prior anthracycline and taxane.[169]

The other chemotherapies with activity in mTNBC include eribulin, capecitabine, ixabepilone, and vinorelbine. In general, each subsequent line of chemotherapy is effective for a shorter duration than the most recent therapy. In a subset analysis of a phase 3 trial comparing capecitabine with eribulin in 1102 previously treated patients with MBC, PFS was similar between treatment arms for the TNBC subset, though there was a trend toward improved survival for patients randomly assigned to receive eribulin (14.4 vs 9.4 months for capecitabine).[170] Both agents are used commonly at MDACC in patients with mTNBC who have received previous anthracycline and taxane chemotherapy.

The activity of ixabepilone as a single agent or in combination with capecitabine in refractory mTNBC has also been carefully reviewed.[171,172] A pooled analysis showed the PFS for ixabepilone/capecitabine versus capecitabine alone in mTNBC patients was 4.2 months versus 1.7 months (hazard ratio 0.64; 95% CI 0.52–0.78). The combination also doubled the RR (31% vs 15%). Median OS was not different between the two arms within the TNBC subset (10.4 vs 9 months).

Patients with *gBRCA* are a special patient population with unique responses to treatment. TNBC is far more common among patients with *gBRCA1*, with rates as high as 60%.[173] In the "Targeted Therapy" section, the efficacy of the PARP inhibitors in patients with *gBRCA* was reviewed. *gBRCA* breast tumors also show pronounced sensitivity to platinum chemotherapies because of an underlying deficit in DNA repair. As an example, the TNT trial randomly assigned 376 patients with mTNBC or *gBRCA* (with any breast cancer subtype) to receive either carboplatin or docetaxel. In the total population (338 with TNBC, 43 with *gBRCA*), the RR was similar (31.4% vs 34%) as was PFS (3.1 vs 4.4 months). However, the 43 patients with *gBRCA* demonstrated a RR of 68% with carboplatin compared with 33% for docetaxel as well as a longer PFS (6.8 vs 4.4 months).[174] Platinum sensitivity in patients with *gBRCA1*-associated breast cancer is also supported by data from the neoadjuvant setting.[175]

Platinum chemotherapies and PARP inhibitors have not been compared head-to-head and both are effective options in patients with *gBRCA* MBC.

mTNBC remains an active area of preclinical and clinical investigation because of its aggressive behavior and the attendant poor prognosis with available therapies. At MDACC, clinical trials are always a consideration for patients with mTNBC for any line of therapy. In addition, there are several rare variants of mTNBC that are outside the scope of this chapter including metaplastic breast cancer[176] and the luminal androgen receptor subtype[151] that have been expertly reviewed by others.

MANAGEMENT OF THE PRIMARY TUMOR

Most patients with MBC were originally treated for early-stage breast cancer before distant recurrence, including surgical resection of the primary breast tumor and axillary lymph nodes. For patients with de novo metastatic disease, the management of the primary breast tumor in the context of distant metastatic disease is controversial, though recent data from a phase 3 randomized trial, E2108, support the nonsurgical approach (discussed below). Standard practice is to treat with systemic therapy alone because the mortality from MBC results from distant metastasis rather than the primary tumor itself. Breast and axillary surgery are considered for palliation, including for skin ulceration, bleeding, and pain.

Conversely, several retrospective studies suggested a survival benefit for primary tumor resection in selected patients with MBC.[177,178] It is unclear whether these reports merely represent selection bias where heathier patients with more indolent disease (and who would be expected to live longer) were those who underwent primary breast surgery. There have been three prospective randomized trials that addressed this question. Investigators in the phase 3 ECOG-ACRIN E2108 trial (NCT01242800) recruited 390 women between February 2011 and July 2015 to determine whether the addition of locoregional treatment improved OS for patients with de novo MBC. Overall, 256 eligible patients were assigned to systemic therapy based on patient and tumor characteristics. Those whose disease did not progress during 4 to 8 months of treatment were then randomly assigned to systemic therapy plus locoregional treatment with surgery and radiation for the intact primary breast tumor (n = 125) versus systemic therapy alone (n = 131). At a median follow-up of 59 months, investigators found no significant difference in OS between optimal systemic therapy plus locoregional therapy compared with optimal systemic therapy alone (3-year OS 68.4% vs 67.9%; hazard ratio 1.09; 90% CI 0.80–1.49; P = .63). The addition of locoregional therapy also failed to improve 3-year PFS. However, locoregional recurrence or progression was significantly higher in the systemic therapy–alone arm (25.6% vs 10.2%; P = .003). In addition, investigators in ECOG-ACRIN E2108 evaluated health-related quality of life using the FACT-B Trial Outcome Index, which measures factors such as depression, anxiety, and well-being. Results showed no quality-of-life advantage associated with locoregional therapy.

A separate study took place at a single center in Mumbai, India and included women younger than 65 years with untreated, de novo MBC. Patients assigned to chemotherapy (96% of patients) had to demonstrate an objective tumor response after 6 to 8 cycles before randomization. A total of 350 patients were randomly assigned (1:1) to systemic therapy plus locoregional treatment of the breast and axilla with surgery and radiation versus systemic therapy alone. After a median follow-up of 23 months, there was no difference in the primary OS end point (19.2 months in the locoregional group vs 20.5 months in the systemic therapy–alone group).[179] The third trial, known as MF07-01, was a Turkish study that included 274 patients with de novo MBC. Patients were randomly assigned to receive up-front locoregional treatment with surgery and radiation followed by systemic therapy versus systemic therapy alone. This study did show an OS benefit for up-front locoregional therapy, and median OS was 46 months versus 37 months for systemic therapy alone (hazard ratio 0.66; 95% CI 0.49–0.88). However, randomization was not stratified by ER/PR status or the presence or absence of visceral disease, resulting in unbalanced arms. The locoregional group was characterized by a higher percentage of ER/PR-positive disease, less TNBC, and more patients with bone-only metastases, potentially confounding the results.[180] The current practice at MDACC is to treat patients with de novo metastatic disease with systemic therapy alone. Breast and axillary surgery are considered for palliative purposes and for patients with low-volume, treatment-responsive, metastatic disease and significant locoregional disease. Breast and axillary surgery (and radiation) are also offered to patients with oligometastatic disease who are treated with curative intent. The decision to proceed with locoregional therapy for a patient with MBC must involve close collaboration and detailed discussions between the patient, medical oncologist, breast surgeon, and radiation oncologist.

INVESTIGATIONAL THERAPY

The pace of discovery for effective agents that improve clinical outcomes for patients with MBC is accelerating. Here, we outline several promising agents and

concepts without providing a comprehensive review. For ER-positive disease, fulvestrant remains a standard treatment both as monotherapy and in combination with newer agents (eg, CDK4/6 inhibitors, alpelisib). However, a major disadvantage of fulvestrant is its requirement for two large-volume gluteal intramuscular injections per month. An oral SERD, AZD9496, was recently tested in a phase 1 trial and proved safe with preliminary evidence of efficacy in heavily pretreated patients.[181] We expect that this agent or a related oral SERD will eventually prove comparable to fulvestrant, filling a longstanding void in the clinic. In addition, for ER-positive disease, results from the recent phase 2 FAKTION trial showed that the addition of the AKT inhibitor, capivasertib, to fulvestrant improved PFS compared with fulvestrant alone. A total of 140 patients with ER-positive MBC and progression on a prior AI were enrolled, and PFS was 10.3 months for the combination versus 4.8 months for fulvestrant alone (hazard ratio 0.58; 95% CI 0.39–0.84). Grade 3/4 hypertension, diarrhea, and rash were more common in the capivasertib arm and a phase 3 trial is now underway.[182]

Tucatinib and trastuzumab deruxtecan are recently approved agents for HER2-positive MBC and are reviewed in the main section. Interestingly, trastuzumab deruxtecan also has activity in breast cancers with low HER2 expression, possibly because of a high drug-to-antibody ratio and a cell bystander effect. In a phase 1b study that enrolled 54 patients with heavily pretreated MBC (median 7.5 prior lines) and low HER2 expression (IHC 1+ or 2+ and negative in situ hybridization), trastuzumab deruxtecan at 6.4 mg/kg achieved an ORR of 37% with a median duration of response of 10.4 months. Most patients (87%) had ER-positive disease. Comparable to the DESTINY-Breast01 trial, myelosuppression was the most common grade 3/4 event, and fatal ILD was reported in three patients.[183]

Immunotherapy is a major focus of investigation in mTNBC owing to the efficacy of atezolizumab. The KEYNOTE-355 trial is testing combination pembrolizumab plus standard chemotherapy (nab-paclitaxel, paclitaxel, or gemcitabine/carboplatin) versus standard chemotherapy alone as frontline therapy for patients with mTNBC. At the virtual ASCO 2020 meeting, the investigators reported that the trial met a co-primary end point in that patients with PD-L1–positive disease (combined positive score ≥10) experienced improved PFS with the addition of pembrolizumab (9.7 vs 5.6 months; hazard ratio 0.65; 95% CI 0.49–0.86). Analysis of survival data for KEYNOTE-355 is ongoing. Another strategy is to augment the tumor microenvironment and sensitize tumors to checkpoint blockade. The TONIC trial studied the effect of induction chemotherapy or radiation before nivolumab in mTNBC and found that short-term doxorubicin or cisplatin induction was associated with an improved RR to nivolumab and a more favorable tumor immune microenvironment.[184] There are ongoing clinical trials in patients with mTNBC combining checkpoint blockade with other immunotherapies including those targeting CTLA-4, 4-1BB, and OX40. It is our hope and expectation that the next decade of innovative breast cancer research will result in continued improvements in outcomes for patients with MBC.

MD ANDERSON PRACTICE TIPS

- We strongly agree with the recommendation to biopsy a metastatic disease site for HR and HER2 receptor testing regardless of the initial primary breast cancer subtype. Ideally, we concurrently utilize this tissue for assaying other biomarkers such as PD-L1 (TNBC).
- Once a diagnosis of MBC is confirmed, we prioritize discussing the goals of care early in the physician-patient relationship to allow patients autonomy in the ensuing treatment decisions that often span many years.
- For HR-positive MBC, we utilize endocrine therapy and a CDK4/6 inhibitor as standard frontline therapy, including in patients with significant visceral disease.
- We generally opt for continuous and sequential, single-agent chemotherapy rather than combination chemotherapy for most patients with MBC.
- We are aggressive in treating carefully selected patients with oligometastatic MBC with combination multimodal therapy, including surgery and radiation.
- We prioritize clinical trials for patients with MBC, including those in early treatment lines.

Management of Locally Advanced Breast Cancer, Including Inflammatory Breast Cancer

Bora Lim
Gabriel N. Hortobagyi

KEY CONCEPTS

- The major difference between early breast cancers and locally advanced breast cancers (LABCs) include the extent of disease involvement and associated poor survivals. Both inflammatory breast cancer (IBC) and noninflammatory LABC are rare yet contribute to high morbidity and mortality.
- Both IBC and noninflammatory LABC require multidisciplinary care including medical oncology, surgical oncology, and radiation oncology. Effective induction strategy starting with the neoadjuvant systemic therapy (NAST) followed by aggressive local therapy including surgery and radiation is the best approach to reverse the poor outcome of these diseases.
- The unique biological cause of LABC that distinguishes it from other types of breast cancer may not be fully elucidated in the near future. In contrast, in IBC, recent enhancement of methods of biological interrogation has led to novel insights and development of novel therapeutic; however, the practice change is yet to follow, emphasizing the importance of ongoing efforts to change the grim clinical outcome.
- Compared with other noninflammatory breast cancer, stage III noninflammatory breast cancer harbor worse event-free and overall survivals. Early recognition, distinction from other LABCs, and early/accurate intervention are critical in the treatment of this dismal disease. The local therapy approach for IBC is different from other LABCs, and adherence to aggressive multimodality therapy has been shown to improve survival.
- Various new strategies are being tested in clinical trial settings to improve the response to the NAST, yet no new systemic therapeutics have been approved by the FDA. We anticipate several agents (eg, anti-programmed cell death–1 agents) to be approved as part of standard care in this setting.
- Additional strategies (eg, alternative/additive adjuvant therapies along with integrated biomarkers such as liquid biopsy to monitor early relapse) should be considered as a next step to improve the outcome of these breast cancers.

