58 Viral Infections in Patients with Cancer

Fareed Khawaja
Roy F. Chemaly

KEY CONCEPTS

- Viral infections caused by herpes simplex virus (HSV) 1 and 2, varicella zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus, and human herpesvirus 6, can reactivate in immunosuppressed patients and lead to increased morbidity and mortality.
- Cutaneous HSV and VZV infections have characteristic appearances on physical examination, and confirmation can be obtained with polymerase chain reaction–based molecular assays. Treatment of patients with severe HSV and VZV infections requires the use of intravenous treatment dose of acyclovir, and if started early, it may reduce serious complications.
- CMV reactivation has varied clinical presentations in patients with hematologic malignancies and hematopoietic cell transplantation (HCT) recipients. Specific viral loads thresholds trigger initiation of antiviral therapy to prevent end-organ disease and serious complications.
- Adenovirus infections can range from upper respiratory tract infection, pneumonia, gastrointestinal infections, or asymptomatic viremia. Treatment is indicated in immunocompromised patients, such as HCT recipients, with disseminated disease. Cidofovir is the only commercially available agent with in vitro activity against adenoviruses.
- Community respiratory viral infections are commonly diagnosed in patients with cancer and are associated with increased morbidity and mortality in immunosuppressed patients in particular.
- Hepatitis B and C viral infections are common in certain parts of the world. Patients with cancer should undergo testing for both viruses before chemotherapy. Prevention of hepatitis B with entecavir or tenofovir is recommended in high-risk patients to prevent fulminant liver failure. Hepatitis C is treated with intent to cure and can be postponed until after chemotherapy.

Viral infections are an important cause of morbidity and mortality in patients with cancer, specifically among patients with hematologic malignancies or recipients of hematopoietic cell transplantation (HCT). Patients with cancer with viral infections may have longer hospitalizations and delays in cancer-related treatment such as chemotherapy, surgery, or radiation. DNA viruses, such as herpes simplex virus (HSV), varicella zoster virus (VZV), and cytomegalovirus (CMV), are well known to cause serious infections in patients with hematologic malignancies or after HCT, resulting in intense monitoring and prophylaxis directed against such viruses.[1] Respiratory viral infections are also common among patients with cancer; these include infections related to adenovirus, influenza, parainfluenza, respiratory syncytial virus (RSV), rhinovirus, human coronavirus (HCoV), and human metapneumovirus (hMPV).[2] Modern tools of diagnosis can quickly identify viral pathogens, but treatment options are limited for many of these infections. This chapter provides an overview of viral infections in patients with cancer. Special focus is placed on those with hematologic malignancies and HCT recipients because this population is uniquely susceptible to viral infections.

HUMAN HERPESVIRUSES

Infections related to human herpesviruses (HHVs) are common among patients with cancer.[3] Morbidity and mortality from these viruses are high among immunosuppressed patients. Herpesviruses are double-stranded DNA viruses. The herpesvirus group has eight members, six of which are important pathogens

in immunosuppressed patients (ie, patients with hematologic malignancies, solid-organ or stem cell transplant recipients).[4,5] This group of pathogens includes HSV 1 and 2, VZV, CMV, Epstein-Barr virus (EBV), and HHV-6.

Herpesviruses establish a latent phase after primary infection. The reactivation of these DNA viruses can be triggered by several stimuli; this is perhaps best recognized in the recurrent blisters and ulcers associated with HSV. The likelihood of reactivation of these viruses is increased during profound T-cell immunosuppression because host defenses against these viruses are dependent on virus-specific helper and cytotoxic T lymphocytes. Over the past decade, substantial improvements have been made in the techniques used to detect these infections, such as real-time polymerase chain reaction (PCR), as well as the development of effective antiviral agents and the use of different strategies for prophylaxis and treatment.

Herpes Simplex Virus

Among the most common causes of mucocutaneous lesions in immunocompromised patients are HSV types 1 and 2.[5] Approximately 40% to 60% of seropositive patients undergoing induction chemotherapy for leukemia or conditioning for HCT will experience HSV reactivation, usually in early stages, when immunosuppression is most intense.[5] HSV reactivation may also cause severe disease during neutropenia. Patients with a CD4 count less than 50 cells per cubic millimeter of blood who received purine analogs or alemtuzumab are at highest risk of reactivation.[5] It was previously believed that HSV-1 infections presented as oropharyngeal or esophageal diseases, and HSV-2 was associated with genital lesions. More recent studies have shown that there is much overlap between the sites of reactivation for HSV-1 and HSV-2.[6–8] Other clinical presentations for HSV-1 or -2 infections can range from fever, malaise, myalgia, dysphagia, and bleeding to severe oral pain and odynophagia. Table 58–1 lists different syndromes associated with HSV infections.

Diagnosis

With the advancement of molecular diagnostics, real-time PCR directly on tissue samples has become the new standard of diagnosis of HSV-1 or -2 infections. Real-time PCR can detect HSV in a number of samples, including skin tissue, cerebrospinal fluid (CSF), and vitreous humor. It is more sensitive than previous diagnostic tools, such as viral cell cultures.[9,10] Other testing includes direct fluorescent antibody testing, which is a rapid antigen test for HSV; the sensitivity is poor compared with real-time PCR. The role of HSV-1 and -2 antibody testing is largely used to detect evidence of prior infections.

TABLE 58–1 Human Herpes Simplex Virus-1 or -2 Related Syndromes

Site	Disease
Oral cavity and gastrointestinal tract	Herpes labialis Gingivostomatitis Pharyngitis Esophagitis Hepatitis
Cutaneous	Herpetic whitlow Herpes gladiatorum Erythema multiforme Eczema herpeticum
Ocular and central nervous system	Keratitis Acute retinal necrosis Conjunctivitis Chorioretinitis Meningoencephalitis

Prophylaxis

Antiviral prophylaxis should be strongly considered in HSV-seropositive patients at risk for reactivation during intensive chemotherapy for acute leukemia and during early stages of HCT.[4,5] Oral acyclovir and valacyclovir are the agents of choice for prophylaxis. If patients are receiving intravenous (IV) foscarnet, ganciclovir, or valganciclovir for treatment of another viral infection, then they do not need to continue acyclovir prophylaxis.[11] Guidelines suggest that continuing prophylaxis for over 1 year after HCT significantly reduces reactivation and may even decrease the risk of acyclovir-resistant HSV.[5,11,12]

Therapy

The available antiviral agents for the treatment of HSV disease include acyclovir, valacyclovir, famciclovir, foscarnet, and cidofovir (Tables 58–2 and 58–3).[4,11] The most commonly used drug is acyclovir. The bioavailability of oral valacyclovir and famciclovir is three to five times superior to that of oral acyclovir. All of these drugs are dependent on the virus-encoded thymidine kinase for their intracellular phosphorylation for activity.

Treatment of patients with HSV with either oral or IV therapy is based on the severity of disease and if the patient can tolerate or absorb oral therapy. Severe HSV-1 and -2 infections in immunocompromised patients with hematologic malignancies or prior HCT, such as herpes meningoencephalitis and hepatitis, are initially treated with IV acyclovir (5–10 mg/kg every 8 hour). Otherwise, an oral regimen can be used for milder HSV disease (famciclovir, 500 mg three times a day, or valacyclovir, 1 g three times

TABLE 58–2 Antiviral Compounds

Antiviral	Dosage	Mechanism of Action	Active Against
Acyclovir	5–10 mg/kg IV every 8 hours	Inhibits DNA polymerase	HSV, VZV
Famciclovir	500 mg PO every 8 hours	Inhibits DNA polymerase	HSV, VZV
Valacyclovir	0.5–1 g every 8–12 hours	Inhibits DNA polymerase	HSV, VZV
Ganciclovir	5 mg/kg every 12 hours	Inhibits DNA polymerase	CMV, HSV
Foscarnet	60 mg/kg IV every 8 hours	Inhibits DNA polymerase	CMV, HSV, VZV, HHV-6
Cidofovir[a]	5 mg/kg IV once a week	Inhibits DNA polymerase	CMV, ADV, HSV, VZV, BK
Letermovir	480 mg PO daily	CMV DNA terminase complex inhibition	CMV
Oral ribavirin	600 mg every 8 hours	Inhibits RNA polymerase	HCV, RSV
Inhaled ribavirin	2 g over 2–3 hours every 8 hours or 6 g continuously over 18 hours	Inhibits RNA polymerase	RSV
Amantadine	100 mg PO every 12 hours or 200 mg PO daily	Inhibits M2 Protein	Influenza A only
Rimantadine	100 mg PO every 12 hours	Inhibits M2 Protein	Influenza A only
Oseltamivir	75 mg PO every 12 hours	Neuraminidase inhibitor	Influenza A and B
Peramivir	600 mg once	Neuraminidase Inhibitor	Influenza A and B
Zanamivir	Two inhalations every 12 hours (IV formulation available, clinical trial)	Neuraminidase inhibitor	Influenza A and B
Baloxavir	40 mg PO once (patient weight, 40 kg to <80 kg) 80 mg PO once (patient weight, ≥80 kg)	cap-dependent endonuclease inhibitor	Influenza A and B

[a]Licensed for cytomegalovirus (CMV) retinitis.
ADV, adenovirus; HCV, hepatitis C virus; HSV, herpes simplex viruses; IV, intravenous; PO, oral; RSV, respiratory syncytial virus; VZV, varicella zoster virus.

TABLE 58–3 Common and Serious Toxicities of Antivirals

Acyclovir	Transient renal insufficiency (IV), nausea, vomiting, agitation, confusion, TTP (rare)
Famciclovir	Headache, somnolence, nausea, diarrhea
Valacyclovir	Headache, nausea, vomiting, TTP (rare)
Ganciclovir	Anemia, neutropenia (more common), thrombocytopenia, fever, phlebitis, anorexia
Foscarnet	Nephrotoxicity (major toxicity), electrolyte disturbances (hypocalcemia, hypophosphatemia, hyperphosphatemia, hypomagnesemia, hypokalemia), diarrhea, nausea, vomiting
Cidofovir	Headache, rash, severe nephrotoxicity, metabolic acidosis, decreased intraocular pressure, neutropenia
Letermovir	Peripheral edema, headaches, GI complaints (nausea, vomiting, diarrhea), arrhythmia (tachycardia, atrial fibrillation), thrombocytopenia
Ribavirin	Fatigue, headache, nausea, rash, pruritus, conjunctivitis (inhalation, health care workers administering ribavirin), hemolytic anemia (cardiac and pulmonary events have occurred), worsening respiratory status, including death (inhalation)
Oseltamivir	Insomnia, vertigo, nausea, vomiting (most common), bronchitis
Zanamivir	Headache, nausea, diarrhea, cough, bronchospasm, decline in lung function (some fatal outcomes)
Peramivir	Hypertension, increased serum glucose, GI complaints (diarrhea, constipation, vomiting), increase in liver enzymes, rash, delirium
Baloxavir	Diarrhea, rash, eyelid edema, delirium, hallucinations

GI, gastrointestinal; IV, intravenous; TTP, thrombotic thrombocytopenic purpura

a day) can be used in patients who can tolerate oral therapy.[4,5] Foscarnet and cidofovir can be used for resistant disease but are only available in IV formulations only.[11]

Varicella Zoster Virus

VZV reactivation occurs primarily in older adults, seropositive organ transplant and HCT recipients, patients with cancer, and those with acquired immunodeficiency

syndrome (AIDS). Disseminated VZV infection can be life threatening in HCT recipients and patients receiving intensive corticosteroid therapy.[5]

The clinical manifestations of VZV infection are primary varicella infection (chickenpox) and herpes zoster (shingles). The clinical presentation includes low-grade fever, malaise, and a vesicular rash that evolves to scabs. Constitutional symptoms usually develop after the onset of rash and include pruritus, anorexia, and listlessness. Primary VZV infection (chickenpox) occurs mainly in children younger than 10 years of age.

Reactivation of latent VZV or herpes zoster is frequently observed among patients with cancer, mainly patients with leukemia or lymphoma, as well as in HCT recipients.[4,5] Comparatively, solid tumor patients do not have as high a risk of VZV reactivation.[13] Visceral herpes zoster may follow cutaneous dissemination in immunocompromised patients and can result in pneumonia, encephalitis, retinal necrosis, hepatitis, and small bowel disease. Cutaneous VZV eruption can be complicated by secondary bacterial infections, thrombocytopenia, and vasculitis (Fig. 58–1).

Diagnosis

In cases of shingles in immunocompromised patients, the diagnosis can be made based on clinical observation of typical dermatomal distribution of a vesicular rash. However, immunocompromised patients commonly develop multidermatomal or disseminated cutaneous disease, which can make the clinical diagnosis less certain on visual inspection alone. The diagnosis can be established with the use of real-time PCR, which has replaced immunofluorescent staining and viral culture.[14] In some cases, a biopsy is required to establish the diagnosis because other diseases can mimic VZV, such as streptococcal impetigo, graft-versus-host disease (GVHD), and various noninfectious bullous diseases.

FIGURE 58–1 Hemorrhagic vesicular lesions of herpes zoster.