Locally advanced breast cancer (LABC) metastasizes and recurs frequently and is associated with poor overall survival (OS). Inflammatory breast cancer (IBC) is a rare form of LABC associated with distinctly worse survival.[1] Timely diagnosis, aggressive neoadjuvant systemic therapy (NAST), surgery, and radiation therapy, combined with novel diagnostic and therapeutic approaches based on new biological insights and delivered by a well-trained and well-coordinated team, is critical to improving the survival of patients with these cancers. Here we present current treatment recommendations for LABC and IBC from a panel of experts at MDACC and discuss future directions in the development of novel therapies for these diseases.

LABC VERSUS IBC

LABC is breast cancer that extends beyond the breast to the chest wall and/or multiple levels of regional lymph nodes but has not spread to distant sites and therefore is curable (ie, stage III). Not all stage III breast cancer falls into the LABC category, but most do. LABC can result from aggressive, rapidly growing

breast cancers such as IBC or from more slowly growing breast cancers when appropriate medical care is not delivered in a timely manner. According to data in the Surveillance, Epidemiology, and End Results Program (SEER) registries, the incidence of non-IBC LABC was similar to that of IBC (2%–4% of all breast cancers).[2] Based on one study in younger women, the rate of stage III breast cancer ranged from 16% to 24% of all diagnosed cases; in older women, the rate of stage III breast cancer was much lower.[3] The 5-year OS of patients with stage III breast cancer is approximately 72%.[1]

IBC is a rare form of LABC that accounts for only 2% to 4% of all breast cancers. Despite its low incidence, IBC accounts for 7% to 10% of breast cancer deaths because of its aggressive nature.[4] The 5-year OS of patients with IBC is approximately 50% to 55%. Despite collaborative international research efforts, the survival of patients with IBC remains poor, owing to lack of effective systemic therapy. The differences in definitions of IBC and the lack of specificity associated with clinical identification of IBC limit the accurate estimation of IBC incidence. However, this issue is slowly resolving as a result of international collaboration. Approximately 30% of patients with IBC are found to have distant metastasis at diagnosis; the remaining 70% are classified as having LABC (stage III disease).[5]

RISK FACTORS AND EPIDEMIOLOGY

Age

According to an analysis of breast cancer cases in the SEER registries diagnosed between 1988 and 2000 (n = 180,224), IBC was diagnosed at a younger age than non-IBC breast cancers overall (median age at diagnosis, 57 vs 61.9 years).[2]

Ethnicity

Both LABC and IBC are more common among Black and Hispanic individuals than other ethnic groups. Data from the United States show that the incidence of IBC is higher among Blacks than among Caucasians (3.1 vs 2.2 cases per 100,000 woman-years; $P < .001$).[2] Even with the same stage, Black patients with IBC have a shorter survival than patients in other ethnic groups.[6]

Family History and Genetic Risk Factors

Approximately 12% of women with breast cancer have a family history of breast cancer in a first-degree relative,[7] but only 5% of breast cancers are directly attributed to inherited germline mutations.[8] A number of hereditary mutations have been identified that are associated with increased breast cancer risk, including mutations in *BRCA1*, *BRCA2*, *PALB2*, *CHK2*, and others.[9–12] To date, no separate studies have investigated the relationship between genetic factors and LABC risk. In a study comparing 68 patients with IBC and 143 patients with non-IBC seen at MDACC, 13% of the patients with IBC versus 8% of the patients with non-IBC had a family history of breast cancer, but the difference was not statistically significant.[13] In a study conducted in Pakistan, 20% of patients with IBC had a family history of breast cancer[13]; however, this rate of family history has not been found in other studies to date.[14]

Obesity

One of the risk factors most consistently associated with IBC is a high body mass index (BMI).[6,15] Especially in hormone receptor–positive (HR+) IBC, a decrease in BMI was associated with better recurrence-free survival and OS.[15] Schairer et al compared 617 patients with IBC with three reference groups: patients with LABC (n = 7600), patients with non-IBC without chest wall or skin involvement (n = 1151), and healthy individuals (n = 93,654), and showed that IBC was the only category associated with high BMI at diagnosis.[16] A retrospective study of 602 patients with LABC, including 111 patients (18%) with IBC, showed that patients with IBC had a higher BMI.[17]

Several groups have studied the association between BMI and the clinical outcome of patients with LABC and IBC. An analysis by Chang et al published in 1998 showed that among postmenopausal women with IBC, obese women had significantly worse survival than those with normal BMI (hazard ratio 1.86; 95% CI 1.02–3.40); however, this pattern was not observed in premenopausal women with IBC.[18] In the aforementioned retrospective study of 602 patients with LABC, obese patients had significantly worse OS, relapse-free survival, and rates of visceral metastasis than nonobese patients.[17]

Geographic Region

The incidences of LABC and IBC are consistently low across the United States. For example, SEER registries showed that from 1992 to 2002, rates of IBC ranged from 2.064 per 100,000 woman-years in San Jose–Monterey, California to 3.042 cases per 100,000 woman-years in Los Angeles, California.[19] However, other parts of the world may have higher incidences; studies showed that 6% of all breast cancers in Tunisia and 10% of all breast cancers in Egypt were IBC.[20,21]

Pregnancy and Lactation

Studies to date regarding the relationships between pregnancy and lactation and the incidences of LABC and IBC have produced inconsistent findings, although a recent study found that women not having breastfed was one of the risk factors for the incidence of IBC according to a multivariate Cox proportional hazard analysis.[6,22]

PATHOLOGY

Molecular Subtypes

Both LABC and IBC are divided into three molecular subtypes: HR+; HER2-positive (HER2+); and triple-negative breast cancer (TNBC), in which both HRs and HER2 are absent. The distribution of cases by molecular subtype differs between LABC and IBC. The exact distribution of molecular subtypes within LABC has not been completely reported, but it is suspected to be skewed toward the more aggressive molecular subtypes (HER2+ and TNBC). In IBC, the distribution of cases by molecular subtypes has been more extensively reported owing to focused research efforts. In IBC, it has been reported that approximately 65% to 70% of cases are HER2+ (35%–40%), 30% are triple-negative,[6] and approximately 30% are HR+.

Tumor Emboli

Microscopic lesions known as tumor emboli within lymphatic vessels are the pathologic hallmark of IBC and explain most of its clinical manifestations, including edema, swelling, and ridges in the skin. Tumor emboli are found in 75% of patients with IBC[23]; however, identification of such emboli is not mandatory for confirmation of the diagnosis.[24] Advanced (T4b) non-IBC LABC may also harbor tumor emboli blocking the lymphatic ducts; therefore, confirmation of tumor emboli is not pathognomonic for IBC. Tumor emboli in IBC usually appear early in the course of disease and migrate readily to distant organs. Although the metastatic potential and reduced survival of IBC have been attributed to the presence of tumor emboli,[25] the prognostic significance of dermal lymphatic invasion remains an area of controversy.

DIAGNOSIS

Distinguishing Between IBC and LABC

To offer the most appropriate therapeutic options, primary IBC must be distinguished from LABC. The major differentiation between IBC and LABC relates to the timing of progression from the initial onset of the signs and symptoms to the full-blown presentation of the breast change. This progression occurs within 3 to 6 months in IBC but often takes more than 6 months in LABC. Previous normal mammograms and a detailed medical history can help clarify the timeline. Often, patients with LABC have not been evaluated with annual mammography. Some patients with LABC do not seek medical care for more than 6 months from the time they first recognized the palpable mass or lymph node. In addition, not all cases of LABC are associated with T4b (secondary changes of the skin or chest wall) or T4d disease. Some cases of LABC are associated with extensive nodal disease; however, LABC tends to be associated with less extensive nodal disease than IBC. Without a detailed clinical history, including the timing of breast changes, differentiation of IBC from LABC may be challenging. Although the majority of patients with IBC present with erythema and edema of the skin, these are not common findings in non-IBC LABC. Conversely, ulcerations and disintegration of the skin are more commonly found in non-IBC LABC and not commonly in IBC during the early phase of the disease. Figure 37–1 shows representative photographs of LABC (Fig. 37–1A) and IBC (Fig. 37–1B).

Distinguishing Between IBC and Benign Breast Diseases

The clinical presentation of IBC is frequently confused with that of more common benign diseases, and accurate diagnosis of IBC requires a high index of suspicion on the part of the diagnosing physician. If IBC is suspected, the physician must obtain pathologic evidence of breast carcinoma to establish the presence of malignancy. Once evidence of breast carcinoma is obtained, the presence of dermal lymphatic invasion helps to confirm the diagnosis but is neither required nor sufficient to make the diagnosis. All other clinical criteria must be satisfied to make the diagnosis of IBC—including erythema and skin changes including peau d'orange and engorgement of the skin that involves more than one-third of the breast and presented within 3 months duration as reviewed in the previous section. Further, these changes in the skin are often accompanied by enlargement of the draining lymph nodes, frequently in the absence of a breast mass. This clinical picture closely mimics that of common inflammatory conditions of the breast, such as simple bacterial mastitis. As a result, many patients with IBC unnecessarily undergo repeated courses of antibiotics before focused imaging is performed and a diagnosis is made. Tumor emboli hiding in the lymphatic duct can make the IBC hard to detect; about

FIGURE 37-1 **Representative photographs of breasts affected by LABC and IBC. A. A woman presented with a mass on her left breast that she had first noticed 2 years earlier and for which she had not previously sought medical care. Biopsy of the mass confirmed invasive ductal carcinoma with 60% of cells positive for Ki-67. Skin punch biopsy showed invasive ductal carcinoma. The patient was found to have N2 nodal diseases but no distant metastasis (T4bN2M0 disease). B. A woman presented for evaluation of erythema of the left breast. She had noted a red streak around the nipple of the left breast after tennis practice 3 weeks earlier, and since that time the area of erythema had grown to cover more than 60% of the left breast. Biopsy of the area of architectural distortion and an axillary lymph node as well as infraclavicular lymph node biopsy all showed invasive ductal carcinoma with 90% of cells positive for Ki-67 (T4dN3M0 disease). Skin punch biopsy showed invasive ductal carcinoma.**

half of patients with IBC do not have a distinctly visible (or palpable) mass at diagnosis. Approximately 70% to 80% of patients with IBC have metastasis to the higher-level regional lymph nodes.[6]

IMAGING MODALITIES

Imaging modalities of the IBC-involved breast, chest wall, and lymph node areas are required to diagnose LABC or IBC. Imaging confirmation of IBC, however, can be tricky, as we review in detail below.