Therapy

The treatment of choice for chickenpox or VZV in immunocompromised patients is high-dose IV acyclovir (10 mg/kg every 8 hours) (see Tables 58–2 and 58–3). Early initiation of acyclovir is paramount because it may reduce progression to end-organ disease and usually prevents death in patients with reactivated infection. Therapy can be changed to an oral agent after clinical improvement has occurred, including resolution of fever or healing or crusting of lesions. The options for an oral regimen for treatment of localized herpes zoster among patients with mild immunosuppression include acyclovir (rarely used because of bioavailability and pills burden), valacyclovir, and famciclovir.[15]

Prevention of Infection and Postexposure Prophylaxis

In immunocompetent patients older than 50 years of age, VZV vaccinations are recommended to prevent reactivation or severe VZV infection. However, immunocompromised patients may not receive the live zoster vaccines (Zostavax) because of the risk for viral reactivation. Additionally, because of concomitant chemotherapy, there are concerns regarding efficacy. Recent studies regarding the use of the recombinant zoster vaccine (Shingrix) in solid tumor patients receiving chemotherapy, patients with hematologic malignancy, and autologous HCT recipients demonstrated both safety and clinical efficacy.[16–18] This has not been replicated in allogeneic HCT recipients, but further studies are underway. In patient who are at high risk of shingles or recurrent VZV disease, antiviral prophylaxis with oral valacyclovir or acyclovir should be strongly considered in VZV-seropositive patients during intensive chemotherapy and during the early stages of HCT.[4,5]

Immunosuppressed patients with negative VZV titers and no history of chickenpox should be offered varicella zoster immune globulin after being in close contact with individuals with either chickenpox or herpes zoster infection. Close contact includes prolonged face-to-face contact, a household or playmate contact, or exposure to a roommate in a shared hospital room. Varicella zoster immune globulins, if available, should be administered within 96 hours of exposure to be most effective in preventing infections.[5] Immunocompromised persons should avoid contact with individuals who developed a rash after receiving the live zoster vaccines. No additional precautions are required if a rash has not developed.[5,11]

Infection Control Considerations

VZV can be transmitted from person to person, potentially resulting in an outbreak in a hospital

or clinic setting. To prevent nosocomial transmission, immunocompromised patients with cutaneous lesions suspicious of VZV eruption and those with disseminated zoster should be placed under contact and respiratory isolation.[19] In addition, it is recommended that the family members, caregivers, and visitors of patients scheduled to undergo transplant be vaccinated against VZV, preferably at least 4 weeks before conditioning regimen.[5,11]

Cytomegalovirus

Evidence of prior CMV infection is present in more than half of the US population.[20] Therefore, reactivation of latent CMV infection is of primary concern in the hematologic malignancy and HCT patient populations.[5,11] CMV reactivation can manifest as asymptomatic viremia, a mononucleosis-like syndrome with lymphadenopathy, or more severe disease with end-organ damage. Other symptoms of CMV reactivation include fever, splenomegaly, lymphocytosis, polyradiculopathy, or pancytopenia. Manifestations of end-organ disease include retinitis, encephalitis, and hepatitis, but pneumonitis and gastrointestinal (GI) disease are the most common after allogeneic HCT.[5]

The most common sites of CMV infection in the GI tract are the esophagus and colon. The hallmarks of CMV colitis are abdominal pain and diarrhea. CMV esophagitis is associated with pain and dysphagia. On upper endoscopy, ulcerations can be seen in the esophagus, and a biopsy must be obtained to rule out other infectious causes, such as HSV and candida esophagitis. Similarly, the diagnosis of CMV colitis requires biopsy. In a retrospective study at our institution, 72% of patients diagnosed with GI CMV disease had hematologic malignancies, 25% had AIDS, and the overall CMV-attributable mortality rate was 42%.[21] Independent predictors of mortality were disseminated CMV and diagnosis of AIDS.[21]

CMV pneumonitis can be associated with a high mortality rate in patients with high-risk leukemia and in HCT recipients.[5] Pneumonitis typically presents with severe dyspnea, hypoxia, and interstitial disease on chest radiographs. Similar to GI disease, finding of CMV from bronchoscopy specimens without accompanying pathology is of unclear significance. Preexisting thrombocytopenia, present in most patients with leukemia and HCT recipients, often prevents acquisition of a biopsy specimen that can accurately confirm a diagnosis of CMV pneumonitis. A study of autopsy-proven CMV pneumonia in HCT and patients with hematologic malignancies showed that incidence decreased over the time of the study (from 1990 to 2004).[22]

Risk Factors

Patients with HCT and hematologic malignancies are at highest risk for CMV infection and reactivation. In patients with leukemia, those at highest risk include patients who have received purine analogs (eg, fludarabine) and T-cell–depleting monoclonal antibodies (mAbs, eg, alemtuzumab).[5,23] Reactivation can occur in almost 5% of those receiving purine analogs and in 15% to 66% of those receiving alemtuzumab, with the highest risk period for the latter group being in the first 1 to 3 months after therapy.[5] Reactivation in the setting of alemtuzumab therapy was, however, significantly reduced (0% vs 35% in the control arm) with prophylaxis using valganciclovir 450 mg orally twice per day compared with 500 mg/day of valacyclovir.[24]

In HCT recipients, the highest risk group is the CMV-seropositive recipient, regardless of donor serostatus, followed by CMV-seronegative recipients with seropositive donors.[5] Nonmyeloablative regimens for HCT recipients have resulted in decreased risk of CMV reactivation, although cases have occurred later after transplant.[25] The period of highest risk is in the first 100 days after transplant, although prophylaxis and preemptive strategies have resulted in CMV infections after day 100 from transplantation.[26] Risk factors for late disease in HCT recipients include GVHD, CMV reactivation before day 100 posttransplant, steroid use, low CD4 count (<50 cells per cubic millimeter of blood), use of unmatched stem cells, cord blood, T-cell–depleted stem cells, and receipt of allograft-negative donors in CMV-positive recipients.[11,27] CMV can also be transmitted to HCT recipients from seropositive donors and from blood products.[5] The use of CMV-seronegative blood for transfusions and leukoreduction of blood products has resulted in significantly reduced CMV infections.[5]

Diagnosis

Diagnosis of CMV depends on the site of infection. For detection of disseminated infection or reactivation, the two types of tests available and recommended for diagnosis of CMV include pp65 testing and detection of DNA.[11] Serologic testing is not useful, except for donor selection for transplant, because CMV antibodies demonstrate evidence of prior exposure rather than active infection. For detection of end-organ disease such as in the liver and lungs, the recommended approach is biopsy with detection of viral inclusions on histopathology or by immunohistochemistry (Fig. 58–2), which has greater sensitivity. If available, in situ PCR and nucleic acid hybridization are also useful diagnostic tools for biopsy samples. Detection of CMV DNA is a widely available test in transplant centers, using quantitative real-time PCR (rt-PCR) for CMV DNA detection.[5,11,28]

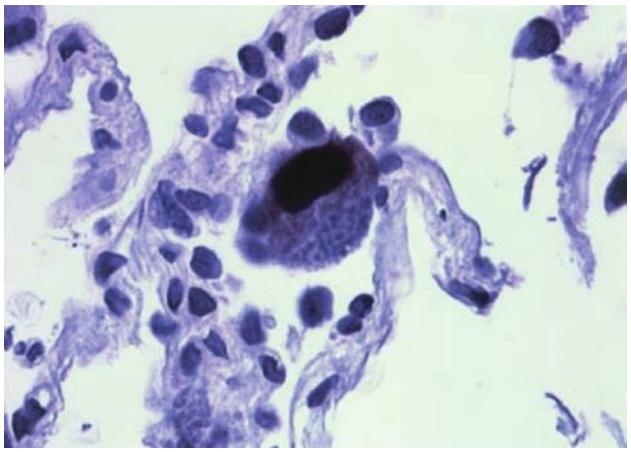

FIGURE 58–2 **Typical cytomegalovirus inclusions in the lung parenchyma of a patient with lymphoma and pneumonia.**

Prevention of Cytomegalovirus Infections in Hematopoietic Cell Transplantation Recipients

There are two main strategies to prevent of CMV infections in HCT recipients, preemptive therapy or chemoprophylaxis.[28–30] Preemptive strategy involves monitoring in whole blood or plasma for CMV DNAemia or antigenemia in HCT recipients on a weekly basis after transplantation. CMV-targeted therapy would be initiated at a predetermined CMV viral load cutoff based on the risk for CMV disease. By initiating therapy early on, the risks of CMV end-organ disease and other virus-associated complications are reduced in HCT recipients.

In HCT recipients with prior evidence of CMV infection based on pre-transplant serology (seropositive), a newly approved agent, letermovir, that works on the viral terminase complex of CMV is indicated as a prophylactic agent for clinically significant CMV reactivation within 100 days after transplantation. Letermovir was found to significantly reduce the incidence of CMV infection in HCT recipients at high risk for reactivation compared with placebo.[31,32] In addition, letermovir has no antiviral activity against any other herpesviruses, and valacyclovir or acyclovir should be given for HSV or VZV chemoprophylaxis in patients at risk. In clinical trials, letermovir was found to be safe and well tolerated.[31,32] The most common side effects were vomiting and development of edema.[31,32] Importantly, letermovir was not found to be myelotoxic or nephrotoxic.[31,32] Table 58–2 lists the available antiviral agents for herpes viruses and respiratory viruses. For HCT recipients with no prior evidence of CMV infection (seronegative), no CMV chemoprophylaxis is indicated.

When ordering blood products for HCT recipients, special considerations are taken in CMV-seronegative HCT recipients who received a bone marrow graft or peripheral stem cells from a seronegative donor to prevent seroconversion and thus increase the risk of CMV reactivation.[28] Two strategies exist to reduce the risk of seroconversion, the use of seronegative blood product donors or leukocytes reduction. It is not clear which of the two options are superior, but seeking CMV seronegative donors is labor intensive and costly for many blood banks.

Therapy

The selection of CMV directed antiviral therapy is limited because the preferred agents are associated with major toxicities. Table 58–2 and 58–3 describe the different specific antiviral agents and related toxicities. The most commonly used antiviral agents for CMV include ganciclovir, valganciclovir, foscarnet, and cidofovir.

Ganciclovir functions as a competitive inhibitor of viral DNA polymerase. Its major side effect is myelosuppression, limiting its use as a prophylactic agent and requiring frequent blood count monitoring.[5] Dosing for treatment is 5 mg/kg intravenously every 12 hours.[5] Valganciclovir, a prodrug of ganciclovir available in capsule form, is significantly better absorbed than its prodrug ganciclovir in oral form.[5] A common induction dose is 900 mg twice daily by mouth.

An alternative agent, foscarnet, functions as a noncompetitive inhibitor of the pyrophosphate-binding site of CMV DNA polymerase, which does not require phosphorylation to become active.[5] Foscarnet is typically used when resistance to ganciclovir is suspected or bone marrow suppression is excessive with ganciclovir. It is also useful in patients with delayed engraftment.[28] Side effects of foscarnet include nephrotoxicity, azotemia, and electrolyte abnormalities.

Cidofovir, a nucleotide analog, has been approved for treatment of CMV retinitis in patients with human immunodeficiency virus (HIV). It works as a competitive inhibitor of the CMV DNA polymerase. Its role in treatment or prophylaxis of CMV in immunocompromised patients, however, is limited because of nephrotoxicity. The long half-life makes once-weekly administration possible but also results in lasting impact of adverse effects.[28] Modalities used to reduce risk of nephrotoxicity include hydration and premedicating with probenecid.

Human Herpes Virus 6

HHV-6 is a β-herpesvirus with two subtypes (A and B). Primary infection with HHV-6 is very common in children. Exanthem subitum, the most common cause of fever and hospitalization of infants younger than 1 year of age, is caused by HHV-6 subtype B.[4,5] In addition to fever, children present with mild upper

respiratory symptoms and a classic diffuse maculopapular exanthem. It is unclear whether HHV-6 subtype A causes any primary infection. In immunosuppressed individuals, typically patients with AIDS and transplant recipients, HHV-6 may cause opportunistic viral infections. Because this infection is very common early in life, positive titers are found in more than 95% of adults. In immunosuppressed individuals, especially HCT recipients, this virus occasionally may cause interstitial pneumonia, fever, encephalitis, hepatitis, and delayed engraftment.[11] Up to 40% to 60% of HCT recipients may demonstrate viremia by PCR, but the significance of this finding is unclear.

Molecular assays such as rt-PCR are used for the diagnosis of HHV-6 DNAemia. Similarly, CSF samples are tested with real-time PCR to detect HHV-6 when viral encephalitis is suspected. Multiplex molecular assays include HHV-6 on the panel in addition to other pathogens. This technology yields fast results and is able to detect other possible pathogens. However, the risk of false-negative result is possible and places patients at risk of receiving toxic antiviral therapy.[33] We advise confirming the presence of HHV-6 DNA in CSF with a quantitative HHV-6 by PCR from CSF and correlating with clinical findings and magnetic resonance imaging of the brain.

A unique phenomena associated with HHV-6 is viral integration into the germline and vertically transmitted, resulting in chromosomally integrated HHV-6 (ciHHV-6).[33,34] The hallmark of ciHHV-6 is markedly elevated viral loads in blood or CSF, possibly exceeding 5.5 log10 copies/mL.[33] Unfortunately, ciHHV-6 may be seen in HCT recipients and can pose a major diagnostic challenge because the presence of ciHHV-6 does not eliminate the possibility of HHV-6 encephalitis.[35] We recommend considering ciHHv-6 when elevated viral loads persist despite lack of clinical symptoms or after effective therapy.

Therapy

Both ganciclovir and foscarnet are used to treat HHV-6 infections, but this is based upon in vitro studies only because clinical experience is minimal. Both ganciclovir and foscarnet have been reported to be effective against HHV-6 meningoencephalitis after HCT in a small number of patients.[4]

Epstein-Barr Virus

EBV infection is very common in the adult population. EBV is the cause of infectious mononucleosis and has also been linked to several geographically defined cancers. EBV-associated posttransplant lymphoproliferative disorder (PTLD) is an important cause of morbidity and mortality in HCT and solid-organ transplant recipients. PTLD is reported in 0.45% to 29% of HCT recipients, depending on the source of hematopoietic cells (cord blood with the highest risk), manipulation of those cells, and immunosuppressive regimen.[36] Although variable in incidence, PTLD can be fulminant and lethal. The disease results from suppression of cytotoxic T-cell function. The first step in the management of PTLD is to reduce the dose of any immunosuppressive therapy if possible. Another therapeutic approach using the anti-CD20 mAb (rituximab) has been tested for therapy of patients with EBV-induced PTLD. It has been successful for the treatment or prevention of PTLD in solid-organ transplant and HCT recipients as well as those with proven EBV-associated lymphomas.[4,5] Another approach is use of EBV-cytotoxic T lymphocytes (CTLs), typically derived from EBV-positive stem cell donors or from third-party donors.[36,37] There is no apparent role for antivirals in treatment of EBV-associated PTLD. Treatment with rituximab and EBV-targeted CTLs has resulted in more than 85% survival compared with less than 20% before these modalities were available.[36]

Adenovirus

Adenoviruses are a common cause of self-limited respiratory and GI infections in normal individuals. Transmission occurs by aerosolized droplets or the oral–fecal route. Adenovirus infections have been recognized in patients undergoing intensive chemotherapy for hematologic and occasionally other malignancies, but they are especially prevalent among HCT recipients.[4] The frequency of adenovirus infections among HCT recipients has varied from 3% to 21%, and it is more prevalent among children than adults. There is no seasonal variation, and the onset of infection from time of transplantation can be quite variable, although the median interval period is about 50 days.[4]

Important risk factors have been identified for adenovirus infections, including childhood, allogeneic transplantation (particularly umbilical cord blood), GVHD, total-body irradiation (in children), T-cell–depleting conditioning regimens, alemtuzumab, corticosteroid therapy, and lymphopenia.[4]

Immunocompromised patients may have asymptomatic infection, single-organ disease, or disseminated disease.[4] The most common disease is gastroenteritis presenting as fever and diarrhea, which may become bloody. Infections of the respiratory tract may vary from mild upper respiratory tract infection (URI) to severe pneumonitis with respiratory failure. Adenovirus may cause nephritis, and as many as 50% of patients with positive urine cultures develop hemorrhagic cystitis.[38] Hepatitis may lead to liver failure and death. Other types of infection include encephalitis, pancreatitis, and disseminated infection with multiple-organ failure.

Diagnosis

Adenovirus may be detected in upper and lower respiratory specimens, urine, stool, blood, and infected tissues. The diagnosis can be established by viral culture, which is considered as the gold standard of detection. Viral culture requires both time and expertise to perform, making it difficult to use in a clinical setting. More rapid diagnosis using commercially available molecular-based, such as real-time PCR, are more commonly used to detect adenovirus DNA in blood or urine. The use of real-time PCR has been adopted as the standard of care for detection of adenovirus in HCT and patients with hematologic malignancies,[39] but in resource-limited settings, rapid antigen detection can also be used. Adenovirus is commonly added to the panel of commercially available multiplex molecular assays for CSF, stool, and respiratory samples.

In allogeneic HCT recipients, the risk of serious adenovirus infections in both adult and pediatric patients may be modified with early intervention.[40] At our center, we recommend weekly adenovirus screening with real-time PCR from blood in high-risk allogenic HCT recipients, such as cord or haploidentical HCT recipients, mismatched transplant recipients receiving postconditioning cyclophosphamide, HCT recipients taking high-dose steroids for treatment of GVHD, and patients treated with alemtuzumab. Because no vaccines are available commercially and no chemoprophylactic agents have been approved, preemptive monitoring remains the only preventive strategy. There is no specific threshold for adenovirus viral load that definitively correlates with clinically relevant infection because some patients with asymptomatic DNAemia may have spontaneous resolution. Some experts recommend treatment if DNAemia exceeds 1000 copies/mL in blood in high-risk HCT recipients.[41] There is no guidance on management of patients with hematologic malignancies or other patients with cancer with asymptomatic DNAemia, and testing should be restricted to patients with suspected adenovirus-related syndromes.

Outcomes

The mortality rate from symptomatic infection is about 25%, but it is 60% to 75% in patients with disseminated disease.[42] Death is mainly caused by pneumonitis, hepatitis, or multiorgan failure. Many patients who die have other concomitant infections. There is no established therapy for these infections, and options are very limited. In one series of 45 patients, IV cidofovir produced successful results in 69% and was as effective in asymptomatic patients as in those with definite disease.[43] In fact, most HCT centers use cidofovir, in conjunction with reduction in immunosuppression, to treat patients with adenovirus infection.[44]

New therapeutic options are under investigation for treatment of patients with adenovirus. Brincidofovir is an oral lipid conjugate of cidofovir with improved bioavailability and reduced toxicity.[45] Early studies in pediatric HCT recipients with asymptomatic adenovirus viremia have demonstrated antiviral efficacy.[46] Immunotherapy with adenovirus-specific CTLs is under investigation. Some centers with access to off-the-shelf CTLs have used them for treatment of patients with adenovirus infections with some success.[37]

Infection Control

Adenovirus can spread via droplets and has led to outbreaks in HCT units.[47,48] Adenovirus can also spread through fomites, necessitating strict hand hygiene practices for anyone interacting with a suspected or confirmed case of adenovirus infection.[19] Patients diagnosed with adenovirus should be placed in a single-patient room. Health care workers should use gloves, masks, and gowns to prevent the spread of adenovirus to other patients.[19]

COMMUNITY RESPIRATORY VIRAL INFECTIONS

Infections caused by community respiratory viruses (CRV) were not recognized as significant infectious complications for patients with cancer until the early 1990s, especially for patients undergoing chemotherapy for acute leukemia and to HCT recipients, allogeneic HCT in particular.[49] Early surveys indicated that about 30% of respiratory illnesses occurring during the winter and spring among these patient populations were caused by CRVs. Recent studies have reported CRVs as the cause of as few as 5% to as many as 48% of respiratory infections.[49] Patients infected with CRVs often have symptoms of rhinorrhea, cough (productive or nonproductive), fever, myalgias, or weakness. More severe signs and symptoms include dyspnea and hypoxia or septic shock caused by complications. This group of viruses include rhinovirus, influenza, RSV, parainfluenza virus (PIV), hMPV, and seasonal HCoV.[2]

The most common, and often lethal, complication associated with CRVs is progression from an URI to pneumonia or lower respiratory tract infection (LRI). In a retrospective study conducted at our institution, progression from URI to pneumonia was noted in 35% of HCT and hematologic malignancy patients who were diagnosed with any CRV infections.[49] Many of these pneumonias may be caused by co-infection with a bacterial or fungal pathogen.[50] CRVs that were previously thought to cause non–life-threatening infections, such as HCoV and rhinovirus, were associated in some

studies with mortality rates of 54% and 41%, respectively, when the CRV was detected in the lower respiratory tract of patients with cancer.[51,52] Additionally, progression to LRI is associated with increased length of hospital stay and increased use of mechanical ventilation. CRVs are also associated with long-term pulmonary impairment in HCT recipients and increased risk of 2-year non–relapse-related mortality.[53] To prevent these complications from occurring, appropriate infection control measures and identification of risk factors for progression to LRI are crucial.

Infection Control

Epidemics of CRV have occurred on leukemia and transplant units, where the virus may be transmitted by patients, visitors, and hospital personnel.[19] Outpatient clinics may serve as an important starting point for epidemics. Also, epidemics may occur among these susceptible patients in the absence of a recognized epidemic in the community. An additional complication from CRVs is that immunocompromised patients may have prolonged viral shedding (in some cases >100 days) after resolution of symptoms.[5,54] Shedding of influenza virus continued despite antiviral therapy, halting only when lymphopenia resolved.[5,54] Patients with symptoms consistent with CRVs should undergo diagnostic workup, and isolation precautions should be initiated while the diagnosis is underway. Isolation precautions include placing the patient in a single-patient room and the use of gloves, masks, and gown for health care workers interacting with the patient, along with enforcement of strict hand hygiene.[19] Visitors and health care workers who display symptoms should undergo testing and be restricted from visiting patients at risk of contracting CRVs. A study from our center also demonstrated that high influenza vaccine uptake among health care workers was associated with decreased nosocomial transmission of CRVs.[55]

Predisposing Factors

Several important predisposing factors for these infections have been identified in HCT recipients and patients with hematologic malignancies. These include age older than 65 years, severe neutropenia, severe lymphopenia, allogeneic transplantation, transplant conditioning regimen, GVHD, and corticosteroid therapy (>1 mg/kg body weight).[4,49,56,57] HCT recipients are at greatest risk within the first 100 days post-transplant, although nonmyeloablative transplant has resulted in an increase in disease occurring after this initial period.[4,56] Neutropenia, lymphopenia, marrow or cord blood as source of transplant, age older than 65 years, GVHD, smoking history, and allogeneic HCT were risk factors for progression from RSV URI to pneumonia.[2,49] Aerosolized ribavirin reduced the likelihood of developing pneumonia in leukemia and HCT recipients who presented with URI.[2] An immunodeficiency scoring index (ISI) developed at MD Anderson Cancer Center has been useful in estimating outcomes and appropriate use of ribavirin for RSV infections in allogeneic HCT recipients with RSV infections.[58] The ISI included risk factors for progression to pneumonia and mortality. Factors given the most weight are neutropenia, lymphopenia, and age 40 years or older followed by other factors like GVHD, corticosteroid use, myeloablative conditioning regimen, and early period after transplantation (pre-engraftment or within 30 days of engraftment).[58] Without therapy, patients in the highest risk category all progressed to pneumonia compared with 15% of those who received antiviral therapy. The subsequent mortality rate in untreated high-risk patients who progressed to pneumonia was 100% compared with 50% for those with pneumonia who received antiviral therapy.[58]

Diagnosis

The diagnosis of CRV infection is established with samples collected from nasopharyngeal wash or swab for URI and bronchoalveolar lavage or tracheal aspirate for LRI.[49,59] The preferred laboratory assay is the nucleic acid amplification test to detect RNA from samples. The use of molecular diagnostic is preferred because of higher sensitivity and rapid results. In addition, commercially available respiratory viral multiplex PCR can detect multiple pathogens and can be used to rule out CRVs.[60] Rapid antigen detection tests are available for influenza, PIV, hMPV, and RSV; however, the sensitivities of these assays are lower compared with molecular assays. Viral culture can be performed, but this is a labor-intensive process that requires expertise, and material many centers do not have access to.

Specific Viruses and Therapeutics

Many of the CRVs have no therapeutic options. In contrast, influenza has multiple therapeutic options that can be used in immunocompromised patients. RSV has limited treatment options for only a subset of patients. There is no treatment available for PIV, HCoV, rhinovirus, and hMPV.

Influenza

Influenza virus infection is associated with a wide spectrum of presentation and natural course of disease in severely immunocompromised patients. In a recent study at the US National Institutes of Health, immunocompromised patients exhibited less prominent symptoms, such as cough, chills, myalgias, or dyspnea, than

non-immunocompromised hosts.[54] Physical examination findings demonstrating pulmonary compromise were also more common in non-immunocompromised hosts, but radiographic abnormalities on chest imaging were more common in the immunocompromised patients.[54] Finally, immunocompromised patients exhibited more severe disease despite similar cytokine profiles, with prolonged viral shedding and higher risk of developing drug-resistant influenza virus.[54] Currently, all patients with cancer diagnosed with or suspected to have influenza should be treated with antiviral therapy because they are at risk for complications.[61] Early treatment of patients with influenza (within 24–48 hours of presentation) is associated with better survival and decreased risk of progression to LRI in immunocompromised patients.[62]

Preferred agents are neuraminidase inhibitors (NAIs), which include oseltamivir (Tamiflu), peramivir (Rapivab), and zanamivir (Relenza). Oseltamivir is the only oral agent available in this class. The duration of therapy in immunocompromised patients is not clear, with most experts recommending 10 days. Oseltamivir is also recommended for treatment of influenza in severely ill patients. Peramivir is a single-dose IV NAI, which has recently been approved by the Food and Drug Administration (FDA); however, it has not been well studied in patients with cancer or severely ill patients. Zanamivir is the only inhaled NAI, and it is not as commonly used as oseltamivir. M-2 inhibitors, such as amantadine and rimantadine, are no longer recommended as first-line therapy because of high rates of resistance of most circulating influenza strains and the high incidence of side effects. Recently, baloxavir (Xofluza) was approved by the FDA for treatment of patients with influenza A and B infections. Baloxavir has a novel mode of action against influenza and acts by inhibiting cap-dependent endonuclease, thus inhibiting viral mRNA replication, and is only available as an oral formulation.[63] Because of its unique mechanism of action, baloxavir has been used when oseltamivir-resistant influenza strains are suspected or confirmed.[64] Another advantage is that baloxavir is given as a single dose because of its long half-life[63]; however, this could be a factor for the emergence of resistance as seen in clinical trials.[64,65] In one of the trials, 13.1% of children treated with baloxavir had a specific mutation conferring resistance to baloxavir (PA/138X) in a cohort of 81 patients.[63,65] Finally, there are no published data yet on the use of baloxavir in patients with cancer with influenza infections. Table 58–3 summarizes the different agents.

Respiratory Syncytial Virus

RSV is associated with high mortality rate among HCT recipients and patients with hematologic malignancies.[2,39,66] RSV, types A and B, occurs year round but peaks during the cold seasons. Risk factors for progression to LRI in immunocompromised patients include neutropenia, lymphopenia, marrow or cord blood as source of transplant, age older than 65 years, GVHD, smoking history, and allogeneic HCT.[66] The ISI is used to identify high-risk patients and initiate antiviral treatment to reduce the risk of progression and mortality. Table 58–4 illustrates the variables used to calculate the ISI, and Figure 58–3 demonstrates the treatment pathway used for RSV at our center using the ISI.

TABLE 58–4 Immunodeficiency Scoring Index for Respiratory Syncytial Virus Infections in Hematopoietic Cell Transplant Recipients

Variables	Allocated Score	
ANC <500/μL	3	Max score: 12
ALC <200/μL	3	Low risk: 0–2
Age 0 years or older	2	Moderate risk: 3–6
Myeloablative conditioning regimen	1	High risk is 7–12
GVHD (acute or chronic)	1	
Corticosteroid use (within 30 days)	1	
Recent HCT (within 30 days) or pre-engraftment period	1	

ALC, absolute lymphocyte count; ANC, absolute neutrophil count; GVHD, graft-versus-host disease.

Ribavirin is the main stay therapy for RSV infections in immunocompromised patients, allogeneic HCT in particular, and patients with hematologic malignancies.[2,66] HCT recipients with RSV infections at moderate to high risk for complications based on ISI had measurable benefits with the use of ribavirin early on in their infection.[58,67] In patients with leukemia, lack of aerosolized ribavirin and high APACHE (Acute Physiology And Chronic Health Evaluation) II scores were independent predictors of developing pneumonia in this population.[58,68] Ribavirin is administered by aerosolization over 2 to 3 hours every 8 hours or continuously over 18 hours, requiring the patient's confinement in a scavenge tent.[66,69] More recently, the rising cost of aerosolized ribavirin has led most centers to switch to oral ribavirin.[70] In a retrospective study, we found that oral ribavirin dosed at 600 mg every 8 hours was safe and equivalent to aerosolized inhaled ribavirin in terms of reduction in progression to LRI.[71] Ribavirin may also be combined with intravenous immunoglobulins (IVIGs) when the infection progresses to the lower tract.[2,66] Palivizumab, a humanized mAb directed against the F glycoprotein of RSV, is

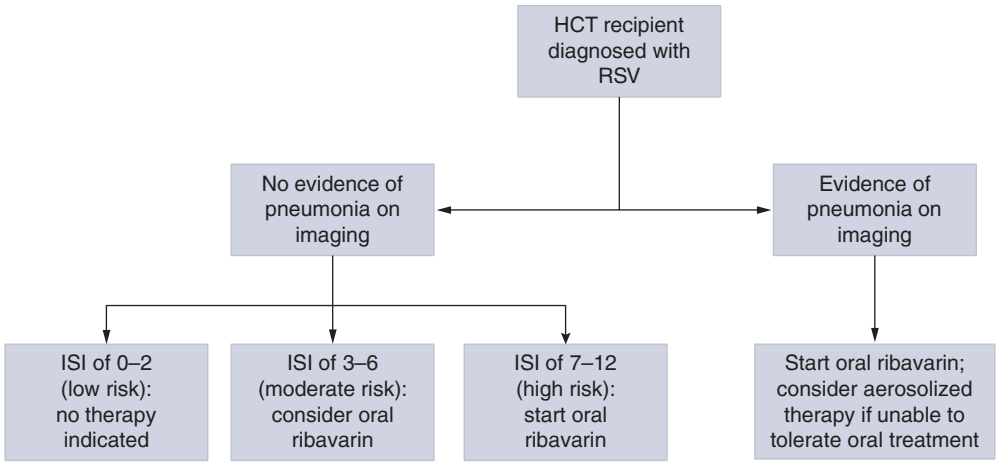

FIGURE 58–3 Management of respiratory syncytial virus (RSV) infection after hematopoietic cell transplantation (HCT) based on the immunodeficiency scoring index (ISI).

currently available and approved for prophylaxis of RSV infection in high-risk pediatric patients.[2] Most patients with RSV pneumonia are being treated with combination therapy, but the limited numbers of patients and lack of clinical trial data reported make interpretation of outcomes difficult.

Parainfluenza

There are four strains of PIV that circulate in the community, PIV 1, PIV 2, PIV 3 and PIV 4; PIV 3 is the most common circulating strain. Mortality rates associated with PIV can range between 10% to 30% in hematologic malignancy and HCT patients.[59] Progression to LRI is associated with lymphopenia, neutropenia, steroids use, high APACHE II score, and infections soon after HCT.[59,72] A study of PIV pneumonia in HCT recipients showed that high oxygen requirement, low monocytes count, relapsed or refractory malignancy and high-dose steroids were associated with mortality rates ranging from 13% to 55%.[72,73] Therapeutic options are limited, with some centers using ribavirin with or without IVIGs.