Mammography

Often the extent of LABC can be measured by standard mammography. However, the mammogram may not be able to capture the full involvement of the regional lymph nodes, especially in cases of advanced nodal disease. In such cases, complementary imaging modalities such as ultrasonography, magnetic resonance imaging (MRI), and computed tomography (CT) of the neck will likely be required. IBC commonly presents with tumor emboli in the lymphatic ducts and lacks a palpable breast mass. Skin thickening is a signature change seen on the mammograms of patients with IBC and is present in 92% of cases.[26] Other common radiologic findings in IBC include increased breast tissue density, trabecular and stromal thickening (in 62% of cases), breast swelling, axillary lymphadenopathy, and nipple retraction (Fig. 37–2A). These findings may be missed by less experienced radiologists and annotated as benign findings. Bilateral mammography is recommended as a standard imaging method in the diagnosis of IBC.[27]

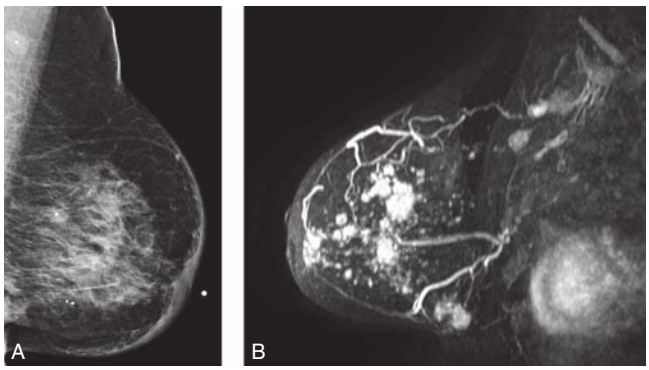

FIGURE 37–2 **Mammography and breast MRI findings in a woman newly diagnosed with IBC. A. Mammogram shows architectural distortion, including a mass-like lesion (marked as *), calcifications, and trabecular thickening. The mammogram also shows global skin thickening in approximately 50% of the central part of the breast. B. Breast MRI from the same patient clearly shows multiple mass-like lesions throughout the breast, engorgement of blood vessels, and locoregional lymph node metastases with high resolution that were not clearly shown on the mammogram. The areas with skin thickening shown on the mammogram exhibit parenchymal fluid accumulation on the breast MRI. Given its sensitivity, MRI is recommended as part of the initial evaluation for IBC. (Used with permission from Dr. Huong Le-Petross.)**

Ultrasonography

Locoregional lymph nodes assessment is critical in both LABC and IBC, and ultrasonography is much more sensitive than mammography in the detection of nodal disease. Thus, ultrasonography is a key part of the initial diagnostic workup in cases of suspected LABC and IBC. In addition, subtle changes such as architectural distortion, thickening of the skin, and trabecular thickening cannot be detected clearly on mammograms but can be detected on ultrasonography.[27] The sensitivity of ultrasonography in the detection of primary breast lesions in IBC is as high as 92% to 96%, whereas that of mammography is only 68%.[24,28]

Breast MRI

The role of breast MRI in the diagnosis of breast cancer in general is still being debated; however, there is no doubt about its sensitivity in detecting both primary breast lesions and locoregional lymph nodes, as well as mediastinal nodes.[29] MRI also depicts unique blood vessel patterns and skin and lymph node involvement. The sensitivity of MRI in the detection of primary breast lesions is the highest among all breast imaging modalities (up to 98%).[26] Findings on mammography and MRI in the same patient with IBC are shown in Fig. 37–2.

CT and PET/CT Scan

Both CT and positron emission tomography–CT (PET/CT) scans can detect distant metastasis in LABC. PET/CT scan offers a complete view of all visceral organs and bone, and it has the bonus of showing metabolic activity. When CT is used, a bone scan should be added to ensure full assessment of metastasis to the bone. In IBC, multiple studies have shown that PET/CT scan has higher sensitivity than conventional CT scan, not only in the detection of distant visceral or bone metastasis but also in the detection of distant lymph node metastases, and therefore it should be used instead of conventional CT whenever feasible.[30–33]

TREATMENT

Trimodality Therapy

Trimodality therapy, consisting of systemic therapy, surgery, and radiation therapy, is important in any breast cancer but is critical in the management of LABC, including IBC. Patients with IBC who did not undergo the recommended trimodality therapy had much worse outcomes than patients who did.[34] In an analysis of the National Cancer Database, underutilization of trimodality therapy was shown to reduce survival of patients with IBC, indicating that the need for this therapy should be taken seriously.[35] In both LABC and IBC, appropriate local therapy to prevent locoregional recurrence is critical, and the surgery and radiation oncology teams need to engage at the time of diagnosis to accurately assess the extent of disease, even though NAST is the first treatment for these breast cancers.

Systemic Therapy

Systemic therapeutic regimens for LABC and IBC, like therapeutic regimens for other types of breast cancer, are chosen on the basis of molecular subtype. However, despite having the same molecular subtypes as other types of breast cancer, LABC and IBC may respond differently to targeted therapy.

Chemotherapy

Anthracycline-Based Chemotherapy

Anthracycline-based regimens have been the cornerstone of systemic treatment of IBC since the 1970s. Although randomized trials of this approach are lacking, a pooled analysis of four prospective trials conducted at MDACC covering a 20-year period examined the outcome of neoadjuvant chemotherapy followed by local irradiation with or without mastectomy. In this analysis, patients who received anthracycline-based regimens had an overall response rate of 71% and 5- and 10-year OS rates of 40% and 33%, respectively.[36] The use of anthracycline-based regimens in patients with HER2+ LABC has declined in recent years given advances in effective anti-HER2 therapy.[37] In IBC, however, the use of anthracycline-based regimens is still strongly recommended given the accumulated data from retrospective studies.[38]

Taxane-Based Chemotherapy

In early studies after the introduction of taxanes at MDACC in 1994, among patients with estrogen receptor–negative tumors, the 3-year OS and progression-free survival rates were significantly higher in patients receiving paclitaxel-containing regimens than in those receiving anthracycline-based therapy without taxanes (OS 54 vs 32 months, $P = .03$; progression-free survival 27 vs 18 months, $P = .04$), and the pathologic complete response rate was 25% for paclitaxel-containing regimens and 10% for anthracycline-based therapy without taxanes ($P = .012$).[39]

Multiregimen Neoadjuvant Chemotherapy

A large, multicenter randomized trial (GeparTrio) prospectively examined the benefit of neoadjuvant docetaxel-and-anthracycline–containing regimens in different subtypes of breast cancer by comparing the outcomes of 194 patients with LABC and 93 patients with IBC with the outcomes of 1777 patients with operable breast cancers. Patients received four or six cycles of docetaxel, doxorubicin, and cyclophosphamide (TAC) or four cycles of TAC followed by four cycles of vinorelbine and capecitabine. In this study, tumor stage, including IBC status, was not an independent predictor of pathologic complete response in multivariate analysis (odds ratio 1.51; 95% CI 0.88–2.59; $P = .13$).[40]

Dawood et al analyzed SEER data from 2004 to 2007 and found that even with anthracycline-and-taxane-based chemotherapy, women with stage III IBC still had worse outcomes than women with stage III non-IBC. In this study, the 2-year breast cancer–specific survival rates in patients with IBC and non-IBC stage III breast cancer were 84% (95% CI 80–87) and 91% (95% CI, 90–91), respectively.[3] Patients with stage III IBC had a 43% increased risk of death from breast cancer compared with the risk in patients with stage III non-IBC. In a larger cohort of 398 patients with IBC diagnosed at MDACC between 1974 and 2005, patients with IBC treated with a taxane had a median survival time of 6.3 years compared with 3.8 years in patients not treated with a taxane.[41]

HER2-Targeted Therapy

As much as 35% to 40% of IBC tumors overexpress HER2, compared with approximately 25% of non-IBC tumors.[6] Trastuzumab has shown efficacy against HER2+ LABC and HER2+ IBC. Pertuzumab has been added as part of standard care in LABC regardless of IBC or non-IBC status and has contributed to an increased response rate in both LABC and IBC. HER2-targeted therapy in the form of trastuzumab or pertuzumab is an integral part of NAST for patients with HER2+ molecular subtype. If patients have large-volume residual disease after NAST, results of the KATHERINE study indicate that trastuzumab emtansine is the best choice for adjuvant therapy.[42] Neratinib, a pan-HER inhibitor, has also shown efficacy in terms of improving distant recurrence-free survival and thus can also be used for adjuvant therapy in patients who did not achieve pCR, and received trastuzumab but not the other adjuvant anti-HER2 therapeutics.[43] As noted, the benefit of alternative adjuvant HER2 therapy seems to be bigger in high-risk groups, thus these approaches should be considered for both non-IBC LABC and IBC without pCR after NAST. As noted, none of these studies was specifically designed for IBC and clinical applications of their results are extrapolated from studies that include small numbers of IBC cases, and thus should be considered cautiously. Further real-life retrospective review of benefit can aid this limitation, while several prospective studies are ongoing.

Surgery

Definitive surgical resection remains a fundamental part of treating IBC/LABC. In LABC, various forms of surgery can be considered, including breast-conserving surgery and sentinel lymph node biopsy, depending on the response to NAST. In some cases of slow-growing LABC, surgery can offer excellent local control if negative surgical margins can be obtained.[44] If breast-conserving surgery is not possible, different types of mastectomy can be applied, as long as negative margins can be achieved. In surgery for IBC, wide excision that includes all potential cancer-affected areas including skin is critical; therefore, modified radical mastectomy is the standard of care.[45,46] Skin- or nipple-sparing mastectomy produces suboptimal oncologic outcomes and should be avoided. When the response to NAST is poor, surgery to prevent local progression should be undertaken with speed and careful planning, given the potential for rapid progression during suspension of systemic therapy. Postmastectomy reconstruction, if undertaken, should be performed in delayed fashion to (1) ensure an appropriate duration of adjuvant therapy to prevent early local recurrence to the chest wall and skin, (2) allow for monitoring for early local recurrence, and (3) avoid poor outcomes as a result of the impact of radiation therapy on a reconstructed breast. Expander insertion may affect the delivery of radiation therapy and should be avoided.[38]

Radiation Therapy

Radiation therapy is delivered immediately after surgery to address the remaining cancer cells. Thus, the standard order of locoregional treatment is surgery followed by radiation therapy.[47] Preoperative radiation therapy may be delivered as part of a clinical trial but only after careful planning and interdisciplinary discussion. Postmastectomy radiation therapy should include the confirmed cancer-affected areas, such as the chest wall, skin, and lymph nodes, including supraclavicular and infraclavicular lymph nodes.[48–50] At MDACC, we prescribe an accelerated hyperfractionation schedule for patients at higher risk of recurrence, with a total dose of 66 Gy. A dose of 51 Gy is delivered in 34 fractions of 1.5 Gy, given twice daily at least 6 hours apart to the chest wall and undissected draining lymphatics, followed by a boost of 15 Gy to the chest wall

and any clinically involved undissected regional nodes, administered in twice-daily fractions of 1.5 Gy over 5 days. This twice-daily delivery of radiation therapy can cause increased fatigue and pose logistical challenges; however, data from retrospective studies support the efficacy of this approach in IBC, and therefore this is the standard of care at MDACC. Clinical trials are currently testing additional agents to improve the efficacy of radiation therapy, based on preclinical data using a poly(ADP-ribose) polymerase inhibitor[51] or capecitabine.[52]

Post-Therapy Surveillance and Follow-Up

After completion of trimodality therapy, patients should be evaluated with clinical examination every 3 to 6 months for 5 years and thereafter every year. Mammography of the contralateral breast should be performed annually.[38] Additional investigation may be requested according to clinical indications. As of this writing, additional modalities of post-therapy surveillance, including assessment for circulating tumor DNA or circulating tumor cells, are being actively developed for patients with a high risk of recurrence, such as patients with LABC and IBC.[53]

MANAGEMENT OF STAGE IV IBC

Approximately 6% of all breast cancers are stage IV at diagnosis. LABC, which by definition is stage III at diagnosis, often progresses to stage IV as a result of recurrence after an initial response or continuous progression caused by therapeutic resistance. When LABC involves the pectoralis muscle or nearby rib or lymph nodes more extensive than N2, local management becomes quite challenging.[54] In comparison, approximately one-third of IBC cases are stage IV at diagnosis. In patients with de novo stage IV IBC, chemotherapy alone resulted in a 5-year OS of less than 10%. The median breast cancer–specific survival was significantly lower for stage IV IBC than for stage IV non-IBC (1.75 years [range 0–15.7] vs 2.3 years [range 0–18.9]; $P < .0001$).[55]

The problem of stage IV IBC is unique and somewhat opposite from that of stage IV non-IBC LABC. The success of multimodality therapy in nonmetastatic IBC has encouraged exploration of a similar approach in metastatic IBC when an expert team is available to deliver trimodality therapy. In a series of patients with stage IV IBC treated with trimodality therapy, the 5-year OS was as high as 50%.[56] These results suggest that in selected patients with metastatic IBC, multimodality treatment, including surgery, may offer better local control and higher quality of life than surgery alone, radiation alone, or without local therapies. The role of definitive surgery to improve the survival in patients with breast cancer presenting with metastatic disease remains controversial, but relevant data are accumulating. Three randomized studies have not clearly shown either benefit or harm, thus specific treatment may need to be approached for individual cases.[57–59] Benefit in this situation may reflect a selection bias for patients who present with less advanced tumors, better performance status, or higher chemosensitivity.