Metapneumovirus

hMPV is a paramyxovirus similar to RSV that was first described in children but recognized as a significant cause of respiratory infection in immunocompetent and immunocompromised adults.[57,74] Fatal cases in HCT recipients were reported with mortality rates as high as 43%,[75] but another study of HCT recipients from France showed a lower mortality rate, even with LRI.[76] At our center, we reported a low 30-day mortality rate of 10% associated with metapneumovirus pneumonia in patients with cancer.[77]

Rhinovirus

Human rhinovirus is a small RNA virus and a member of the Picornaviridae family.[78] With the increased use of molecular assays, rhinovirus has become the most diagnosed cause of URI in HCT recipients, as well as the general population.[52,79] Rhinovirus is unique in many ways because it is able to circulate all year round. Among HCT recipients, rhinovirus infections may present with mild to severe disease such as LRI, and these infections can result in prolonged shedding.[80] Furthermore, rhinovirus LRI in HCT recipients could be associated with an increased mortality rate, up to 41% in one study, comparable to RSV-related mortality rates.[52] Hypoalbuminemia and the presence of coinfections were associated with progression to LRI.[52] Unfortunately, no commercially available therapeutic options are available for management of rhinovirus infections.[81]

Human Coronavirus

HCoV is a member of the notorious Coronaviridae family. There are four common strains that circulate in the community, 229E, NL-63, OC43, and HKU1. Zoonotic Coronaviridae may mutate and jump to humans, resulting in endemic or pandemic spread of new strains of coronavirus such as the severe acute respiratory syndrome coronavirus 1 and 2 (SARS-CoV 1 and SARS-CoV 2) and the Middle Eastern respiratory syndrome coronavirus (MERS-CoV). The discussion of these zoonotic viruses is outside of the scope of this chapter.

Similar to rhinovirus, seasonal HCoV has become more commonly diagnosed with the use of molecular assays.[51,59] HCoV among HCT recipients carries significant mortality rates when the disease progresses to

LRI.[51] HCT recipients also shed HCoV for prolonged periods of time after the initial infection.[51] No therapeutic options are available for HCoV so far.

HEPATITIS VIRUSES

Hepatitis B

Hepatitis B (HBV) and C (HCV) infections are common in many countries. There is a global epidemic of HBV infections, affecting more than 350 million individuals worldwide. Chronic HBV or HCV infections can lead to progressive liver disease, cirrhosis, and hepatocellular cancer. Hepatitis can be a serious problem in patients with cancer for various reasons. Chemotherapy-induced immunosuppression may lead to reactivation and fulminant infection in patients with chronic HBV infection. Furthermore, the presence of hepatitis may require substantial delays in the administration of antineoplastic therapy. In HCT recipients, reactivation is more likely in those who have received high-dose steroids, fludarabine, rituximab, or alemtuzumab.[11] To prevent reactivation in high-risk patients, antiviral therapy is recommended before immunosuppressive therapy.[82] Normally, entecavir (Baraclude) is used as a first-line antiviral agent in patients who do not have co-infections with HIV. In cases of co-infection with HIV or resistant hepatitis B virus, tenofovir can be used instead.[83] Patients who are not eligible for antiviral prophylaxis should undergo serial HBV DNA monitoring by PCR while on active chemotherapy.[82]

Hepatitis C

HCV is one of the most common chronic bloodborne pathogen worldwide. In the United States, four million individuals (1.6% of the population) have been infected.[84] HCV is the leading indication for liver transplantation. HCV transmission occurs primarily through exposure to infected blood. It can be acquired from IV drug abuse, blood transfusion before 1992, solid-organ transplantation from infected donors, unsafe medical practices, occupational exposure to infected blood, birth to an infected mother, sexual contact with an infected person, and possibly intranasal cocaine use.[4]

Antibody testing should be the first test used to assess exposure to HCV, but in cases of persistent liver disease with immunocompromised status that may prevent adequate response, HCV RNA testing is recommended.[84] Patients who are seropositive for HCV should be tested for HCV RNA to determine if or the amount of circulating virus (Fig. 58–4).[84] The combination of pegylated interferon-α (INF-α) plus ribavirin produced sustained virologic responses (SVRs) in only 4% of genotype 1 infections.[84] Notably, even treated patients without SVRs exhibited slower progression to cirrhosis and portal hypertension.[84] In addition, there is an important link between HCV infection and various cancers, including hepatocellular carcinoma; lymphomas; and esophageal, prostate, and thyroid cancers.[84] This led to an expanded role for testing and treatment of HCV infection for prevention or treatment of malignancies. The treatment of HCV is also being revolutionized by new directly acting antiviral that are being introduced and promise to reduce the complications associated with HCV infections as well as improving outcomes. Treatment is uniformly recommended for HCV-infected HCT recipients, although timing should be at least 2 years after transplant with no evidence of GVHD and off immunosuppression.[11] No active or passive immunizations are available for HCV.

PARVOVIRUS B19 INFECTION

Parvovirus B19 causes erythema infectiosum in children. It has been associated with aplastic crises in diseases in which the lifespan or production of red blood cells is reduced.[85] Anti-B19 immunoglobulin G has been found to be more prevalent among patients with cancer undergoing chemotherapy than among the general population. In one study, 63% of the seropositive patients with cancer had unexplained anemia.[86] Prolonged erythroid aplasia in childhood acute lymphocytic leukemia was associated with detection of parvovirus B19 DNA in the bone marrow. Several chronic lymphocytic leukemia patients have developed severe parvovirus B19 infections that manifested by a flulike illnesses followed by anemia from pure red cell aplasia in the bone marrow. These infection could be associated with incapacitating polyarthritis. IVIGs are used as treatment options this infection but with significant risk of relapse.[87] A new concern is the potential risk parvovirus B19 infection or reactivation for patients taking dasatinib (a tyrosine kinase inhibitor).[88]

POLYOMAVIRUS INFECTION

BK Virus

Polyoma hominis, or BK virus, infects 80% of the general population without recognized clinical manifestations.[4] It persists in the genitourinary tract and is a major cause of hemorrhagic cystitis among allogeneic HCT recipients. About 60% to 80% of these patients may have persistent viruria, and 5% to 15% may develop hemorrhagic cystitis.[4] Risk is higher in high-risk allogeneic HCT recipients, such as after cord blood transplantation.[4] Patients with hemorrhagic cystitis have higher viral loads in the urine, as detected by PCR.[11] The disease may vary from asymptomatic microscopic hematuria to

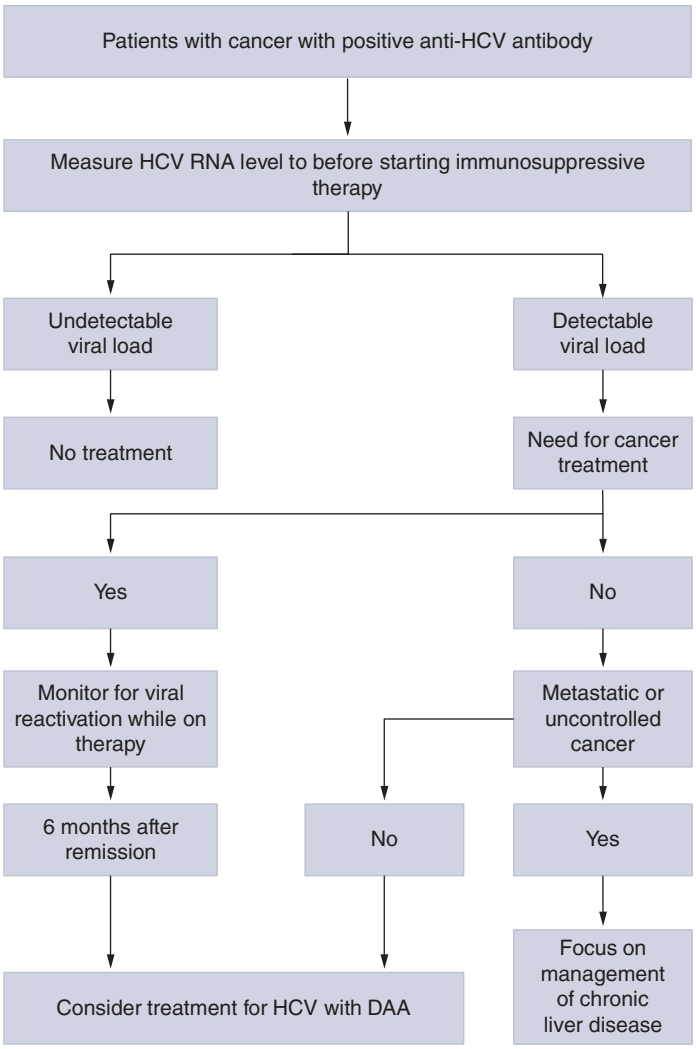

FIGURE 58–4 **Management of hepatitis C viral (HCV) infection. DAA, direct-acting antiviral.**

severe dysuria, frequency, and passage of clots, which may cause outflow obstruction and renal failure. Supportive therapy includes red blood cells and platelets transfusions, saline bladder irrigations, and cauterization. The use of quinolones is of unclear benefit. IV cidofovir has been used and successful treatment of refractory cystitis with hyperbaric oxygen therapy was reported,[89] but no specific therapy is currently recommended.[4] The use of third-party CTLs are under investigation.[37]

JC Virus

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of the brain caused by the JC virus, a polyomavirus related to BK virus.[90] The disease results from reactivation of latent infection. About 80% of adults demonstrate JC virus antibodies by middle age. PML was first described in patients with CLL and Hodgkin disease. During the AIDS pandemic, PML was common during HIV infection.[91] With the advancement of effective antiretroviral therapy and public health initiatives to screen patients early, the incidence of PML in this patient population decreased over time.[91–93] With the use of immunomodulating therapies for different diseases, drug-related PML became more notable.[92,93] Symptoms related to PML include visual disturbances, speech defects, and mental deterioration leading to dementia and coma. The mortality rate is 80% at 1 year, and the mean time from diagnosis to death is 4 months. An association has been reported with steroid use, fludarabine, cyclophosphamide, methotrexate, mycophenolate, and mAbs such as rituximab and natalizumab.[90,94] Therapeutic choices are limited, with therapy attempted with cytarabine, cidofovir, interleukin-2, IFN-α, IVIGs, zidovudine, ganciclovir, donor lymphocytes infusion, and, if possible, discontinuation of GVHD prophylaxis.[95]

MD ANDERSON CLINICAL PRACTICE TIPS

- Clinical suspicion for HSV or VZV infections in high-risk, immunocompromised patients should prompt empiric therapy until a diagnostic workup is completed. This is important because early antiviral therapy can help reduce the duration of symptoms and reduce the risk of progression of the disease.
- In adult HCT recipients who are CMV seropositive, letermovir for at least 100 days after transplantation reduced the incidence of clinically significant CMV infections with possible improvement in all-cause and nonrelapse mortality.
- Because of the chromosomal integration of HHV-6, presence of DNA in blood may not accurately reflect an active infection. Correlating with clinical findings and brain imaging can help prevent unnecessary and toxic antiviral therapy.
- Patients with suspected community-acquired respiratory viral infection should be immediately placed in a single-patient room, and infection control precautions should be implemented. Visitors and health care workers who show signs of respiratory viral infection should be restricted from patient care areas. By using safe and aggressive infection control practices, outbreaks of respiratory viral infections can be prevented among most vulnerable patients.
- Influenza occurs most commonly during the fall and winter season. Early start of directed antiviral therapy in immunocompromised patients may reduce progression to pneumonia and other complications.
- Among high-risk HCT recipients and patients with hematologic malignancies with RSV infections, oral ribavirin is recommended to reduce the risk of progression to pneumonia. Additionally, patients who receive ribavirin have improved survival. Use of aerosolized ribavirin is no longer recommended because of its exorbitant cost.

59 Fungal Infections in Patients with Cancer

Bruno P. Granwehr
Dimitrios P. Kontoyiannis

KEY CONCEPTS

- Fungal infections are common in patients with cancer.
- Morbidity and mortality associated with fungal infection complicate cancer treatment outcomes.
- Invasive candidiasis is the most common fungal infection in patients with cancer, requiring careful assessment for dissemination, selection of appropriate antifungal agent, removal of infected devices, and duration of therapy.
- Invasive aspergillosis (IA) is the most common mold infection in patients with cancer, requiring vigilance to detect pulmonary or sinus infection, which may require resection or debridement in addition to aggressive antifungal therapy.
- Rare molds that infect patients with cancer include *Fusarium* and *Mucorales* spp., typically affecting patients with hematologic malignancy, with recovery of neutrophils the most important factor in improving mortality.

Fungal infections remain a significant cause of morbidity and mortality in patients with cancer. In the United States, fungal infections were estimated to cost $7.2 billion in 2017, with $4.5 billion for 75,033 hospitalizations.[1] Modern management of infections in cancer requires knowledge of the epidemiology, pathogenesis, treatment, and prevention of such infections. Fungal infections range from nosocomial infections with *Candida* spp. to endemic fungi acquired outside the hospital, such as *Histoplasma capsulatum*.[1] Opportunistic fungi, especially molds, have emerged as a leading cause of death in patients with leukemia or hematopoietic stem cell transplant (HSCT).[2] *Candida auris*, recently identified and disseminating throughout the globe, poses a unique risk, forming biofilm capable of surviving for prolonged periods on surfaces, exhibiting multidrug resistance, often to all approved antifungals, and with a mortality rates as high as 40% to 60%.[3,4]

Fungal infections pose a continuing challenge for oncology patients. Exposure to fungi is common, typically occurring from the natural environment. Patients with cancer are not only susceptible to new infection with endemic fungi (such as *H. capsulatum*) but also reactivation of latent infections. In addition to *Aspergillus* spp., other less opportunistic molds, such as *Fusarium* spp., *Scedosporium* spp., and *Mucorales* spp., cause devastating disease in hematologic patients. Cases of nosocomial infection caused by molds are reported in the setting of hospital construction, leading to routine air sampling and filtration. In contrast, *Candida* spp. are a common component of patients' and health care workers' endogenous microbial flora. Manifestations of infection may not present until the patient receives chemotherapy or undergoes HSCT. In this chapter, we describe the general approach to diagnosis and assessment of risk factors for fungal infection and discuss common and rare causes of fungal infections in patients with cancer.

DIAGNOSIS

Fungal infections may involve several organs, ranging from the skin, brain, lungs, kidneys, and spleen to the liver and other tissues. In addition, evidence of infection may be identified from blood samples, demonstrating active, via polymerase chain reaction (PCR) or antigen testing, or past infection, via antibody testing. In the past two decades, the focus, as with other infectious etiologies, has shifted from culture or other

direct identification of organisms to molecular identification of invasive fungal infections (IFIs). These techniques use biomarkers of IFI, ranging from lateral-flow immunoassays, which can be used at point of care, to PCR-based assays, to antigen identification and next-generation sequencing of blood and other tissue samples, and "nanodiagnostic" testing. These approaches are discussed in more depth in discussion of specific fungal infections.

The diagnosis of IFIs remains problematic, however, despite increased use of fungal biomarkers.[5] The skin and lungs are commonly affected by fungal pathogens and most easily accessible to examination and biopsy. In our institution, a retrospective study of skin biopsies in patients with leukemia suggested that ulcerated or necrotic skin lesions in the context of bacteremia or fungemia were predictive of infection.[6] In fact, skin biopsy revealed infection in 39% of all patients undergoing biopsy.[6] Of patients with biopsy-proven skin infection, 39% of those infections were fungal, led by *Candida* (25%), *Fusarium* (19%), *Mucorales* (13%), *Aspergillus* (9%), *Alternaria* (6%), and *Curvularia* (3%) spp.[6]

The identification of fungal pneumonia, however, is particularly important among patients with hematologic malignancies, with invasive aspergillosis (IA) overtaking invasive candidiasis as the leading cause of IFI in immunocompromised patients.[7] A recent study of patients with acute myeloid leukemia (AML) or undergoing HSCT showed that 10.3% had evidence of IFI on baseline screening chest computed tomography (CT).[8] However, sampling of the lung is more challenging than skin biopsy, particularly in patients with hematologic malignancies, who have increased risk of bleeding with frequent thrombocytopenia.

The gold standard for diagnosis of IFI is culture of biopsy or bronchoscopy samples, but given the challenges of invasive sampling of lung tissue, other approaches are used. To differentiate between fungal infection and other causes of pulmonary infection, studies conducted in Italy examined the impact of high-resolution CT pulmonary angiography (CTPA) on diagnosis of invasive fungal lung disease, in the setting of classical findings of fungal infection of the lungs, such as the halo sign, reverse halo sign, hypodense sign, and pleural effusion.[9,10] In the initial study, involving patients with hematologic malignancies, CTPA resulted in an upgrade of patients from possible to probable or proven diagnosis of IFI.[9] A subsequent study from the group examining the impact of CTPA showed that a vessel occlusion sign (VOS), in which there was "interruption of a vessel at the border of a focal lesion without depiction of the vessel inside the lesion or peripheral to the lesion," was highly associated with fungal pneumonia.[10] In the subset of patients with VOS who underwent bronchoalveolar lavage (BAL), fungal culture results were positive in 11% (vs 0%), and tissue evidence of mold was found in 58% (vs 0%).[10] Approaches such as CTPA may help to differentiate fungal from other causes of pneumonia, but biopsy of a suspicious lesion, such as a pulmonary nodule, remains the most definitive approach to diagnosis.

In the setting of peripheral pulmonary nodules, CT-guided biopsy show a yield of approximately 60% for a specific diagnosis.[11] In a study of patients with hematologic malignancy at our center, 34% of cases whom underwent CT-guided biopsy documented previously unidentified infection, predominantly fungal.[12] Another retrospective study of open lung biopsy revealed 19% previously undiagnosed infectious etiologies.[11] Among the organisms identified, 58% were endemic molds (*Histoplasma* spp., *Coccidioides* spp.), 14% *Aspergillus* spp., and 7% *Cryptococcus* spp.[12] Figure 59–1 suggests an approach to identification of fungal pulmonary pathogens. Important steps include early CT chest to determine pattern and extent of possible fungal infection followed by prompt treatment and diagnostic workup, which may include BAL or biopsy of lung or skin lesions. Despite these efforts, diagnosis is often a challenge if infection is more diffuse or thrombocytopenia is too severe to safely permit biopsy.

Autopsy has historically been another approach to diagnosis of IFIs, but autopsy rates have fallen almost 90% from 0.63 in 100 deaths in 1989 to 1993 to 0.06 in 100 deaths in 2004 to 2008 at our institution.[13] Diagnosis of fungal infections, often manifesting as pulmonary nodules or skin lesions, is challenging but important, given the modification of therapy that may occur based on identification of a particular spp. of fungus or discovery of co-infection, malignancy, or other alternative diagnosis. Other diagnostic tools to detect fungal infection are discussed in the sections specific to each pathogen.

RISK FACTORS

The risk factors for IFI in patients with cancer derive from various defects in the immune response. These immune defects may be attributable to anatomic injury from surgery or radiation, impairment of function of the immune system by malignancy (eg, AML), the effects of chemotherapy or other systemic cancer treatments, and various infections,[14] including cytomegalovirus,[15] influenza,[16] and human immunodeficiency virus (HIV).[17] Severe neutropenia, particularly prolonged, has long been associated with IFIs.[18,19] Chemotherapy resulting in prolonged and severe CD4 lymphocytopenia can also result in infections similar to those seen in untreated patients with HIV or acquired immunodeficiency syndrome (AIDS), such

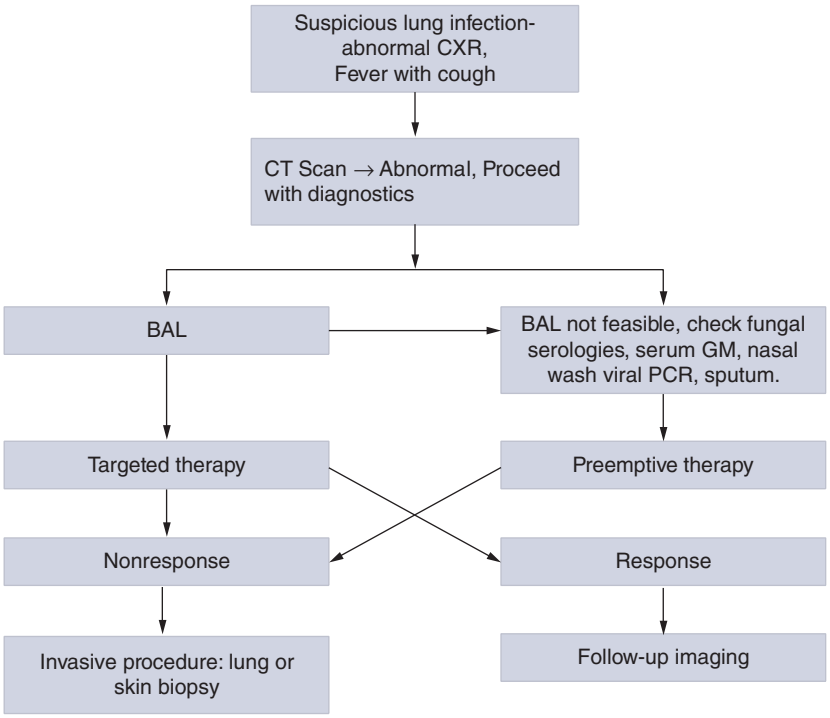

FIGURE 59–1 **Evaluation of suspicion of lung infection.**

as cryptococcosis and endemic fungal infection, such as histoplasmosis and coccidioidomycosis. In addition, conditioning regimens for stem cell transplant and immunosuppressive medications to treat or prevent graft-versus-host disease result in deficient cell-mediated immunity, thus increasing risk for IFI.[13,20] Ongoing work is ascertaining the risk posed by chimeric antigen receptor T-cell (CAR T) therapy for IFI, with a study showing that 5% of patients developed IFI after CAR T infusion.[21] The primary risk factor, however, was severity of cytokine release syndrome (CRS). This finding leads to the question regarding the relative role of treatment of CRS with corticosteroids, tocilizumab, and other medications, the preceding conditioning regimen, persistence of neutropenia, and preceding cancer treatments for the underlying malignancy, as opposed to the CAR T therapy per se.[21–23]

Progress in treatment of patients with cancer by harnessing components of the immune system against tumors has identified new risk factors for IFI. The use of ibrutinib and other kinase inhibitors for treatment of chronic lymphocytic leukemia (CLL), mantle cell lymphoma, and primary central nervous system (CNS) lymphoma has improved outcomes for patients with these cancers. Randomized clinical trials with these agents, however, did not initially demonstrate an increased risk for IFI, including cryptococcosis, histoplasmosis, IA, and *Pneumocystis jirovecii* pneumonia (PJP).[14] A recent multinational "real-life" survey examining ibrutinib-associated IFI showed that 74% of these patients with IFI had CLL, with 63% of IFIs consisting of IA and 26% cryptococcosis.[24] In contrast, the role of checkpoint inhibitors (CPIs) in modulation of immune response and outcomes is unclear. CPIs may play a beneficial role in overcoming the immune exhaustion that accompanies chronic candidiasis, endemic mold infection, and aspergillosis.[25,26] In contrast, treatment with steroids or other immunosuppressive medications for CPI-mediated immunotoxicity, such as pneumonitis or colitis, may increase risk of IFI.

In addition to changes in risk for IFI attributed to immunomodulatory treatments for cancer, disruption of mucocutaneous barriers, including oral and gastrointestinal (GI) mucositis from chemotherapy, as well as skin from central venous catheters (CVCs), predisposes to invasive candidal infection. The disruption of mucosal barriers is further emphasized by the finding, in a recent study, that 9% of patients with candidemia patients were co-infected with *Clostridium difficile*.[27]

Given the many risk factors associated with IFI in patients with cancer, various models have been developed to predict this important complication of cancer treatment. These models help to guide prophylaxis and enhanced monitoring of those at highest risk, particularly patients with hematologic malignancy. A recent study used a retrospective cohort of patients with hematologic malignancy to develop a risk prediction score for IFIs.[20] The score emphasizes the central roles played by lymphopenia, relapsed or refractory malignancy, prolonged neutropenia (>10 days), and

prior history of IFI in identifying patients at highest risk of IFI.[20]

Finally, a recently identified risk for development of IFI is the change in the microbiome attributable to broad-spectrum antibacterial therapy. Prolonged use of broad-spectrum antibacterials may result in suppression of normal bacterial flora and candidal overgrowth in the oropharynx and GI tract. Antifungal therapy or prophylaxis may also alter the mycobiome, leading to breakthrough infection with non–*Candida albicans* spp., such as *Candida krusei* (resistant to fluconazole).[28]

In summary, treatment for patients with cancer may result in increased risk of IFI, deriving from destruction of mucosal barriers due to direct injury (eg, surgery, Interventional radiology-guided drainage), cytotoxic chemotherapy, or radiation. New cancer treatments have also altered the immune response to attack malignancy, unexpectedly leading to identification of IFI. This has led to the suggestion to conduct systematic assessments of novel cancer treatments for immunosuppressive effects that may lead to infection, including IFI.[14]

FIGURE 59–2 **Typical appearance of oropharyngeal candidiasis on the palatal and buccal mucosa.**

CANDIDIASIS

Candidiasis remains the most common IFI in patients with cancer. Modern medical care continues to increase in complexity, involving frequent use of antimicrobials and devices that alter patient flora and disrupt the mucocutaneous barrier, respectively. *Candida* spp. commonly arise from the patient's endogenous flora, but hospital-acquired cases have been attributed to contaminated equipment, solutions, and hospital personnel.[28] Manifestations of candidiasis range from local infection of the skin or oral mucosa to candidemia and widely disseminated infection. These syndromes of candidiasis are discussed in the sections to follow, with treatment recommendations for candidemia and disseminated candidiasis detailed in the Therapy section at the end of this Candidiasis portion of the chapter.

Superficial Candidiasis

Oral Infection

Thrush is the most common superficial candidal infection among patients with cancer, typically those with cancers involving the head and neck undergoing chemoradiation.[29] Oropharyngeal candidiasis is characterized by whitish plaques on the buccal mucosa, palate, or tongue (Fig. 59–2) that may be painful if removed, exposing the erythematous base. Oral thrush may also be a manifestation of esophagitis.[29] The diagnosis is commonly made clinically but is typically confirmed by finding yeasts and pseudohyphae on scraping or culture. Treatment may consist of clotrimazole 10-mg troches or nystatin suspension for 7 to 14 days.[28] In moderate to severe cases affecting patients with cancer, however, oral or intravenous (IV) fluconazole daily may be required, with voriconazole, echinocandins, and very rarely amphotericin B formulations used in refractory cases.[28]

Esophagitis

Esophageal candidiasis may cause dysphagia, retrosternal pain, and odynophagia in patients with cancer.[30] Serious complications of this infection can occur, including chronic esophageal strictures, bronchoesophageal fistulas, and mediastinitis. Esophagoscopy with biopsy and culture are necessary to confirm the diagnosis of candidal esophagitis.[28] Unfortunately, thrombocytopenia often makes esophagoscopy challenging, so empiric therapy is often used. Esophageal candidiasis requires systemic therapy of 14 to 21 days' duration, typically using fluconazole 200 to 400 mg (3–6 mg/kg) daily as initial therapy.[28] Caspofungin or other echinocandins may be used if fluconazole fails or is not well tolerated, but it is available only as an IV preparation.[28] Itraconazole, voriconazole, posaconazole, and amphotericin B formulations are rarely indicated for these infections.[28] Reduction in immunosuppression, if possible, and treatment of HIV in infected patients, also enhance recovery from esophageal candidiasis.

Urinary Tract Infection

Patients with cancer, as with many other hospitalized patients, may develop primary infections of the

urinary tract in the setting of urinary obstruction and particularly Foley or nephrostomy catheters. Differentiating between colonization and infection is challenging in the presence of urinary catheters. Urinalysis may be normal, and high organism counts alone are insufficient to confirm infection. In febrile neutropenic patients, however, candiduria should be considered as a harbinger of disseminated candidiasis. Recent guidelines recommend treatment with fluconazole for 14 days with fluconazole 400 mg (6 mg/kg/day). IV lipid amphotericin B formulations may be used to treat resistant *Candida* spp.[28] Amphotericin B deoxycholate bladder irrigation 50 mg/L in sterile water may be administered for 5 days. Of note, echinocandins are not excreted in the urinary tract, so they should not be used in this setting. Relapse of infection will, however, be likely unless the urinary catheter and other indwelling devices, such as nephroureteral stents or nephrostomy tubes, in the urinary tract are removed.

Candidemia

The US Centers for Disease Control and Prevention (CDC) estimated that there were 22,660 cases of candidemia in 2017.[31] Candidemia remains the most common etiology of fungemia in patients with cancer, with *Cryptococcus* spp. and mold less frequently isolated in a European cancer cohort.[32] Rates of infection were highest among patients 65 years of age or older, men, and those of Black race, with an all-cause mortality rate of 25%.[31] Neutropenia, colonization of the oropharynx and other sites, corticosteroid use, presence of CVCs, active malignancy, recent abdominal surgery, hemodialysis, receipt of total parenteral nutrition, and persistent fever in the setting of broad-spectrum antibacterial therapy are associated with candidemia.[31,33] Recent work also demonstrates an association between *Clostridioides difficile* infection and candidemia, with 9% of patients with candidemia also having *C. difficile* infection.[27]

A study from a multicenter database suggested that the species of *C. albicans* may soon represent a minority of candidemia episodes, particularly among patients with hematologic malignancy.[32] Updated nationwide CDC surveillance shows that 38% of candidemia cases are caused by *C. albicans*, 30% *C. glabrata*, then less common *Candida parapsilosis* (14%) and *Candida tropicalis* (8%).[31] With increasing use of prophylaxis against fungal infections in at-risk patients, *Candida* spp. identified in breakthrough cases vary according to the duration and type of antifungal prophylaxis. *C. albicans* is more common in patients with less than 7 days of, or altogether without, antifungal prophylaxis.[34] Breakthrough candidemia in patients on longer duration of prophylaxis, such as patients with leukemia, are identified as *C. glabrata* or *C. krusei*.[34] Studies also point to increased incidence of multidrug-resistant *C. glabrata* candidemia in patients given fluconazole or even caspofungin prophylaxis.[34,35] The latter finding is of concern because caspofungin is often used as an empiric antifungal to manage *C. glabrata*.