SURVIVAL

Overall Survival

Overall, patients with LABC have worse OS than patients with early-stage (stage I–II) breast cancer regardless of molecular subtype, although OS of patients with LABC differs according to molecular subtype. The recently updated American Joint Committee on Cancer staging system for breast cancer reflects the contribution of molecular subtypes[60]; for example, LABC of less aggressive subtypes, eg, HR+ disease, will have a lower prognostic stage than LABC of more aggressive subtypes. The survival of patients with IBC is significantly worse than that of patients with non-IBC LABC; 5-year OS was 40.5% for IBC versus 63.2% for non-IBC LABC ($P < .0001$).[61] Interestingly, the survival of patients with stage III IBC does not differ by molecular subtypes, but the triple-negative subtype of IBC has the worst survival.[62]

Locoregional Recurrence-Free Survival

IBC has significantly higher rates of locoregional (skin and lymph nodes) and distant metastasis than do other forms of LABC. Furthermore, the absolute risk of subsequent diagnosis of contralateral breast cancer was higher in IBC than in other subtypes of LABC (4.9% vs 1.1% at 2 years), irrespective of age or hormonal status, and remained high even 15 years after initial diagnosis. The majority of IBC recurrences occurred within 2 to 23 months after initial diagnosis, suggesting that careful monitoring is required during the early follow-up period after adjuvant therapy.[16]

Distant Recurrence-Free Survival

The detailed pattern of distant recurrence in non-IBC LABC is not well established, but it is known that the distant recurrence rate is higher in LABC than in early-stage breast cancers. In a pooled analysis of 10 clinical trials conducted at MDACC, patterns of recurrence

were compared between 240 patients with IBC and 831 patients with stage-matched non-IBC.[61] In this study, 5-year recurrence-free survival for patients with IBC was 35% (95% CI 29.4–41.8).

NEW TARGETS AND BIOLOGICAL INSIGHTS

New Biological Targets

LABC may not exhibit unique biomarkers or biological features compared with other types of early-stage breast cancer, but when LABC occurs as a result of a treatment delay, de novo resistance to standard therapy may exist because of accumulative genetic changes. PAM50-based genomic discovery work to detect and diagnose IBC has led to identification of several gene signatures.[63] Unfortunately, these gene signatures were not successful in distinguishing IBC from non-IBC. Analysis of metastatic IBCs by next-generation sequencing showed that the most frequently altered genes based on DNA analysis overlapped with the most frequently altered genes in advanced breast cancer and included *TP53* (altered in about 60% of IBCs), *MYC* (32%), *PIK3CA* (28%), *HER2* (26%), and *FGFR1* (17%). Also shown to be altered in IBC are markers of epithelial-to-mesenchymal transition and stem cell markers, including zinc finger E-box-binding homeobox 1 and E-cadherin,[64] and the stem cell markers aldehyde dehydrogenase 1 and neurogenic locus notch homolog protein 3 (Notch 3).[65,66] Recent trials of neoadjuvant therapy that aimed to improve survival by assigning treatment on the basis of molecular features of the disease, eg, the ARTEMIS trial (NCT02276443), uncovered significant correlations of the molecular signatures and the response to standard therapy and metastatic progression. Nuclear receptors, transcription factors, including NF1, and androgen receptors have been recognized to be altered in advanced breast cancers, and inhibitors of these molecules are being tested as part of combination therapy in clinical trials. As another strategy, well-developed targeted therapies that are proven to be effective in metastatic breast cancer are also being tested in LABC. A CDK4/6-inhibitor combined with endocrine therapy has been tested in HR+ LABC and showed efficacy in terms of reducing the tumor volumes or number of Ki-67–positive cells.[67,68]

Tumor Microenvironment

Most genomic studies of IBC have focused on IBC tumor cells and have failed to identify mutations distinct from those in non-IBC; few genomic studies of IBC have investigated the role of the tumor microenvironment in IBC progression and resistance. International efforts to study IBC tumor cells by standard "bulk" transcriptomic and genomic analysis have failed to identify unique IBC-specific mutations.[63,69] As mentioned earlier in this chapter, unlike non-IBC tumors, which form distinct solid masses, IBC presents with scattered agglomeration of tumor cells and dermal lymphatic invasion, identified as tumor emboli, in 75% of cases.[70] Tumor emboli are thought to be the result of IBC tumor cells interacting with the aberrant immune system and vascular/lymphatic cell types in the microenvironment. Thus, an unbiased analysis of cell types in the IBC tumor microenvironment (TME) and tumor emboli may reveal novel targets.[71] Furthermore, detailed information about stromal and immune components in the IBC TME, including T lymphocytes, tumor-associated macrophages, and dendritic cells, need to be unraveled for effective targeting.[72,73] To date, most studies of the IBC TME have been conducted using targeted immunohistochemical markers such as CD68 for macrophages and CD3 for T-cells, which can only estimate the cell type frequencies without defining their transcriptionally reprogrammed cell states, which we plan to resolve with single-cell RNA sequencing.

CONCLUSION AND FUTURE DIRECTIONS

LABC and IBC both pose unique therapeutic challenges that require careful sequencing of treatment modalities. The major challenges include resistance to systemic therapy and the difficulty of achieving local control in many patients. Evolving systemic therapy and the integration of neoadjuvant systemic therapy followed by local therapy in the overall therapeutic strategy have improved the survival of LABC and IBC, yet there is much room for further improvement. The unique biological cause of LABC that distinguishes the LABC from other types of breast cancer may not be fully elucidated in the near future. In contrast, in IBC, recent enhancement of methods of biological interrogation has led to novel insights and development of novel therapeutics; however, the change in practice is yet to follow, emphasizing the importance of the ongoing efforts to improve the clinical outcome. Efforts to unravel the epigenetics, detailed genomics, proteomics, and circulating biomarkers of LABC and IBC need to continue, along with careful development of the precision therapeutic approach based on individual risk and precise biomarkers.

MD ANDERSON PRACTICE TIPS

- We recommend that practicing oncologists strongly consider the possibility of IBC when a patient presents with breast inflammation or clinical features suggestive of a breast infection. Distinguishing between IBC and noninflammatory LABC can be challenging, but IBC tends to have a short time (3 months) from onset of signs and symptoms to marked breast changes, whereas LABC tends to develop more slowly.
- For both LABC and IBC, we recommend early engagement of a multidisciplinary team to discuss and plan treatment.
- Systemic therapies for LABC and IBC, like systemic therapies for other types of breast cancer, are chosen on the basis of molecular subtypes, as the first treatment before local therapies: surgery and radiation.
- For IBC, modified radical mastectomy and axillary node dissection with resection of all gross disease whenever possible remains the gold standard for optimal local control. For LABC, modified radical mastectomy is not mandatory; breast-conserving surgery can be performed in certain cases at the surgeon's discretion.

38 Special Situations in Breast Cancer

Rachel M. Layman

KEY CONCEPTS

- Management of pregnancy-associated breast cancer requires careful multidisciplinary care and coordination for optimal outcomes.
- Pregnancy after a breast cancer diagnosis is not associated with worsened outcomes, based on retrospective data.
- Male breast cancer management is largely extrapolated from data on female breast cancer; however, tamoxifen is the preferred endocrine therapy agent.
- Combined hormone replacement therapy with estrogen and progesterone in postmenopausal women increases the risk of developing breast cancer, but risk is not clearly increased with estrogen-only therapy.
- Adjuvant endocrine therapy with tamoxifen or an aromatase inhibitor can be considered for estrogen receptor–positive ductal carcinoma in situ.
- Patients with pathogenic mutations in breast cancer susceptibility genes should be counseled regarding the risks and benefits of screening and prevention options.

BREAST CANCER DURING PREGNANCY

Epidemiology

Pregnancy-associated breast cancer (PABC) is defined as breast cancer diagnosed during pregnancy, the 12 months after delivery, or during lactation. Breast cancer is one of the most common cancers diagnosed during pregnancy. Because many women delay pregnancy, and age is a risk factor for breast cancer, the incidence of PABC appears to be rising. A Swedish National Health Registry study showed increased incidence from 16 to 37.4 per 100,000 deliveries between 1963 and 2002.[1] Factors associated with PABC included age 35 years or older, private insurance, and delivery in an urban teaching hospital.[2] Pregnancy itself is associated with a transient increase in breast cancer risk, followed by a reduced risk later in life.[3]

Diagnosis

PABC most commonly presents as a painless mass that is self-detected or noted on clinical examination. The duration of symptoms is often longer in patients with PABC compared with their nonpregnant counterparts. Physiologic changes in a pregnant woman's breast, especially in women older than 30 years, lack of physician familiarity with PABC, and socioeconomic and cultural factors may contribute to delays in diagnosis.[4]

Biopsy

Although the majority of breast masses during pregnancy are benign, a breast mass that does not resolve within 2 weeks requires further investigation.[5] Any clinically suspicious breast mass should be biopsied for a definitive diagnosis. Although a number of small studies have demonstrated diagnostic accuracy of fine-needle aspiration, a core or excisional biopsy is necessary to identify invasion (Fig. 38–1).[6]

Two large surgical series of pregnant patients who had general anesthesia for various medical problems failed to demonstrate an increased risk of congenital malformations compared with those not undergoing surgery.[7,8] Ultimately, the least invasive, but most technically accurate method(s) available are recommended to determine the nature of a breast mass in a pregnant woman.

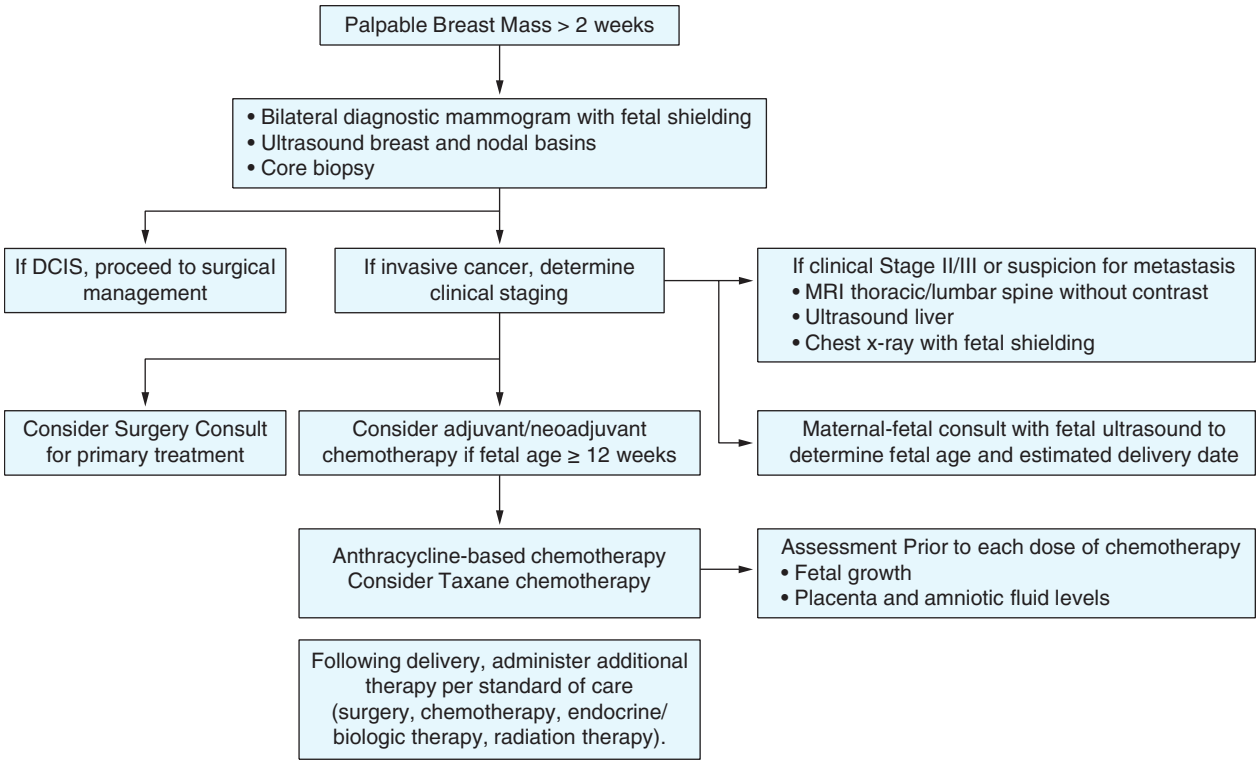

FIGURE 38–1 **Algorithm for the evaluation and treatment of a suspicious breast mass during pregnancy. DCIS, ductal carcinoma in situ; MRI, magnetic resonance imaging.**