Candidemia results in an overall 12-week crude mortality rate of 49% in patients with cancer.[32] *C. parapsilosis* candidemia has been associated with CVCs.[36] Patients with *C. parapsilosis*, including noncancer patients from a multicenter database, were less likely to be neutropenic and immunosuppressed, perhaps explaining the lower mortality rate.[36] *C. krusei* has been associated with prior antifungal use, hematologic malignancy (including stem cell transplant), neutropenia, and corticosteroid use.[36]

Disseminated Candidiasis

Disseminated candidiasis is difficult to differentiate from other disseminated fungal and bacterial infections. Persistent fever in the setting of antibacterial therapy with associated liver dysfunction may suggest consideration of disseminated candidiasis.[36] In patients with cancer, disseminated candidiasis typically originates from the GI tract or CVCs. Dissemination can affect multiple organs, such as the kidneys, heart, GI tract, lung, liver, spleen, and skin.[37] This syndrome typically affects patients with prolonged immunosuppression, with predisposition for liver and spleen leading to the characterization as hepatosplenic candidiasis. *C. tropicalis* is more likely to cause the characteristic skin lesions associated with disseminated candidiasis and occasionally causes a syndrome of skin lesions and painful myositis.[38] Lesions may appear as clusters of pustules or larger nodules and may even develop necrotic centers similar to ecthyma gangrenosum.[39] The common presentation is nontender, firm, nonblanching, raised nodules that are pink to red in color (Fig. 59–3). The variety of syndromes associated with candidiasis is diverse, overlapping with syndromes associated with other fungal, as well as bacterial and viral etiologies. This diversity of presentations emphasizes the importance of approaches to diagnosis of invasive candidiasis.

Diagnosis

When *Candida* infection is suspected, appropriate samples of blood and other available tissues need to be obtained and processed to identify the organism. Identification should be to the *Candida* species level, given the relevance of species in management. Culture-based techniques continue to provide the foundation for the laboratory identification of candidiasis, although 40% of patients with widespread infection demonstrated at autopsy examination had multiple negative blood cultures.[37] The diagnosis of disseminated candidiasis

FIGURE 59–3 Widespread nodular skin lesions in a patient with disseminated candidiasis.

may also be difficult to establish because culture of the organism from nonsterile sites, such as sputum, urine, and feces, may be positive in patients without infection. Identification of *Candida* spp. in respiratory samples is common but of unclear significance. A recent study showed that there was an association between colonization with *Candida* spp. in a cohort of HSCT patients and increased mortality, but treatment with antifungals did not have an impact on mortality.[40] Nonculture diagnostic approaches include β-D-glucan,[41] mannan antigen with antimannan antibody,[42] *Candida* PCR, and T2Candida.[43] These US Food and Drug Administration–approved tools for identification of candidemia have sensitivities that range from 58% to 91% and specificities that range from 80% to 98%.[44] The gold standard, however, remains culture.[28] Notably, blood cultures typically demonstrate *Candida* spp. within 72 to 96 hours, but *C. glabrata* requires longer incubation.[33] Given the challenge of appropriate diagnosis and morbidity associated with failure to treat the severely immunocompromised, empiric therapy for invasive candidiasis is commonly given for those who continue to be ill in the setting of broad-spectrum antibacterial therapy.

Therapy

Therapy for patients with candidiasis includes three classes of medications: azoles (eg, fluconazole, voriconazole), echinocandins (eg, caspofungin), and the polyenes (eg, amphotericin B).[28] Dosing regimens, major toxicities, and general considerations for antifungal agents are shown in Tables 59–1 to 59–3. Timely appropriate therapy, within 24 hours, is necessary because the mortality rate for candidemia ranges from 24% for *C. parapsilosis* to as high as 53% for *C. krusei*.[36] *C. glabrata* exhibits decreased susceptibility to fluconazole.[33] The mortality rate, however, is not significantly different from *C. albicans* candidemia.[33] *C. krusei*, inherently resistant to fluconazole, is increasingly isolated in institutions where fluconazole is commonly used for prophylaxis.[45] *C. lusitaniae*, more commonly seen in patients with stem cell transplant or neutropenia, is of concern because of amphotericin B resistance.[46]

TABLE 59–1 Dosage Regimens for Serious Fungal Infections

Drug	Loading Dose	Daily Dose	Route
D-AMB	—	1–1.5 mg/kg	IV only
Lipid AMB	—	3–5 mg/kg	IV only
Fluconazole	800 mg (12 mg/kg)	400–800 mg (6 mg/kg/day)	IV, PO
Isavuconazole	372 mg q 8 hours ϕορ two days	372 mg	IV, PO
Itraconazole IV	200 mg bid ϕορ two days	200 mg	IV
Itraconazole solution	200 mg bid ϕορ two days	200 mg	PO
Posaconazole tablets	300 mg bid ϕορ two doses	300 mg	PO
Posaconazole IV	300 mg bid ϕορ two doses	300 mg	IV
Posaconazole (suspension)	—	200 mg every 6h	PO
Voriconazole IV	6 mg/kg every 12 hours ϕορ two doses	4 mg/kg every 12 hours	IV
Voriconazole tablets	—	200 mg every 12 hours (>40 kg)	PO
		100 mg q 12 hours (<40 kg)	
Caspofungin	70 mg ϕορ one dose	50 mg	IV
Micafungin	—	150 mg	IV
Anidulafungin	200 mg ϕορ one dose	100 mg	IV

bid, twice a day; D-AMB, amphotericin B deoxycholate; IV, intravenous; PO, oral; q, every.

TABLE 59–2 Major Toxicities of Antifungal Agents

Amphotericin B	Infusion related (eg, headache, chills, hypotension), nephrotoxicity, hypokalemia, hypomagnesemia, anemia
Fluconazole	Nausea, vomiting, headache, hepatotoxicity (rare), drug interactions
Isavuconazole	Nausea, vomiting, diarrhea, headache, shortening of QT interval
Itraconazole	Nausea, vomiting, headache, hepatotoxicity (rare), pulmonary edema, drug interactions
Posaconazole	Hepatotoxicity (rarely requires discontinuation)
Voriconazole	Visual disturbances, rash, nausea, vomiting, headache, hepatotoxicity, drug interactions
Echinocandins (eg, caspofungin)	Fever, nausea, flushing, rash, some drug interactions, phlebitis

TABLE 59–3 Therapeutic Options for Disseminated and Major Organ Candidiasis

Regimen	Advantages	Disadvantages
D-AMB	Broad-spectrum activity	Acute chronic toxicities; minimally effective in patients with neutropenia and with chronic disseminated candidiasis; IV preparations only
Lipid formulations of AMB	Broad-spectrum activity, reduced nephrotoxicity; higher doses can be administered	Only prospective randomized trial showed no advantage in efficacy over D-AMB despite higher doses; more expensive; IV preparations only
Fluconazole	PO and IV preparation; as effective as AMB in randomized trials of nonneutropenic individuals; minimal toxicity; more effective for chronic disseminated candidiasis; little experience in neutropenic patients but appears to be as effective as AMB	Variable activity against *Candida glabrata* and *Candida dubliniensis*; inactive against *Candida krusei*; some drug–drug interactions
Voriconazole	PO and IV preparation; may be used for stepdown oral therapy; provides antimold activity for at-risk patients; excellent ocular and CNS penetration	QT prolongation, ocular toxicity, drug–drug interactions
Echinocandins (eg, caspofungin)	Broad-spectrum activity; minimal toxicity; in randomized trials, as active as AMB and fluconazole; limited experience in neutropenic patients	No oral preparation
Flucytosine	Synergistic with AMB and fluconazole; combination of flucytosine and AMB may be superior to AMB alone for chronic disseminated candidiasis and *Candida tropicalis* infection	No IV preparation; causes myelosuppression; often need monitoring of serum concentrations; emergence of resistance if used alone

AMB, amphotericin B; CNS, central nervous system; IV, intravenous; PO, oral.

Recently published guidelines suggest that echinocandins be used as first-line therapy in neutropenic patients with candidemia, with lipid formulations of amphotericin B as second-line therapy.[28] Species-specific recommendations, however, are provided, given inherent differences in resistance. The guidelines emphasize that if a therapeutic approach is resulting in clinical improvement, then current therapy can be continued. For treatment of *C. glabrata* infection, an echinocandin or lipid formulation of amphotericin B is recommended.[28] For infection with *C. parapsilosis*, an azole or lipid formulation of amphotericin B is recommended. For *C. krusei*, fluconazole is contraindicated because of innate resistance.[28] For neutropenic patients with invasive candidiasis, echinocandins are now first-line therapy, with lipid formulations of amphotericin B an alternative but avoided because of the potential for toxicity, especially renal. Voriconazole is recommended in patients who also require mold coverage or as stepdown therapy in treatment of susceptible isolates.[28] In candidemia and invasive candidiasis, fluconazole may be used in patients who have no prior exposure to azoles and are not critically ill.[28] If fluconazole is used, the initial recommended dose is 12 mg/kg followed by 6 mg/kg/day to avoid inadequate doses (see Table 59–1). Notable is that isavuconazole,

the newest azole, with antimold activity, is not recommended for management of candidemia. It was recently shown in a clinical trial to be inferior to an echinocandin (caspofungin) in the treatment of patients with invasive candidiasis.[47]

Caspofungin was the first Food and Drug Administration (FDA)–approved echinocandin, showing broad-spectrum activity against *Candida* spp. In comparison with amphotericin B deoxycholate (D-AMB) in a study of invasive candidiasis (80% of which was candidemia), caspofungin showed similar outcomes with fewer adverse events.[28] Of note, however, few patients were neutropenic in this study. There are three currently available echinocandins: caspofungin, micafungin, and anidulafungin. They are comparable in their efficacy, although only one study in nononcologic candidemia patients directly compared micafungin and caspofungin and showed equivalent outcomes.[48]

Management of candidemia involves several important points, included in the recent guidelines. These include identification of the species causing candidemia, use of echinocandins as first-line therapy, daily blood cultures until negative, 14-day duration of appropriate therapy after negative blood culture results, echocardiography to assess for valvular vegetation, funduscopic eye examination for endophthalmitis, and stepdown from IV therapy to oral therapy with fluconazole, depending on clinical picture and susceptibility of species isolated.[49] An additional recommendation is to remove CVCs, which are further discussed later, given the challenge of removal in select patient populations.[49]

Patients with cancer with indwelling intravascular catheters typically require them for chemotherapy or supportive care. The removal of surgically implanted catheters is particularly difficult, given thrombocytopenia is often present in the oncologic patient population. Studies suggest a role for catheter removal, particularly if it is clear that the catheter is the source, or in the setting of persistent candidemia without other source. Removal of the catheter may improve response rates to treatment and reduce duration of candidemia.[28] Infection with *C. parapsilosis*, in particular, is associated with persistent candidemia without catheter removal.[28]

Given the complexity of diagnostic, pharmacologic, and non-pharmacologic interventions to optimize mortality in invasive candidiasis, several studies have explored the utility of routine infectious disease consultations for management of candidemia.[50–52] A study conducted in a tertiary hospital examined the impact of infectious disease consultation on mortality rate using propensity analysis to match underlying comorbidities. The study found that infectious disease consultation resulted in longer median duration of antifungal use and more frequent use of eye examination and echocardiography.[53] Implementation of infectious disease consultation resulted in a significantly lower 90-day mortality rate (29% vs 51%). In the group without infectious disease consultation, 14% of patients were not treated for candidemia. This group considered candidemia a "contaminant" in 10% of cases. Notably, this study included patients with solid (33%–36%) and hematologic (14%–20%) malignancy. These findings emphasize that adherence to guidelines-based therapy improves outcomes, with potential benefit for involvement of infectious disease specialists in management of candidemia.

In summary, *Candida* spp. cause a wide spectrum of syndromes from superficial oral candidiasis to candidemia in patients with cancer. The therapeutic approach should take into consideration host risk factors, medication interactions, antifungal toxicities, and comorbidities when selecting an approach to diagnosis and development of treatment plan. As with other syndromes, a systematic approach using "bundles" of care has been proposed as an approach to improving diagnosis and management of patients with invasive candidiasis.

ASPERGILLOSIS

One of the most common and important IFIs is aspergillosis. *Aspergillus* spp. are the most common invasive mold infections in patients with hematologic cancer.[54] *Aspergillus fumigatus* is the species most commonly associated with infection, although *Aspergillus terreus* and *Aspergillus flavus,* more resistant *Aspergillus* spp., are becoming increasingly common.[54] Infections are typically acquired by spore inhalation, but construction in hospitals and surrounding areas have been associated with infection.[55] The most important risk factor is prolonged neutropenia.[54] In stem cell transplant patients, reported risk factors for increased mortality include poor baseline pulmonary status, high doses of corticosteroids (≥2 mg/kg/day), disseminated aspergillosis, proven IA, increased bilirubin, increased creatinine, human leukocyte antigen–mismatched stem cells, and IA occurring 40 or more days after transplant.[56] Recent pandemics have also identified respiratory viral infections, such as influenza, as a risk factor for invasive pulmonary aspergillosis (IPA). Initially seen with H1N1 pandemic but subsequently noted in other influenza seasons, of those with IPA during influenza infection, a multicenter cohort study showed that 19% of patients admitted to an intensive care unit (ICU) with influenza infection were diagnosed with IPA compared with 5% of those without influenza infection. Risk factors for IPA in the multicenter cohort included male gender, corticosteroid exposure, and influenza but not hematologic malignancy.[57] The viral etiology of the most

recent pandemic, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has also been associated with IPA, although there are ongoing efforts to carefully define postviral IPA, particularly in hosts without other significant risk factors.[58]

Pulmonary Infection

The most common syndrome associated with aspergillosis is pneumonia. Because of the angioinvasive nature of the infection, symptoms suggesting pulmonary involvement are pulmonary embolism, pleuritic chest pain, fever, hemoptysis, and friction rub.[59] Initial chest x-ray examination may initially be unremarkable with fever proceeding in the setting of broad-spectrum antibacterials.[59]

Radiologic findings are variable, with wedge-shaped infarcts, necrotizing bronchopneumonia, lobar consolidation, or diffuse infiltrates noted.[59] If suspicion is high for infection, early CT scan of the thorax is essential, potentially demonstrating a halo sign (area of low attenuation surrounding a nodular infiltrate), an important early sign that disappears in 75% of cases within the first week[59] (Fig. 59–4). Analysis of radiologic studies from a clinical trial suggested that patients with the halo sign had an improved response to treatment and an improved mortality rate compared with those who did not exhibit the halo sign.[60] Cavitation occurs as the infection progresses, with lesions often increasing in size until neutrophil recovery occurs. Differentiation from other molds such as mucormycosis can be difficult. A study suggested that CT scans of the thorax with more than 10 nodules and pleural effusion are more often seen in pulmonary mucormycosis rather than IPA.[60]

FIGURE 59–4 Computed tomography scan showing nodular lesions in lung of patient on high-dose adrenal corticosteroid therapy who developed sudden onset of pleuritic chest pain and a pleural friction rub caused by pulmonary aspergillosis. The chest radiograph was normal.

Sinusitis

Immunocompromised patients may exhibit acute sinusitis as a component of invasive diseases, occurring in 15% to 20% of neutropenic patients.[61] Fever, headache, cough, epistaxis, and sinus discharge are signs and nonspecific symptoms suggestive of fungal sinusitis.[61] On examination, necrotic lesions may be seen in the nose or palate, with accurate diagnosis improved by examination and confirmed by biopsy by experienced otolaryngologists.[62] Imaging of the sinuses by CT or MRI scan may show opacification of the sinuses or bony destruction. The mortality rate may be as high as 20% in patients with leukemia in remission to 100% for those with invasive sinusitis who have refractory leukemia or undergoing HSCT.[61]

Skin Infection

Aspergillosis as part of dissemination is discussed later, although primary cutaneous infection occurs with direct inoculation. These infection are rarely associated with central venous access device.[63] Mechanism of spread is presumed to be via inoculation during catheter insertion or possibly dressing changes or application. Initially, lesions may appear as erythematous plaques, progressing to necrotic ulcers with black eschars.[63] *A. flavus* is the most common cause of cutaneous IA.