Diagnostic Imaging

Mammography and Ultrasound

Mammography can be safely performed during pregnancy with abdominal shielding. The estimated fetal radiation exposure is <0.01 Gy, which is considered to cause minimal fetal risk (Table 38–1).[9] Ultrasound imaging is preferred because of its lack of radiation exposure and better sensitivity in young patients. Ultrasonography is also a valuable tool for nodal basin evaluation before treatment, and disease response monitoring during preoperative chemotherapy.[9]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) for evaluation of breast masses in pregnant or lactating women has not been studied. Gadolinium crosses the placenta and causes fetal abnormalities in animal studies. As such, gadolinium is a FDA Class C drug in pregnancy (Table 38–2) and should not be routinely used during pregnancy.[5]

Table 38–1 Fetal Radiation Exposure

Background fetal radiation exposure through pregnancy	1 mGy
Threshold of acceptable fetal exposure	<50 mGy
Threshold for congenital fetal loss, congenital anomalies, intellectual effects	60–200 mGy
Mammogram 2 views	0.001–0.01 mGy
Chest radiograph	0.0005–0.001 mGy
Chest CT	0.01–0.66 mGy
Bone scan T99	4–5 mGy
Abdominal CT	1.3–3.5 mGy
Pelvic CT	10–50 mGy
Pet CT whole body	10–50 mGy

Pathologic Features of Breast Cancer During Pregnancy

The most common subtype of PABC is invasive ductal carcinoma. In an MDACC case series of patients with breast cancer treated with chemotherapy during pregnancy, PABC was diagnosed at a more advanced stage, had more lymph node involvement, and poorer histologic and prognostic features, including high Ki67 and estrogen receptor (ER) and progesterone receptor (PR) negativity. HER2-positive tumors comprised 28% of the specimens. The authors observed that the features

Table 38–2 FDA Pregnancy Category Definition

A. Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester, and the possibility of fetal harm appears remote.
B. Animal studies do not indicate a risk to the fetus and there are no controlled human studies or animal studies to show an adverse effect on the fetus, but well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.
C. Studies have shown that the drug exerts animal teratogenic or embryocidal effects, but there are no controlled studies in women, or no studies are available in either animals or women.
D. Positive evidence of human fetal risk exists, but benefits in certain situations (eg, life-threatening situations or serious diseases for which safer drugs cannot be used or are ineffective) may make use of the drug acceptable despite its risks.
X. Studies in animals or humans have demonstrated fetal abnormalities or there is evidence of fetal risk based on human experience, or both, and the risk clearly outweighs any positive benefit.

Reproduced with permission from Litton JK, Theriault RL. Breast cancer and pregnancy: current concepts in diagnosis and treatment, *Oncologist* 2010;15(12):1238-1247.

were similar to those reported in young nonpregnant women, concluding that age, rather than pregnancy, may be the determinant of tumor biology.[10]

Staging

The American Joint Committee on Cancer's tumor-node-metastasis system is used for staging in PABC. Because stage at diagnosis may have significant treatment and psychosocial implications, accurate staging is important.

A complete history and physical examination and laboratory work, including complete blood cell counts and metabolic panel, is recommended before treatment. Locoregional imaging should include mammography and ultrasonography of the breast and draining lymphatics. Because women with PABC often present with advanced-stage disease, the major sites of metastatic disease (lung, liver, and bone) should be evaluated in patients with concerning symptoms or stage II or higher disease, with modifications for fetal protection. Evaluation includes chest radiography with abdominal shielding, liver ultrasonography, and MRI of the spine without contrast. A transthoracic echocardiogram before initiation of anthracycline chemotherapy is recommended.[5]

Treatment of Breast Cancer During Pregnancy

The goals of treatment in both pregnant and nonpregnant women are the same: control of locoregional and systemic disease. Although the treatment strategies are similar, the impact of the treatment on the fetus and pregnancy outcome should be considered in PABC.

Local Therapy

As previously discussed, anesthesia during pregnancy is not associated with an increased risk of fetal malformation.[7,8] Often, surgery is delayed until the end of the first trimester to minimize the risk of spontaneous abortion. Most reports show that women largely undergo total mastectomy with axillary staging, possibly reflecting treatment practice during that time period, later stage at diagnosis, or concern about the need for radiation with breast-conserving surgery (BCS). Fortunately, surgical therapies have evolved, even in women with PABC. Breast radiation is generally contraindicated during pregnancy given the risk of fetal radiation exposure. As modern practices recommend systemic therapy and surgery as initial treatment strategies, radiation therapy can usually be delayed until after delivery.[5,11]

In a MDACC series of 67 women with PABC who received chemotherapy during pregnancy before surgery, 47 had mastectomy and 20 had BCS. Of six postoperative complications (four with mastectomy, two with BCS), all could be managed in the outpatient setting. The authors concluded that BCS is feasible with no increased complication rates.[12]

A report from the Cancer and Pregnancy Registry of 130 women with PABC showed that 95 patients had surgery while pregnant: 38 in the first trimester, 48 in the second, and nine in the third. Fifty-four patients had mastectomy, 34 had lumpectomy, and 15 had an excisional biopsy with no additional surgery. The miscarriage rate in the first trimester was not increased compared with the general population.[13]

There are limited data on the use of sentinel lymph node biopsy (SLNB) in pregnant patients. Isosulfane blue dye is not recommended because of reports of anaphylaxis as well as concerns for fetal safety.[5] Radiolabeled sulfur colloid appears to be safe for SLNB in pregnancy, with a very low fetal radiation absorption[14,15] and has demonstrated accurate mapping.[16] However, the data are very limited, consisting of reports of small case series, and should be interpreted with caution.

Systemic Therapy

The indications for systemic therapy in a pregnant patient with breast cancer are similar to those in the nonpregnant patient. Most of the chemotherapy agents used in pregnancy are Category D (Table 38–2). There are limited data on the pharmacokinetics of antineoplastic agents in the setting of the physiologic changes of pregnancy. Retrospective data of pregnant cancer patients treated with chemotherapy for a variety of malignancies demonstrated that the 14% to 19% incidence of fetal malformations in the first trimester exposure dropped to 1.3% with exposure in the second and third trimesters.[17] Another series reported an overall 3.8% rate of congenital malformations, which is not increased compared with the general population.[13]

Chemotherapy

A prospective cohort study of 81 patients with PABC treated with systemic chemotherapy during the second and third trimesters was performed at MDACC.[18] Chemotherapy with FAC (5-fluorouracil 500 mg/m^2 intravenous [IV] on days 1 and 4; doxorubicin 50 mg/m^2 IV continuous infusion over 72 hours; and cyclophosphamide 500 mg/m^2 IV on day 1; every 21–28 days) was administered for a median of four cycles. Chemotherapy was held after 35 weeks to avoid maternal neutropenia at the time of delivery. All women had live births, one child had Down syndrome, and two children had congenital anomalies (clubfoot; ureteral reflux). Based on collected survey data, at a median age of 7 years, the children with prior exposure to chemotherapy in utero did not exhibit an increased rate of serious medical problems than that expected in the general population.

The European registry published a report detailing outcomes of 413 women who received systemic chemotherapy during pregnancy. Multiple regimens were used, including taxanes, cyclophosphamide/methotrexate/fluorouracil (CMF), and anthracyclines. Obstetric complications were more common in women receiving chemotherapy compared with those who did not (17% and 9%, respectively). At the same gestational age, infants exposed to chemotherapy in utero had lower birth weights, deemed to be clinically insignificant by the authors, and had an increased risk of complications compared with infants not exposed. Most complications were observed in premature infants and the authors concluded that continuing pregnancy to term delivery is crucial to decrease the risk of infant complications.[19]

A systematic review of 50 women with PABC who received various taxane regimens after the first trimester revealed that 77% of the neonates were healthy at birth, and 90% of the children were completely healthy at their 16-month follow-up. One child had recurrent otitis media, another had immunoglobulin A deficiency and constipation, and one had delayed speech.[20] Safety may be related, in part, to fetal protection from excessive taxane exposure through high placental P-glycoprotein expression, and increased taxane clearance during the third trimester.[21] An international consensus meeting concluded that taxane chemotherapy is reasonable during the second and third trimesters, with small maternal and fetal risk.[22]

At MDACC, pregnant women with breast cancer are treated with anthracycline-based and taxane chemotherapy. Administration of methotrexate is not recommended because it is teratogenic and associated with spontaneous abortion.[23]

Endocrine Therapy

Tamoxifen use during pregnancy is contraindicated given animal data suggesting that it could be teratogenic. In addition, case reports in humans describe congenital malformations, including Goldenhar syndrome, ambiguous genitalia, vaginal bleeding, and spontaneous abortions.[5,22]

Biologic Agents

Trastuzumab use in pregnancy is not recommended given multiple reports of oligohydramnios and anhydramnios in the literature.[5,24] Lapatinib exposure during pregnancy was described in one patient who received lapatinib until 11 weeks of gestation, followed by drug discontinuation and an uneventful pregnancy, with eventual delivery of a healthy baby.[25] However, lapatinib is not recommended given insufficient safety data. Accordingly, inadequate data exist to guide the use of pertuzumab or ado-trastuzumab-emtansine during pregnancy.

Prognosis

The literature regarding PABC prognosis is mixed. A large meta-analysis of 30 studies included 3628 PABC and 37,100 control cases.[26] Overall, women with PABC were at increased risk for death with hazard ratio (HR) of 1.44 (95% CI 1.27–1.63). Outcomes were worse for patients diagnosed after pregnancy (HR 1.84, 95% CI 1.28–2.65), whereas women diagnosed during pregnancy were not clearly at increased risk (HR 1.29, 95% CI 0.74–2.24). A cohort study of 311 European women with PABC revealed no significant difference in disease-free survival (DFS) or overall survival (OS) when compared with a cohort of nonpregnant women.[27]

Data from MDACC showed no difference in locoregional recurrence, distant metastasis, or OS between 104 young women 35 years old or younger with PABC and their 564 nonpregnant counterparts, treated between 1973 and 2006.[28] In addition, data on 75 patients treated for PABC in a controlled setting on

a MDACC protocol with FAC chemotherapy during the second and third trimesters revealed improved DFS and OS compared with age- and stage-matched nonpregnant control patients.[29] Therefore, a multidisciplinary approach to the management of PABC is able to provide patients with at least as favorable outcomes as their nonpregnant counterparts.

Monitoring the Pregnancy

The pregnant patient with breast cancer should be referred to a high-risk obstetrician skilled in maternal-fetal medicine, who will be charged with monitoring the health of the mother and fetus while undergoing cancer therapy.

Ultrasonography for fetal viability, gestational age, and expected date of delivery is important for treatment planning. Ideally, ultrasonography is performed before every chemotherapy dose for fetal growth and development assessment. Amniocentesis may be recommended if the fetus is thought to be at higher-than-average risk for karyotype abnormalities or based on concerning ultrasound findings. Although not part of the routine evaluation, amniocentesis may also be necessary to assess fetal lung maturity, particularly if early induction of labor is being considered.

Timing of delivery should be optimized with relation to systemic treatment, ideally occurring no less than 3 weeks after the last dose of chemotherapy to minimize the risk of cytopenias.[22] Planned inductions of labor and cesarean deliveries are often performed to minimize pregnancy-associated complication risk.[11]

Breastfeeding

Many cancer therapeutic agents are excreted in breast milk and can carry risk to the infant. Therefore, breastfeeding should be avoided during the administration of chemotherapy, biologic agents, endocrine therapy (ET), and radiation therapy.

Long-Term Implications for the Offspring

MDACC reported on 81 children born to mothers who underwent chemotherapy in the second or third trimesters. Surveys performed by parents/guardians of children exposed to anthracycline-based chemotherapy in utero assessed the child's health, development, and school performance. Developmental delays were reported in 12% of the children, similar to the reported prevalence of 10% in the general population.[18] At the time of the most recent survey, the median age was 7 years (range <1–21). Allergies and eczema were the only reported long-term health problems that were more common than those expected in the general population. However, longer follow-up is needed to evaluate possible late side effects, such as cognitive impairment and fertility problems. Another study described similar outcomes for children born to mothers who received chemotherapy for hematologic malignancies during pregnancy.[30] Eighty-one children had cardiac evaluation by clinical evaluation and echocardiography every 5 years after birth until 29 years of age (mean 17.1 y) with no evidence of cardiac dysfunction.[30]

A multicenter case-control study evaluated 129 children who were in utero while their mothers had cancer and were compared with matched controls.[31] A nonsignificant increase in small-for-gestational-age infants was seen in the cancer cohort compared with controls, 22% versus 15.2% (P = .16). Premature birth, regardless of receipt of cancer therapy, was associated with decreased cognitive outcomes, again emphasizing the importance of avoiding early delivery in patients with PABC. A large international cohort study published the outcomes of 1170 women who had cancer while pregnant, 39% of whom had breast cancer.[32] Overall, 21% of neonates were small for gestational age. A trend for chemotherapy association with small-for-gestational-age infants was reported; however, the relationship was most convincing with platinum chemotherapies and it is difficult to draw conclusions for other agents. Prematurity was common, representing almost half of births, with the vast majority of premature births, 88%, being iatrogenic.

Pregnancy Termination

A number of case series do not support the previously held belief that pregnancy termination improves the survival with PABC. In contrast, there appears to be a trend toward shorter survival with termination of pregnancy.[33] Patients must be made fully aware of the evidence, or lack thereof, regarding pregnancy termination and survival. In situations of known or suspected fetal teratogenesis, or if maternal health is in jeopardy, pregnancy termination may be an appropriate medical recommendation.

PREGNANCY AFTER A DIAGNOSIS OF BREAST CANCER

Epidemiology

Of the women in the United States diagnosed with breast cancer from 2012 to 2016, 1% were 20 to 29 years old, 4% were 30 to 39 years, and 14% were 40 to 49 years.[34] In 2017, the mean age of first-time mothers in the United States was 26.8 years,[35] and data from the National Center for Health Statistics demonstrates the trend of women bearing children at later ages.[35,36] The first birth rates in women aged 35 to 44 have

increased, but have decreased in women younger than 30, especially in the age group younger than 20.[35,36] Thus, younger women diagnosed with breast cancer may not have completed childbearing at the time of their diagnosis and may seek to do so after their treatment is complete.

Chemotherapy-Related Amenorrhea

Chemotherapy-related amenorrhea (CRA) is variable defined as cessation of menstruation for 3 to 12 months in women with chemotherapy exposure.[37] The incidence of CRA varies with age, cytotoxic agent used, and cumulative cytotoxic dose.[37] A study of 183 women who underwent systemic therapy, including chemotherapy and tamoxifen, for breast cancer revealed that age and chemotherapy were the primary predictors of menopause.[38] Taxanes may result in a higher CRA rate in the first year, but after two years, the rates of CRA are similar regardless of taxane administration. Women older than 40 also had higher rates of CRA.[39]

The preferred fertility preservation approach recommended by the American Society of Clinical Oncology (ASCO) is controlled ovarian stimulation followed by oocyte or embryo cryopreservation.[40] Concurrent administration of an aromatase inhibitor (AI) can be used to decrease estrogen exposure during ovarian stimulation. A prospective study revealed no significant difference in DFS compared with women who did not undergo ovarian stimulation, based on short follow-up of approximately 2 years.[41] A large retrospective study evaluated the outcomes of assisted reproductive technology by query of the Society for Assisted Reproductive Technology Clinic Outcome Reporting System database. Although women with a history of breast cancer had successful pregnancies, the live birth rate was significantly lower compared with women without a history of cancer. Use of autologous oocytes in women diagnosed with breast cancer 6 months to 5 years prior had a 23.3% live birth rate. However, birth rate improved to 62.5% with donor oocytes, similar to women without cancer.[42]

Unfortunately, cryopreservation is not practical for many women, in which case, ovarian suppression by a gonadotropin-releasing hormone analogue (GnRHa) can be offered. However, evidence of efficacy is inconsistent and ovarian suppression should not be considered as a replacement for proven techniques. GnRHa used to reduce CRA risk has been evaluated in clinical trials. For example, a study that randomly assigned 60 premenopausal women with hormone receptor–negative (HR–) breast cancer to chemotherapy with or without goserelin revealed no significant difference in amenorrhea at 6 months, and only one patient did not have resumption of regular menses at 2 years.[43]

The PROMISE-GIM6 (Prevention of Menopause Induced by Chemotherapy: A Study in Early Breast Cancer Patients-Gruppo Italiano Mammella 6) trial randomly assigned 281 women with stage I–III breast cancer to chemotherapy with or without triptorelin. Women treated with triptorelin were more likely to regain ovarian function with resumption of menses (age-adjusted HR 1.48, 95% CI 1.12–1.95; $P = .006$),[44] and there was no significant difference in 5-year DFS. In the ER-positive population, outcomes were very similar with 5-year DFS—85.1% in the triptorelin arm compared with 85.2% with control[44]; however, the study was not adequately powered for this exploratory end point.

The POEMS/SWOG (Southwest Oncology Group) 0230 trial randomly assigned 257 premenopausal women with stage I–IIIA HR– breast cancer to receive cyclophosphamide-containing chemotherapy with or without goserelin. There was a decrease in premature ovarian failure (POF) at 2 years (8% vs 22%) and more successful pregnancies in the goserelin arm.[45] A meta-analysis revealed a significant decrease in POF (odds ratio [OR] 0.43, 95% CI 0.22–0.84; $P = .013$) in patients receiving GnRHa.[46]

Impact of Pregnancy After Breast Cancer

Meta-analysis[47] and a number of reviews have concluded that pregnancy after a breast cancer diagnosis does not worsen survival.[48–50] In a retrospective case-control study, data from three Surveillance, Epidemiology, and End Results (SEER) populations were linked to vital records data to identify women with breast cancer who were younger than 45 years at diagnosis and who had live births 10 months or more after diagnosis. When matched with nonpregnant women with a history of breast cancer, women who became pregnant had a decreased risk of dying (relative risk [RR] 0.54, 95% CI 0.41–0.71).[51,52] Another retrospective cohort study that matched breast cancer patients by multiple factors, including ER status, revealed similar DFS and improved OS in patients who had pregnancy. Although OS was improved in the women with ER– tumors (HR 0.57, 95% CI 0.36–0.90; $P = .01$), but not in ER+ tumors (HR 0.84, 95% CI 0.60–1.18, $P = .32$),[52,53] this demonstrated that that pregnancy was not harmful with history of ER+ breast cancer. The improved survival noted in this and other studies may reflect a "healthy-mother effect," whereby women who become pregnant may have already been at decreased risk of recurrence.

Women considering pregnancy after a breast cancer diagnosis should understand that most data derive from retrospective case-control studies in different populations and with different data collection techniques. Patients must be aware of their personal risk

of recurrence and should weigh this against their desire to have a child. In addition, patients should not become pregnant while receiving anticancer therapy. Although it has been suggested that women should wait 2 years after their breast cancer diagnosis before becoming pregnant, there are no data suggesting that a pregnancy in the first 2 years increases the risk of recurrence; rather, data indicate that this is the period of increased recurrence regardless of pregnancy.[54] Patients with ER+ breast cancer receive adjuvant ET; the risk of interruption of therapy for pregnancy is unknown and is being evaluated in clinical trials.

Infant outcomes may also need to be considered. A retrospective study using the North Carolina Central Cancer Registry and vital statistics revealed that breast cancer patients who received chemotherapy, and women with delivery less than 2 years from diagnosis had higher rates of preterm birth, low-birth-weight infants, and small-for-gestational-age infants.[55] Another study using data from the FUCHSIA Women's Study also revealed increased risk of preterm birth and low birth weight in infants of breast cancer patients who become pregnant less than 1 year after completion of chemotherapy with or without radiation.[56]

MALE BREAST CANCER

Epidemiology

Male breast cancer is rare, accounting for less than 1% of male cancers and less than 1% of all breast cancers. It was estimated that 2670 new cases of male breast cancer would be diagnosed in the United States in 2019 and that 500 would die of the disease.[57] Despite its rarity, the incidence is increasing.[58,59] As with women, incidence increases with age, but men diagnosed with breast cancer are older compared with women, with the average age of diagnosis being approximately 5 years higher.[59]

Genetic mutations can influence the risk of breast cancer developing in men. BRCA mutation is a known risk factor, with a lifetime risk of 4% to 16% with *BRCA2* and up to 4% for *BRCA1*.[60] A study evaluating 1939 families using the National Cancer Institute's Cancer Genetics Network revealed that the estimated cumulative risk of breast cancer in men by age 70 was 6.8% for *BRCA2* carriers and 1.2% *for BRCA1*.[61] Other genetic mutations, such as *CHEK2*, *PALB2*, and *PTEN* may also increase the risk.[59,60] It is estimated that more than 20% of male patients with breast cancer will have detectible genetic mutations; therefore, genetic counseling is recommended for all men with breast cancer, per ASCO and National Comprehensive Cancer Network (NCCN) guidelines.[60,62]

Other risk factors include positive family history, radiation exposure, and increasing age. Elevated estrogen levels increase the risk of male breast cancer, which can occur in conjunction with liver disease, testicular abnormalities, obesity, gynecomastia, and Klinefelter syndrome.[59] There is a doubling in risk in men with a first-degree relative with breast cancer.[63]

Diagnosis and Staging

The most common presenting symptom of breast cancer in men is a painless lump, often in the retro-areolar location. Other symptoms include nipple retraction, local pain, skin ulceration, nipple bleeding or discharge, or axillary lymphadenopathy.[59] The mean age of diagnosis is 68 years and diagnosis below the age of 40 is rare.[64] Men are more likely to have a delay in diagnosis compared with women and, accordingly, tend to be diagnosed in a later stage of the disease.[65,66] Although this may, in part, account for observations of worse prognosis in men, a study evaluating outcomes from the SEER database demonstrated increased mortality compared with women in a multivariate analysis that controlled for major risk factors, such as stage and hormone receptor status (HR 1.43, 95% CI 1.26–1.61).[65] Another study utilizing the National Cancer Database also demonstrated worsened prognosis in men, which could partially be accounted for by lower administration of appropriate standard treatment in the male population.[66]

Breast imaging with mammography and/or ultrasonography of any suspicious breast mass is recommended, followed by biopsy, if indicated. If breast cancer is diagnosed, staging evaluation appropriate for the given tumor stage should be performed.