Disseminated Infection

Given the angioinvasive nature of aspergillosis, hematogenous dissemination occurs in approximately 20% of patients with active hematologic malignancy or HSCT.[64] Common sites of dissemination include the CNS, GI tract, and skin. GI involvement is apparent in 40% to 50% of cases, affecting the esophagus and large bowel.[65] Perforation or massive hemorrhage may occur in this setting. Skin infection may also occur, evolving from erythematous plaques to ulcers that ultimately may be covered by black eschar.[66] Given the broad differential diagnosis of skin lesions in this patient population, skin biopsy is critical.

Diagnosis

A continuing challenge in management of aspergillosis is early and reliable diagnosis.[59] Tissue biopsies from infected tissue may reveal invading hyphae. Paradoxically, cultures of the biopsy specimens fail to grow the fungus in more than 50% of cases. Histology correlates with culture in 78% of cases.[67] Similarly, blood cultures will rarely (except in the case of *A. terreus*) demonstrate the organism, in contrast to fusariosis.[68] Unfortunately, *Aspergillus* spp. also fail to grow well from sputum

or bronchoscopy, with only 30% of biopsy-proven aspergillosis cases growing mold in sputum cultures.[69] In BAL specimens, cytology may show evidence of pulmonary aspergillosis in up to 42% of culture positive cases, using Gomori-methenamine-silver stain, as opposed to calcofluor white stain.[70] The yield of bronchoscopy is improved by performing this procedure as early as possible after identification of abnormalities on chest imaging. Among stem transplant patients, the yield ranges from 72% to 78% with early bronchoscopy (<4 days) compared with 22% to 28% with late bronchoscopy (≥5 days), with consequent impact on mortality.[71] Because of these challenges of diagnosis, patients commonly receive preemptive antifungal therapy for presumed fungal pneumonia while undergoing workup.

To further increase the likelihood of detection of pulmonary aspergillosis, various non–culture-based tests have been developed. Galactomannan and 1,3-β-D-glucan are the most commonly used tests.[44,61] A sandwich enzyme-linked immunosorbent assay used to detect the polysaccharide cell wall component of *Aspergillus* spp., galactomannan can be detected in the serum and BAL fluid of infected patients.[59] The most recent guidelines from the Infectious Diseases Society of America (IDSA) suggest performing bronchoscopy, when feasible, with routine galactomannan on serum and BAL specimens.[61] Sensitivity of serum galactomannan ranges from 60% to 80% and specificity from 80% to 95%,[72] but the test has been studied primarily in hematologic malignancy patients with profound neutropenia. The positive predictive value of this test is poor in patients with solid tumors and other cancers.[59] In BAL specimens, galactomannan shows 85% to 90% sensitivity and 90% to 95% specificity.[72] A recent study of BAL specimens compared performance of galactomannan and a novel lateral-flow device test.[73] The study found that specificity of lateral flow was significantly better than galactomannan, particularly among patients without hematologic malignancy. Among solid tumor patients, for example, specificity was 16% for galactomannan compared with 100% for the lateral-flow device.[73] An additional challenge occurs in interpreting a galactomannan in context of prophylaxis with antimold activity. A recent study suggested a false-positive rate up to 86% for those on active antimold therapy.[74] In fact, the most recent guidelines from the IDSA do not recommend routine screening of blood for galactomannan in patients who are on mold-active antifungal prophylaxis or treatment.[61]

1,3-β-D-Glucan is an integral component of the cell-wall of several yeasts and fungi.[59] The serum assay for 1,3-β-D-glucan has cross-reactivity with other molds but may be used to detect IA.[61,72] Sensitivity ranges from 67% to 80% and specificity of 80-% to 95%, but false positives are noted because of cirrhosis, hemodialysis, and some chemotherapeutic agents.[59,72] Blood-based *Aspergillus* PCR tests are available but include various methodologies and are not FDA approved, so care is recommended in using PCR alone to diagnose IA.[44,61] Appropriate selection of patients with risk factors for IA, for example, with hematologic malignancy and HSCT, will increase the positive predictive value of serum galactomannan and 1,3-β-D-glucan, improving the utility of these tests (see Fig. 59–1).

Therapy

Early diagnosis of aspergillosis using the various available tools has allowed for earlier treatment, but challenges continue in assessing the impact of various treatments, given categorization of infection as proven, probable, or possible.[62] Table 59–4 describes various principles for management of aspergillosis. Persistence of neutropenia is a host factor that is critical in determining the outcome of infection, regardless of therapy.[75] In fact, in a study comparing voriconazole and isavuconazole, the 6-week mortality rate was approximately 45% in both treated groups with persistent neutropenia.[75]

Voriconazole is currently recommended as first-line therapy for patients with IPA.[61] A randomized trial comparing voriconazole with D-AMB for patients with definite or probable aspergillosis showed a decreased mortality rate in the voriconazole group (71% vs 58%). Both oral and IV formulations are available, with decreased nephrotoxicity compared with amphotericin B. Voriconazole does, however, cause visual disturbances, hallucinations, and liver dysfunction in a subset of patients.

Posaconazole was previously only available as an oral solution. Posaconazole tablets are now available, with considerably improved absorption, with minimal impact from food, mucositis, or elevated gastric pH.[76] Despite resultant elevated liver function test results caused by dramatically increased posaconazole levels

TABLE 59–4 Principles of Therapy for Aspergillosis

Early, aggressive treatment with high doses of voriconazole, isavuconazole, or a lipid formulation of D-AMB
Rapid tapering of dose of adrenal corticosteroids if possible
Consideration for G-CSF–primed granulocyte transfusions in select cases
Long-term antifungal therapy, which should be individualized based on response
Debridement of necrotic tissue of localized disease (onychomycosis, sinusitis, abscess)

D-AMB, amphotericin B deoxycholate; G-CSF, granulocyte colony-stimulating factor.

in tablet form, no clinically significant hepatotoxicity occurred.[76] In a retrospective, monocentric study, posaconazole given as salvage therapy was associated with increased response to therapy and decreased mortality rate compared with liposomal amphotericin B (L-AMB) with or without caspofungin.[77] In addition, nephrotoxicity and change in liver function test results were more likely in the L-AMB–containing regimens.

Isavuconazole, the most recent FDA-approved azole approved for treatment of IA, is available in oral and IV formulations.[78] This antifungal is approved for treatment of IA and mucormycosis. The oral and IV formulations are well tolerated, with fewer drug–drug interactions than other azoles, such as voriconazole. The QTc is shortened, rather than prolonged, by this agent. Unfortunately, however, a recent study of breakthrough IFIs in hematologic malignancy and HSCT patients showed a 10.2% rate of breakthrough IFI in those on isavuconazole prophylaxis.[79] In addition, IPA complicated 6.8% of courses of prophylaxis with isavuconazole, compared with 1.3% of posaconazole and 0% of voriconazole courses.[79] Although adding another azole to the armamentarium of antifungals against IA is helpful, clinicians need to remain vigilant of IFIs that may develop while patients are taking even the newest antifungals.

Lipid formulations of amphotericin B are now recommended in lieu of amphotericin B deoxycholate, given the decreased risk of nephrotoxicity. In a randomized study of early treatment of aspergillosis, in neutropenic patients, dosages of 10 mg/kg/day were compared with 3 mg/kg/day with comparable outcomes (46% high dose vs 50% low dose), but the higher dosage resulted in greater nephrotoxicity (32% vs 20%).[61]

Echinocandins inhibit the synthesis of β-(1,3)-D-glucan, an essential component of the fungal cell wall. A disadvantage of echinocandins is that they are available only as an IV preparation.[61] In a noncomparative trial of 90 patients with definite or probable aspergillosis who had failed other therapy, a complete or partial response occurred in 45%.[80] Responses were observed in 50% of patients with pulmonary infection but in only 26% of those with neutropenia.[80]

Treatment of IA is challenging, particularly in the setting of prolonged neutropenia. This has led to the use of combination therapy. A recent randomized, placebo-controlled trial of HSCT recipients and patients with hematologic malignancy of voriconazole combined with placebo or anidulafungin failed to demonstrate a difference in overall or 6-week mortality rate.[81] In a subgroup with radiographic findings consistent with IA and elevated serum galactomannan, the mortality rate was significantly higher in the monotherapy group (15.7% vs 27.3%; $P = .037$).[81]Antifungal agents used for prophylaxis against aspergillosis in high-risk patients have included posaconazole, itraconazole, voriconazole, aerosolized or nebulized formulations of amphotericin B, and micafungin.[54,61] Posaconazole is the only agent currently FDA approved for the indication of prevention of IA in patients with acute leukemia and high-risk stem cell transplant recipients, but significant expense continues to limit the utility of this agent.[80]

The diagnosis and selection of the appropriate antifungal form the foundation of management in IA. An often-overlooked aspect is the appropriate follow-up of patients with IA. IDSA guidelines recommend therapeutic drug monitoring to assure appropriate levels to address infection.[61] In addition, guidelines suggest that serum galactomannan (GM) should be measured periodically (eg, weekly) in patients with baseline elevated serum GM, given correlation with response.[61] Data do not suggest serum β-D-glucan can be monitored in the same way, to demonstrate treatment response. Efforts are ongoing to establish systematic approaches to assessment of radiologic response to treatment of IA.

In summary, IA includes a variety of syndromes, from isolated sinusitis, to pneumonia, to disseminated infection. Key elements of management begin with assessment of risk factors for IA, leading to diagnostic imaging (chest, head, or both if there is evidence of sinusitis); serum GM, serum β-D-glucan, or both; and timely bronchoscopy with cultures and GM from BAL fluid (if pneumonia is present)[44,61] (see Table 59–4). If the diagnosis is established, then there should be careful selection of appropriate antifungals; examining drug–drug interactions, with assessment of drug levels to assure adequacy; discontinuation of unnecessary immunosuppressive medications; and finally appropriate follow-up imaging and biomarkers (eg, serum GM) to monitor the course of IA[44,61] (see Table 59–4).

CRYPTOCOCCOSIS

Cryptococci are encapsulated yeasts that have a worldwide distribution, with a dramatic increase in incidence corresponding with the HIV/AIDS.[82] *Cryptococcus neoformans* is the most common pathogen, found in the pigeon excretions, with infection acquired by inhalation into the lungs. Patients with HIV/AIDS had the highest incidence of infection before the initiation of highly active antiretroviral therapy.[82] Factors associated with cryptococcosis in patients with cancer include lymphopenia, chemotherapy, and corticosteroid use less than 1 month before diagnosis.[83] Those at particular risk include those with lymphoma or CLL. In addition, as mentioned earlier in the chapter, the use of ibrutinib and other kinase inhibitors for treatment of CLL, mantle cell lymphoma, and primary CNS lymphoma has been shown to increase risk for IFI,

including cryptococcosis, histoplasmosis, IA, and PJP.[14] Risk in patients with hematologic malignancy remains generally low because of widespread use of fluconazole and other agents for antifungal prophylaxis.

Pneumonia

Given inhalation as the mechanism of entry, the lungs typically serve as the primary sites of infection. However, fewer than 40% of patients present with symptoms suggestive of pneumonia.[82] Symptoms may, however, include chest pain, fever, or dyspnea. Chest radiographic findings may include single or multiple nodules, airspace consolidation, reticular patterns, ground-glass opacities, cavitary lesions, and occasionally pleural effusions, with all findings unilateral or bilateral.[82] Cryptococcal pneumonia can rapidly progress, resulting in higher mortality rates in patients with cancer. For susceptible patients, finding of this organism in a patient with chest radiography and symptoms consistent with infection is sufficient indication for therapy. In a series from a cancer center, fine-needle aspiration, BAL, and open lung biopsy had a yield of more than 90% on culture.[83]

Central Nervous System Infection

Many series showed a predominance of CNS infection in patients with cancer, primarily with meningoencephalitis, but rarely with meningitis alone or with cryptococcoma. Depending on degree of immunosuppression, patients may exhibit an indolent course with initial symptoms of fever and headache.[82] As the disease progresses, symptoms may include nausea, vomiting, dizziness, somnolence, irritability, confusion, photophobia, or obtundation. Absence of nuchal rigidity (a finding exhibited in only 15% of patients), does not rule out infection.[82] Patients infected with *Cryptococcus gattii* can include those with no apparent immunosuppression, but with high predilection for CNS involvement.[82] In patients with CNS disease, findings include elevated opening pressure, decreased glucose, and high protein concentration. Leukocyte count may also be elevated, with lymphocyte predominance.[83] Available diagnostic tests include India ink, serum cryptococcal antigen, and fungal culture. India ink detects 50% of infections, whereas serum cryptococcal antigen is positive in 90% of cerebrospinal fluid (CSF) and 70% of blood in patients with CNS infection.

Disseminated Infection

Multiple organs, including the liver, prostate, eyes, skin, and bone, may serve as sites of dissemination. Serum cryptococcal antigen has greater than 90% sensitivity and specificity for invasive cryptococcal disease.[82] Skin lesions, present in only approximately 10% of patients, tend to be painless and located on the face, neck, and scalp.[82] The lesions may appear as papules, plaques, ulcerations, acneiform lesions, or even draining sinuses. With wide use of azole-based antifungal prophylaxis, skin, soft tissue, and osteoarticular lesions appear to be less common.[82]

Therapy

Treatment of patients with cryptococcal disease depends largely on the site of infection. D-AMB combined with flucytosine is the traditional approach of choice for severe pulmonary cryptococcosis and CNS disease in non-HIV-infected immunocompromised patients as induction therapy.[82] Flucytosine is available only as an oral preparation with myelosuppressive toxicity (see Tables 59–1 and 59–2). The recommended dosage is D-AMB 0.7 to 1.0 mg/kg/day plus flucytosine 100 mg/kg/day for 2 week, as induction therapy, consolidation with fluconazole 400 to 800 mg/day for 8 weeks, and then 200 mg/day maintenance therapy for 6 to 12 months.[82] In mild to moderate cases of pulmonary disease, fluconazole 400 mg/day alone may be given for 6 to 12 months.[82] Of note, synergy has been noted between some antifungal agents and calcineurin inhibitors, associated with improved outcomes for solid-organ transplant patients,[84] potentially of relevance in HSCT recipients (although not established).

Management of cryptococcal meningitis requires monitoring of CSF pressure and appropriate measures if elevated pressures (>25 cm) are noted to prevent complications and reduce mortality rates.[82] Complications of elevated intracranial pressures (>25 cm) include papilledema, hearing loss, vision loss, severe headache, and cognitive impairment. Therefore, management is aggressive, including daily lumbar punctures, if the CSF pressure remains greater than 25 cm. If necessary, a temporary lumbar drainage or ventriculostomy catheter may be placed, although permanent ventricular shunt placement should be avoided unless all other measures have failed.[82] Timely intervention is necessary to prevent irreversible neurologic complications and death.

Given the complexity of treatment and toxicity of the treatment regimens, involvement of infectious disease consultants has shown a benefit in mortality, similar to findings in invasive candidiasis.[85] Patients with an infectious disease consult were more likely to undergo lumbar puncture and receive treatment with amphotericin B and 5-Flucytosine (when appropriate) and had a significantly lower mortality rate at 90 days (27% vs 45%; P <.001). Cryptococcal infections may cause significant complications and death if not considered early and treated. This has become particularly important because innovative new treatments for cancer, such as ibrutinib and other kinase inhibitors, modulate the immune response in unpredictable way, leading to IFIs, such as cryptococcosis.