Pathologic Features of Male Breast Cancer

Approximately 85% of male breast cancers are infiltrating ductal carcinoma, with only 1% to 2% being invasive lobular.[64,67] The rarity of lobular carcinoma may be the result of little terminal lobule development in men.[10,59,64] Breast cancers in men are primarily hormone receptor–positive (HR+) with a low rate of HER2 positivity. Most are positive for androgen receptor (AR). Central pathology assessment of 1054 early-stage male breast cancers from the International Male Breast Cancer Program database revealed that 99% were ER+, 82% PR+, 8.7% HER2+, and 97% AR+ (Fig. 38–2B).[64] Small studies suggest that genomic profiles may also differ between male and female breast cancers. For example, male breast cancers are more likely to be Luminal B (Fig. 38–2A).[64,68] Genomic analysis has detected lower rates of somatic mutations in *PIK3CA*, PI3K/AKT/mTOR pathway genes, and *TP53* in men with ER+, HER2– breast cancer compared with

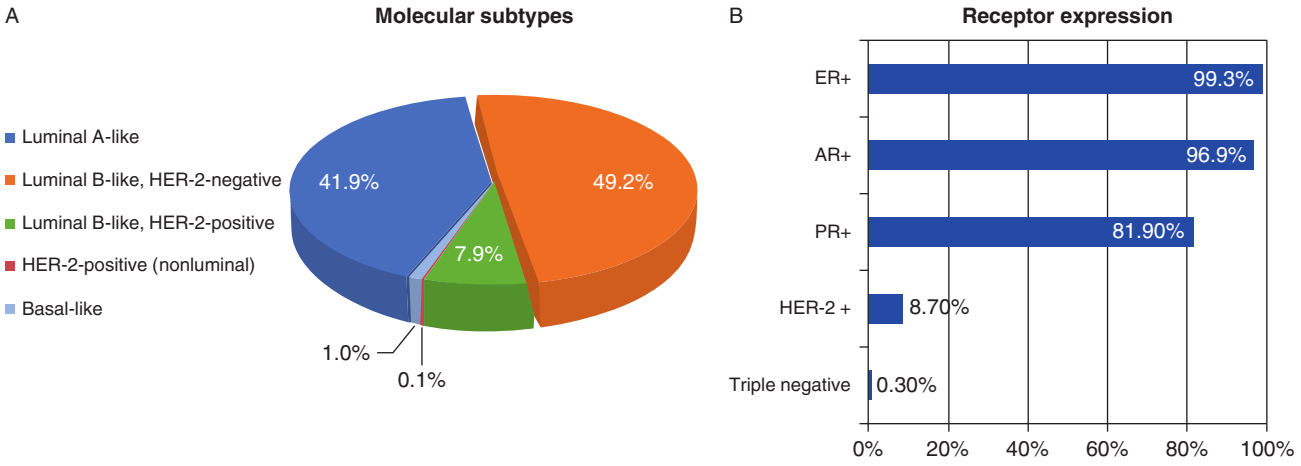

FIGURE 38–2 **A. Molecular subtypes of 1483 male breast cancer tumors based on the 2013 St Gallen Consensus definition.[64] B. Relative proportion of biomarker expression in a cohort of 1054 male breast cancers.[64] ER+, estrogen receptor–positive; AR+, androgen receptor–positive; PR+, progesterone receptor–positive. breast cancers in postmenopausal women, but there was an increase in DNA repair pathway mutations.[68]

Surveillance

There is a lack of evidence to inform standard surveillance in male breast cancer, and so men are treated similarly to women. Consensus-based recommendations based on expert opinion offer some guidance. ASCO guidelines recommend yearly ipsilateral mammography in men who have BCS.[60] The relative risk of developing a subsequent contralateral breast cancer (CBC) is increased, with the highest risk in men younger than 50 years at initial diagnosis, but the absolute risk is low, approximately 0.1% per year.[69] Given this, the NCCN guidelines state that routine mammography is not required in men.[70] The ASCO guidelines recommend consideration of yearly contralateral mammography in men with a predisposing genetic mutation, but consensus was not met for men without mutations.[60] Both NCCN and ASCO recommend monitoring of bone mineral density in men taking GnRHa therapy.[60,70]

Treatment of Male Breast Cancer

The goals of treatment are the same as for women: local and systemic disease control. Although some randomized clinical trial data are available to guide systemic therapy in men, data for locoregional therapy does not exist. Many treatment decisions are made based on extrapolation of data in women.

Surgery

There are no randomized trials comparing surgical interventions for male breast cancer. Clinical practice is based on retrospective data as well as extrapolation from female breast cancer. Although total mastectomy and BCS are both appropriate, historically, most men have mastectomy; scant breast tissue nonpermissive for appropriate surgical margins and a tendency for central tumor location may contribute to this trend.[64,71] SEER data in men with T1–2N0 breast cancer yield similar 5-year cause-specific survival in patients who had BCS compared with mastectomy[72] and a separate analysis of men with T1N0 breast cancer revealed no difference in OS.[73]

As in women with breast cancer, evaluation of the axilla with SLNB or axillary lymph node dissection, as indicated, is considered part of standard of care.[59] Interrogation of SEER registry data reveals that axillary lymph node removal and examination in male patients with breast cancer is associated with improved OS.[73] Retrospective data demonstrate that SLNB is feasible and accurate[74,75] and appears to be reasonable in appropriately selected patients.

Radiation Therapy

Although no randomized studies have been conducted to inform on the benefit of locoregional radiation in men, treatment should be based on standards of care for female breast cancer.[59] Of concern, published data suggest that radiation is often inappropriately omitted in male patients with breast cancer, even with BCS.[64,73]

A study of 81 male patients with breast cancer between 1977 and 2006 revealed that locoregional therapy consisted of mastectomy for 26 patients and mastectomy with postmastectomy radiation therapy (PMRT) for 46 patients. There was no difference in OS between the two groups; however, there was a significant decrease in locoregional recurrence in the PMRT group, with benefit primarily observed in patients with high-risk features.[76] Another study used the SEER database to evaluate the benefit of PMRT in men who had modified radical mastectomy, demonstrating improved OS in patients with lymph node involvement.[77] A German cancer registry study revealed improved OS with PMRT in men with stage III breast cancer at 20 years of follow-up.[78]

Adjuvant Systemic Therapy

As with women, men with HR+ breast cancer also benefit from adjuvant systemic therapy. At MDACC, between 1944 and 2001,135 men with early-stage breast cancer were evaluated and treated; 51 received adjuvant systemic therapy: 13 received chemotherapy alone, 19 received ET alone, and 19 received both. There was a significant increase in time to recurrence (HR 0.49, 95% CI 0.27–0.9) and survival (HR 0.45, 95% CI 0.25–0.84) in patients receiving ET.[79] Additional retrospective data also indicate mortality benefit in men with HR+ breast cancer treated with adjuvant tamoxifen.[80]

The role of AIs in the adjuvant setting of male breast cancer is currently limited. A German Cancer Registry retrospective study of 257 male patients with breast cancer treated with adjuvant tamoxifen (n = 207) or an AI (n = 50) revealed survival benefit with tamoxifen. On multivariate analysis, AI was associated with increased mortality compared with tamoxifen (HR 1.55, 95% CI 1.13–2.13; P = .007).[81] Retrospective SEER data also demonstrate mortality benefit with adjuvant tamoxifen, but not with AI.[80] The poor performance of AI therapy may be related to lack of GnRH inhibition. AI administration in men results in an increase in testosterone, luteinizing hormone, and follicle-stimulating hormone, and a decrease in estradiol; however, complete estradiol suppression is not attained.[59] Further, estradiol levels with AI therapy are much higher in men compared with postmenopausal women. The finding is likely related to feedback from the pituitary and conversion of testosterone to estradiol, which can be circumvented with concurrent administration of a GnRHa.[59,60] Accordingly, the ASCO guidelines recommend tamoxifen as the preferred adjuvant ET agent; however, AI combined with a GnRHa is appropriate for men with a contraindication to tamoxifen.[60]

At a median follow-up of 3.9 years, 53% of men treated with tamoxifen experienced at least one toxicity, according to a review from MDACC. The most common side effects were weight gain and sexual dysfunction; 20% of men prematurely stopped tamoxifen because of side effects.[82] A study evaluating tamoxifen adherence in men with HR+ breast cancer revealed 65% adherence at year 1, decreasing to 18% at year 5. Five- and 10-year DFS and OS were significantly worsened in the low-adherence group.[83] Therefore, assessment and management of side effects with appropriate counseling on the importance of therapy compliance is necessary to optimize outcomes in male patients with breast cancer.

Although there is a lack of randomized data, male patients with breast cancer should generally be treated with (neo)adjuvant chemotherapy and HER2-directed therapy as indicated for women.[59] Nonrandomized prospective[84] and retrospective studies[85,86] suggest benefit from chemotherapy in men with breast cancer. As with women, molecular profiling assays can offer important prognostic information for male patients and can assist in identifying men most likely to benefit from chemotherapy. A study interrogating the SEER database confirmed that Oncotype Dx recurrence score in men correlated with prognosis. However, differences compared with women were observed, such as a greater number of very low (<11) and high (≥31) recurrence scores in men.[87]

Therapy for Metastatic Disease

As in early-stage breast cancer, strategies for management of metastatic breast cancer in men are largely derived from those in female patients. ET is favored as frontline treatment for men with HR+, HER2– metastatic breast cancer in most cases.[60] The recommended use of chemotherapy and therapies targeted to HER2, PIK3CA mutations, programmed death ligand 1 (PD-L1), and germline *BRCA1* and *BRCA2* mutations are the same as for women with metastatic breast cancer.[60]

The ASCO guidelines offer tamoxifen, AIs, preferably with a GnRHa, and fulvestrant as appropriate ET.[60] Although data in men are limited, the improved outcomes observed with ET combined with CDK4/6 inhibitors[88,89] and mTOR inhibitors[90] in women warrants similar use in men.[59,60] Case reports and series of AI therapy with or without GnRHa have been published.[91–94] One study showed an overall response rate of 40% in 15 patients with metastatic breast cancer receiving AI monotherapy.[93] Unfortunately, a phase 2 SWOG trial investigating anastrozole and goserelin for the treatment of male patients with metastatic or recurrent HR+ breast cancer closed in 2007 because of lack of enrollment. Available data on fulvestrant in men, administered at the previously approved 250-mg dose, include a pooled analysis of 23 male patients, revealing partial response in 26% and stable disease in 48%.[95]

THE RISKS AND BENEFITS OF HORMONE REPLACEMENT THERAPY

Postmenopausal Hormone Replacement Therapy

A great debate occurred over several years regarding the value of hormone replacement therapy (HRT) in women as a cardiovascular protective agent when weighed against the risk of developing breast cancer. The combined estrogen and progesterone arm of the Women's Health Initiative (WHI), a large, randomized clinical trial designed to evaluate HRT for primary prevention of coronary artery disease, demonstrated an increased risk of breast cancer and ischemic stroke without a decrease in cardiovascular events.[96] Combined HRT failed to improve cognitive function and health-related quality of life, although there was an improvement in vasomotor symptoms and sleep disturbances.[97,98] Combined HRT was effective at increasing bone mineral density and decreasing fractures in healthy postmenopausal women.[99] Given the WHI data, recommendation for combined HRT for vasomotor symptoms of menopause or bone health must be carefully considered by weighing the risks and benefits for the individual.

The estrogen-only arm of the WHI study closed for a lack of improvement in cardiovascular health.[100] Although there was a non–statistically significant decrease in breast cancer in women randomly assigned to the estrogen arm, the risks and benefits for the individual patient need to be taken into account when deciding whether to recommend estrogen-only HRT.

A Cochrane review, last updated in 2012, evaluated the effect of long-term HRT by reviewing 19 trials involving 41,904 women.[101] Continuous combined HRT significantly increased the risk of breast cancer, among other conditions. However, continuous estrogen-only HRT did not significantly increase breast cancer risk. HRT was only effective at decreasing the incidence of fractures. Therefore, HRT is not indicated for the routine management of chronic disease at this time, and more evidence is needed regarding its safety.

Hormone Replacement Therapy in Breast Cancer Survivors

The HABITS (Hormone Replacement After Breast Cancer—Is It Safe?) trial[102] is a randomized, non–placebo-controlled, noninferiority trial that evaluated the new breast cancer risk in women with a history of breast cancer and subsequent HRT use. Of the planned recruitment of 1300 subjects, 447 women were randomly assigned: 221 women received HRT and 221 women acted as controls. The study was terminated early after the results of the WHI trials became available. At a median follow-up of 4 years, the risk of developing a new breast cancer with HRT (HR 2.4, 95% CI 1.3–4.2), as was the cumulative incidence of breast cancer at 5 years (22.2% vs 8%).[102]

Given the available data, one must carefully consider the use of HRT for postmenopausal breast cancer survivors. Among postmenopausal women without a history of breast cancer in the WHI cohort, combination HRT increased the risk of breast cancer and was most beneficial for the treatment of vasomotor symptoms and the prevention of bone loss and fracture. Accordingly, in women with a history of breast cancer, other pharmacologic therapies for bone health or vasomotor symptoms are strongly preferred over HRT.

DUCTAL CARCINOMA IN SITU

Epidemiology

Ductal carcinoma in situ (DCIS), or intraductal carcinoma, is a noninvasive breast histologic entity whose incidence rose from 5.8 to 32.5 per 100,000 women between 1975 and 2004.[103] Because DCIS most commonly presents with an abnormal mammogram demonstrating suspicious microcalcifications,[104] increased incidence is likely secondary to screening mammography and better detection of lower-grade lesions. The incidence of noncomedo DCIS had increased up to the late 1990s when it began to level off, whereas the rate of comedo DCIS, a more aggressive subtype, has remained fairly stable.[105] The primary goal of therapy for DCIS is prevention of invasive breast cancer because the prognosis of DCIS with no invasion is excellent, with risk of distant metastasis or death far less than 1%.[106]

Pathologic Features

Pathologic assessment of DCIS includes the architectural pattern (solid, papillary, micropapillary, or cribriform), the presence or absence of comedonecrosis, and nuclear grade (low, intermediate, or high) (Fig. 38–3).[104] DCIS classification can correlate with the extent of disease. For example, micropapillary DCIS is more likely to involve more than one quadrant, 71% of cases in one series,[107] whereas the solid DCIS subtype is most likely to be fully excised at surgery.[107]

ER expression should be assessed in patients for whom adjuvant ET would be considered.[108] In general, ER expression is inversely correlated with nuclear grade, and ER-negative DCIS is associated with worse prognosis and higher rates of recurrence.[109] Some studies suggest that HER2+ DCIS is associated with higher grade and worse prognosis; however, results have

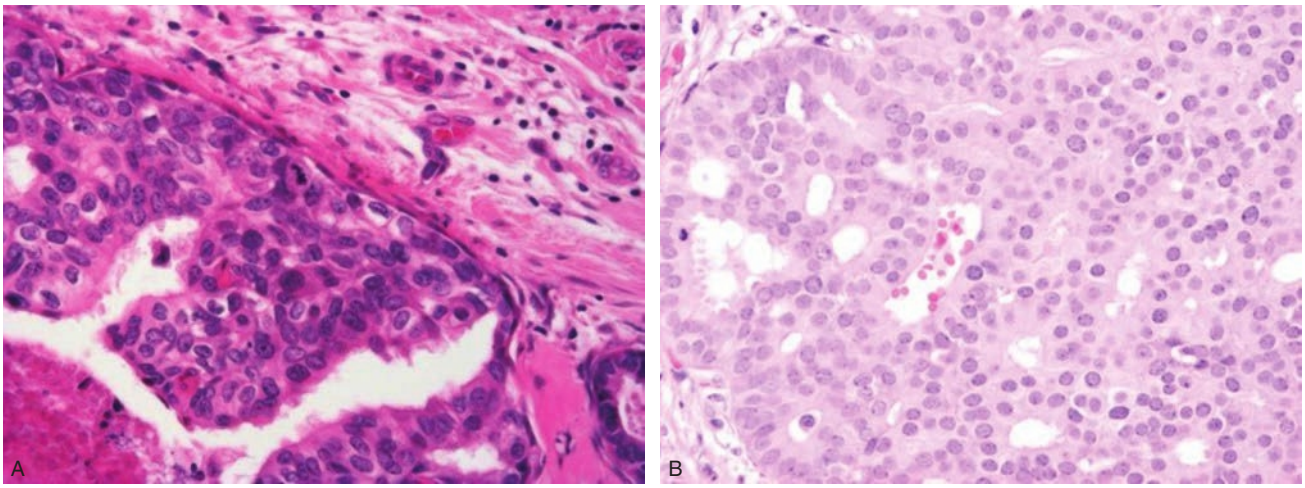

FIGURE 38–3 **High-grade and low-grade DCIS. A. High-grade ductal carcinoma in situ (DCIS) seen as neoplastic cells more than 2.5 erythrocytes in diameter with clumped chromatin, some with multiple, prominent nucleoli. Central comedo-type necrosis is also present (bottom left). B. Low-grade DCIS of cribriform architecture. Small nuclei (predominantly 1.5–2 erythrocytes in diameter), some with prominent nucleoli, are seen with mild pleomorphism. (Reproduced with permission from Pinder SE: Ductal carcinoma in situ (DCIS): pathological features, differential diagnosis, prognostic factors and specimen evaluation, *Mod Pathol* 2010 May;23 Suppl 2:S8-S13.)**

been mixed.[109] At this time, HER2 assessment is not standardly performed.[110]

For DCIS diagnosed by core-needle biopsy, invasive carcinoma is subsequently identified in approximately 10% to 15% of surgical resection specimens.[111] The chance of invasive disease increases with the extent of DCIS.[104] When invasive or microinvasive disease is detected, further management should be based on guidelines for invasive breast cancer.[104] Microinvasion is diagnosed if the invasive component is less than or equal to 1 mm in its greatest dimension.[112] With multiple foci of microinvasion, the size of the largest area is used.[112]

Treatment

Local Therapy

The options for the surgical management of DCIS range from BCS to mastectomy; SLNB can also be performed in select cases. Mastectomy achieves excellent outcomes, with risk of locoregional recurrence of approximately 1%.[113] SEER registry data reveal lower ipsilateral invasive recurrence with mastectomy compared with lumpectomy, but mastectomy does not offer significant Breast Cancer Specific Survival benefit.[114] With BCS, consensus guidelines recommend at least 2-mm margins to minimize the risk of recurrence in the ipsilateral breast.[115] Although mastectomy is highly effective, it may be an excessive approach for patients who are candidates for BCS.

Although axillary lymph node dissection or SLNB is not the standard of care for all women presenting with DCIS, a small proportion have axillary lymph node involvement. A NCDB review of almost 11,000 women with DCIS who had lymph node dissection between 1985 and 1991 found axillary metastases in 3.7%.[116] Two studies investigating pure DCIS without microinvasion reported 0.98% (1/102)[117] and 6% (5/87)[118] rates of sentinel lymph node positivity. Another study revealed positive sentinel lymph nodes in 12% (9/76) of patients with high-risk DCIS and 10% (3/31) with DCIS with microinvasion.[119] Currently, routine lymph node evaluation is not recommended for all patients with DCIS. However, SLNB may be considered for those undergoing a simple mastectomy for DCIS because the opportunity for SLNB is lost if invasive or microinvasive disease is detected because the tumor bed is no longer in place.[120,121]

The addition of adjuvant radiation therapy to BCS has been extensively evaluated. Radiation primarily reduces the risk of an ipsilateral/in-breast recurrence. The National Surgical Adjuvant Breast and Bowel Project (NSABP) B-17 study compared lumpectomy with or without radiation for women with primarily small-volume DCIS (≤2 cm) and negative resection margins. Through 8 years of follow-up, the use of radiation therapy significantly reduced noninvasive breast recurrence from 13.4% to 8.2% and that of invasive disease from 13.4% to 3.9%.[122] Of interest, degree of comedonecrosis was found to be an independent predictor for ipsilateral breast tumor recurrence.[123] Long-term outcomes were assessed in a combined analysis of the B-17 and B-24 studies. Radiation therapy was associated with a significant decrease in invasive ipsilateral breast recurrences (HR 0.48, 95% CI 0.33–0.69; $P < .001$), but did not impact the risk of contralateral

breast cancer, OS, or breast cancer–related mortality.[124] Patients who had an invasive ipsilateral breast recurrence, but not DCIS, had a higher risk of death (HR 1.75, 95% CI 1.24–2.45) and breast cancer–related death (HR 7.06, 95% CI 4.14–12.03).[124]

The European Organisation for Research and Treatment of Cancer) 10853 trial randomly assigned more than 1000 women with DCIS 5 cm or smaller to no further treatment or radiation therapy. At 10 years, 85% of patients assigned to radiation were free from local recurrence compared with 74% of those without radiation (HR 0.53, 95% CI 0.4–0.7; $P < .0001$).[125] Multivariate analysis identified risk factors significantly associated with local recurrence risk, including age 40 years or younger, symptomatic detection, intermediate/poor differentiation, cribriform or solid growth pattern, involved or close margins, and treatment with local excision alone. The beneficial impact of radiation therapy was consistent throughout all assessed risk factors.[125]

Cochrane meta-analysis confirmed the reduction in ipsilateral breast events (IBE) with the addition of radiation therapy to BCS for DCIS (HR 0.49, 95% CI 0.41–0.58; $P < .00001$), with reduction in both invasive and DCIS recurrences.[126] More recent retrospective SEER data suggest that radiation may be associated with a small survival benefit, which is most evident in patients with high-risk factors.[127,128] A patient prognostic score based on grade, patient age, and tumor size correlates to survival benefit.[128] Another analysis revealed greater improvement in breast cancer mortality with radiation in Black women who were younger than 50 years or who had ER- DCIS.[127] Therefore, additional studies evaluated the omission of radiation in certain patients.

ECOG-ACRIN E5194 is a prospective study that observed two cohorts of patients with DCIS treated with lumpectomy with more than or equal to 3-mm margins without radiation. Approximately 30% of patients received adjuvant tamoxifen.[129] Cohort 1 included patients with low/intermediate grade DCIS with tumor small than or equal to 2.5 cm (median tumor size 6 mm); cohort 2 included patients with high-grade DCIS measuring 1.0 cm or smaller (median tumor size 7 mm).[130] At 5 years, IBE occurred in 6.1% of patients in cohort 1 and in 15.3% of patients in cohort 2.[129] At 12 years, the risk was 14.4% and 24.6%, respectively.[130] Increasing size also correlated with increased risk of IBE.[130] There was no significant difference in OS or CBC events between the two cohorts.[130]

The RTOG 9804 study randomly assigned 636 of the planned 1790 patients who had lumpectomy for good-risk DCIS to radiation versus observation. Eligibility characteristics of DCIS included screen or incidental detection, low/intermediate nuclear grade, unicentric, tumor size less than 2.5 cm, and margins 3 mm or larger. Tamoxifen was permitted and was administered in 62% of patients.[131] At 7 years, ipsilateral local failure was 0.9% with radiation and 6.7% with observation (HR 0.11, 95% CI 0.03–0.47; $P = .001$).[131] There was no significant impact of radiation on OS, DFS, or CBC.[131]

Gene expression assays, such as Oncotype Dx DCIS, may also assist in risk stratification regarding benefit of radiation after BCS.[132] Overall, the cumulative data demonstrate that patients with low-risk DCIS based on various factors have a lower risk of IBEs compared with those with higher-risk features. However, even with low-risk DCIS, radiation does decrease the risk of IBE, albeit without benefit in OS or CBC.[130,131] Therefore, it may be reasonable to omit radiation in certain patients after a discussion of the risks and benefits, because some patients will find that the risk of IBE without radiation is acceptable. Patient life expectancy and comorbidities need to be considered when making this treatment decision.

Systemic Therapy

The goal of systemic ET for DCIS is to reduce the risk of IBE or CBC. As such, treatment in patients who have had ipsilateral mastectomy is controversial, because systemic therapy will only serve as chemoprevention to reduce the risk of CBC. Systemic therapy is not indicated for patients with DCIS who have had bilateral mastectomies (Table 38–3).