FUSARIOSIS

Humans are exposed to various *Fusarium* spp. found in the air and soil. Syndromes include superficial (cutaneous, keratitis, onychomycosis), locally invasive, and disseminated infection. The most common species that cause human disease are isolates belonging to the *Fusarium solani* complex (~50% of cases), but others include *Fusarium moniliforme, Fusarium oxysporum,* and *Fusarium dimerum*.[86] Entry points for infection by *Fusarium* spores are typically the skin, onychomycosis, and respiratory tract. Risk factors for invasive fusariosis among patients with hematologic malignancy include uncontrolled hematologic cancer (71%), stem cell transplant (47%), and neutropenia (82%).[86] The mortality rate was highest in patients with fungemia in one retrospective study, with an abysmal 6% survival rate at 12 weeks.[86] The all-cause mortality rate was 66% but with 50% attributable to fusariosis.

Sinus infection and pneumonia occur in 80% of patients, and blood culture results are positive in 50% to 70% of cases.[87] In neutropenic patients, dissemination occurs 75% of the time and is characterized by multiple skin lesions.[88] Skin lesions may appear as red or gray macules, pustules, or classically papules with central necrosis or eschar (Fig. 59–5). Lesions may also appear to be different types of lesions at different stages of evolution.[88] Myalgias or subcutaneous lesions can also be noted in disseminated fusariosis. In non-neutropenic patients with less severe immunocompromise, infection may be relatively localized, with paronychia, erythematous nodules, hemorrhagic bullae, or trauma-associated tender, necrotic lesions.[87]

Therapy

The significance of in vitro susceptibility results is unclear, with conflicting reports of species-specific susceptibility to amphotericin B in some series but others not demonstrating such an association. Azoles, particularly voriconazole and posaconazole, exhibit variable in vitro activity against different *Fusarium* spp.[87] Posaconazole and voriconazole have both been used as salvage therapy after initial monotherapy with high-dose lipid formulations of amphotericin B failed.[87] Combination therapy has been used with anecdotal success, but definitive evidence of effectiveness is lacking. Mortality remains in the 50% to 60% range, with new treatment options needed.[89] In neutropenic patients, however, neutrophil recovery is the critical component improving outcomes.[86]

FIGURE 59–5 Skin lesions in a patient with disseminated fusariosis.

MUCORMYCOSIS

Mucormycosis is an infection caused by molds of the order *Mucorales* present in the environment, acquired by inhalation of spores.[80] These molds, similar to *Aspergillus* spp., are angioinvasive, causing thrombosis and infarction. Macrophages and neutrophils are key components of the immune response to mucormycosis. Patients with acute leukemia, diabetic ketoacidosis, or iron overload; HSCT recipients; and patients treated with adrenal corticosteroids are at risk for mucormycosis.[80] Syndromes include rhinocerebral, pulmonary, GI, and cutaneous.[90] Whereas patients with hematologic malignancies tend to have pulmonary or disseminated disease, those with diabetes have predominantly sinus involvement.[91]

The overall mortality rate is 44%, but patients with cancer with definite or probably mucormycosis have a mortality rate of 71%.[80] Patients with neutropenia are more likely to have disseminated disease, which has a mortality rate greater than 90%.

Therapy

Amphotericin B, more recently in lipid formulations, has been the most commonly used approach to treatment for mucormycosis.[90,91] High doses of amphotericin B (5–10 mg/kg per day) can be provided with lipid formulations.[91] Other modalities that have been used include hyperbaric oxygen, surgical intervention, immunomodulatory therapy with granulocyte-macrophage colony-stimulating factor (GM-CSF) or interferon-γ (INF-γ), and granulocyte transfusions.[91] The addition of posaconazole typically occurs in transition to oral therapy but rarely may be used as a front-line agent if there is a contraindication to amphotericin B formulations or relatively mild, localized disease that has been surgically resected.[91] Isavuconazole, useful in IA, also has activity against *Mucorales* spp., providing an option for stepdown to oral therapy as well.[78] In addition to monotherapy with amphotericin B formulations, various combinations of antifungals, including echinocandins, are given with any or all of the these modalities.[91] A review of the common nonendemic fungi and associated syndromes is provided in Table 59–5.

TABLE 59–5 Major Fungal Infections and Syndromes

Organism	Infections/ Syndromes	Comments
Candida spp.	Thrush Esophageal candidiasis Urinary tract infection Candidemia Disseminated candidiasis	*Candida parapsilosis* can be resistant to echinocandins *Candida krusei* fluconazole resistant *Candida glabrata* can be fluconazole resistant
Aspergillus spp.	Pulmonary Sinusitis Skin infection Disseminated	Bronchoscopy or biopsy of nodules Head and neck surgery evaluation, debridement Biopsy skin; rare blood culture positive
Cryptococcus spp.	Pneumonia CNS Disseminated	Check serum *Cryptococcus Ag* Low threshold for lumbar puncture in immunocompromised patients
Fusarium spp.	Sinus infection Pneumonia Skin infection Dissemination	Bronchoscopy or biopsy of nodules Head and neck surgery evaluation, debridement Biopsy skin; blood culture positive
Mucormycosis	Rhinocerebral Pulmonary Gastrointestinal Cutaneous	Urgent debridement of rhinocerebral disease Bronchoscopy or biopsy of nodules Hyperbaric oxygen

Ag, antigen; CNS, central nervous system.

ENDEMIC FUNGI

The list of common endemic fungi that may infect patients with cancer in North America include *Coccidioides immitis* and *H. capsulatum*.[92] The distribution of these organisms is determined by climate and geography. These may infect patients without severe immunosuppression and may manifest as lung lesions that may even be confused with malignancy, such as lung cancer, or as disseminated disease.[92] In patients with hematologic malignancies with cellular immunity impaired by the disease process or by treatments including corticosteroids (eg, CLL) and more recently, ibrutinib and other kinase inhibitors, these infections may represent reactivation of latent infection.[92]

Histoplasmosis

Presentation of histoplasmosis is with pulmonary lesions in solid tumor patients but is predominantly with disseminated disease in patients with hematologic malignancies.[92] In the United States, histoplasmosis is most common in the Ohio and Mississippi River valleys. Hepatosplenomegaly and mucocutaneous ulcerations, particularly in the oral cavity, may be present.[92] Histoplasmosis is identified by culture from infected tissues, including respiratory samples and rarely the bloodstream on culture. Histoplasmosis antigen testing can be used to detect evidence of histoplasmosis in urine.[93] Guidelines suggest using liposomal AMB (3–5 mg/kg/day) for severe pulmonary or disseminated disease followed by itraconazole (200 mg twice daily for 2 days; then 200 mg/day).[93] For most infections requiring treatment, therapy is provided for 6 to 9 months.[93] Severely immunocompromised patients may require even more prolonged therapy. Successful therapy with voriconazole has been used for histoplasmosis.[94]

Coccidioidomycosis

C. immitis is reported to cause fever, hypoxemia, and diffuse pulmonary infiltrates in immunocompromised patients.[92] In the United States, coccidioidomycosis is endemic to west Texas, central California, southern New Mexico, and southern Arizona. Disseminated infection may involve the skin and bone. In patients with hematologic malignancy, results of serologic tests may be negative. As in most cases, specimens from the lung, CSF, or other tissue provide the best approach for diagnosis.[95] The most recent guidelines recommend therapy for severe pulmonary or severe disseminated infection with an amphotericin B formulation, D-AMB (0.7–1.0 mg/kg/day) or L-AMB (3–5 mg/kg/day).[96] For meningitis, guidelines recommend fluconazole (400–800 mg/day), initially with increase in fluconazole dose and then with IV amphotericin B formulations if failing to response to therapy.[95,96] Suppression with fluconazole is recommended to be lifelong after coccidioidal meningitis. Voriconazole and posaconazole are additional options available for treatment failure with other agents.[96] In addition, recent guidelines emphasize the role of surgical resection in cases of cavitary lung infection not responsive to therapy.[96] After starting aggressive therapy for most symptomatic syndromes on presentation, fluconazole (400 mg/day) or itraconazole (400 mg/day) is continued for at least 1 year for most cases and indefinitely for immunocompromised patients.[95,96] Lifelong therapy with fluconazole or voriconazole, which penetrate the CNS, is recommended for those with meningitis.[95]

ADJUVANT THERAPY FOR FUNGAL INFECTIONS

White Blood Cell Transfusions

Recovery of neutropenia is essential to recovery from IFI. Almost five decades ago, transfusions of leukocytes

were first used to assist neutropenic patients in recovery. Some studies have suggested that this approach could be effective in management of IFI, but doubts remain. Issues include the challenge of the dose of cells and the length of time when they remain active.[97] Administration of granulocyte colony-stimulating factor (G-CSF) has allowed healthy volunteers to provide adequate numbers of cells.[97] The effectiveness of this approach may be as a bridge to recovery of bone marrow. Finally, clinical issues with granulocyte transfusions include an initial worsening of respiratory symptoms, although skin and soft tissue infections appear to improve.

Cytokines

Proinflammatory cytokines, exemplified by IFN-γ, tumor necrosis factor α, and interleukin-2, are produced by Th1 lymphocytes, activating effector immune cells.[98] Treatment with IFN-γ, sometimes in combination with GM-CSF, has been used to stimulate immune response to fungal infections.[98] IFN-γ enhances hyphal damage to fungal pathogens by neutrophils and monocytes.[98] The duration and depth of neutropenia can be decreased by use of colony-stimulating factors, including G-CSF (filgrastim) and GM-CSF (sargramostim, molgramostim).[80] GM-CSF may be of particular use because it not only increases number of granulocytes but also improves function of macrophages and granulocytes.[98] Case reports and case series have suggested potential benefit of several of these adjunct therapies, although data are not adequate to make firm recommendations for use of these immunomodulators.

Surgical Resection

Surgical resection is a valuable adjunct to therapy for IFI. A recent study describes patients undergoing resection as a component of therapy for a broad array of fungal infections from 1984 through 2009.[99] Patients with hematologic malignancy and suspected pulmonary IFI on appropriate systemic antifungal therapy underwent resection in select circumstances. These included progression of fungal infection despite therapy, importantly with neutropenia not considered a contraindication. If needed, platelets were transfused over 50 × 10^9/L. After surgery, nearly 90% of patients underwent further chemotherapy or stem cell transplant, with mortality rates of 7% and 48% at 30 days and 1 year, respectively.[99] Fungal organisms isolated were predominantly *Aspergillus* spp. (88%) and *Mucorales* spp. (8%). Over the time of the retrospective study, the surgical procedures became less invasive, shifting from lobectomy and open limited resections to video-assisted thoracoscopic procedures.[99] Therefore, surgical resection, via open or video-assisted thoracoscopy, presents a viable option for management of focal fungal infection that fails to respond to antifungal therapy alone, even in patients with hematologic malignancies.

SUMMARY

Fungi are ubiquitous in nature, often forgotten with the focus on bacterial and viral organisms. The fungi known to complicate cancer treatment, including aspergillosis, invasive candidiasis, pneumocystis, and mucormycosis, are associated with the largest economic burden.[1] Fungal infections remain significant causes of morbidity and mortality in patients with cancer. Increasing use of immunomodulatory agents with unknown effect on immune response to infection and aggressive cancer treatment of sicker patients with multiple comorbidities have led to increasing concern for infectious complications of cancer treatment. The identification, careful workup of complications, and management of patients with fungal infections will play a central role in improving outcomes of cancer treatment.

MD ANDERSON PRACTICE TIPS

- If patients remain febrile on broad-spectrum antibacterial therapy with negative bacterial culture results, consider IFIs.
- Perform thorough physical examination to find skin nodules, oral lesions, nuchal rigidity, genital lesions, or other findings that may suggest fungal infection, such as skin lesion suggesting disseminated candidiasis, nuchal rigidity suggesting cryptococcal meningitis, or an oral ulcer suggesting histoplasmosis.
- If obtaining a biopsy of a lung or skin nodule or other suspicious lesion, send for fungal culture in addition to pathology.
- Perform early bronchoscopy and send samples for cytopathology, fungal cultures, and galactomannan, which can detect possible IA or other IFI.
- In patients with cancer, particularly in the ICU, dose antifungals aggressively with therapeutic drug monitoring to avoid inadequate drug levels in this population.
- Assess for infected devices or lines, other sites of disseminated infection, underlying immune defects, and degree of immunosuppression and use this information to guide the duration of antifungal therapy.

Endocrine and Metabolic Complications of Cancer Therapy

Rachael Hosein
Sara Bedrose
Rebecca Jeun
Jeena M. Varghese
Sonali N. Thosani

KEY CONCEPTS

- Immune checkpoint inhibitors have become mainstays of therapy for a broad range of cancers and can lead to a variety of endocrinopathies, including hypophysitis, thyroiditis, primary hypothyroidism, Graves disease, primary adrenal insufficiency, lipodystrophy, and autoimmune diabetes.
- A broad range of antineoplastic agents, including agents that target the phosphoinositide 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathway and tyrosine kinase inhibitors (TKIs), alter glucose homeostasis and can lead to hyperglycemia, which may require monitoring and treatment.
- Hormone-suppressive therapies, radiation treatments, chemotherapeutics, and corticosteroids can all lead to increased bone fragility, which may be ameliorated by antiresorptive agents such as bisphosphonates or denosumab.
- Patients who receive cranial or craniospinal radiation therapy are at risk for hypothalamic and pituitary dysfunction, and those who receive radiation to the head and neck or other sites close to the thyroid are at risk for hypothyroidism and thyroiditis.
- Cytotoxic chemotherapy and radiation therapy are common causes of hypogonadism and infertility in both male and female cancer survivors and should be discussed with patients before initiation of therapy.
- Childhood cancer survivors, especially those who received abdominal radiation or total-body irradiation, are at increased risk of diabetes mellitus and metabolic syndrome as long-term sequelae of cancer treatment and need continued follow-up and screening for these conditions in survivorship care.

In the past two decades, cancer research has rapidly advanced, spurred by the development of high-throughput technology and the maturation of genomic and proteomic research methods. These advances have resulted in treatments that have substantial effects on the outcomes of certain cancers.

Current cancer treatments include surgery, radiation, cytotoxic chemotherapy, hormonal therapy, targeted therapy, and immunotherapy. Adverse effects of antineoplastic agents on the endocrine system are caused by several different mechanisms and can range from a subtle laboratory abnormality with limited clinical significance to potentially lethal clinical syndromes. Antineoplastic agents are cytotoxic to endocrine cells and result in glandular dysfunction and can also interfere with the synthesis or postsynthesis processing of hormones at different levels (ie, transcription, translation, or posttranslation). An agent may inhibit or induce secretion of a hormone by interacting with receptors, perturbing intracellular second messenger metabolism, interfering with hormone delivery by changing carrier protein levels in serum, competing for binding on the carrier protein, or interacting with signal transduction pathways, which can alter hormonal action in the end organs.

Immune checkpoint inhibitors have become a cornerstone for the treatment of different advanced cancers. These drugs, represented mainly by monoclonal antibodies, anti–cytotoxic T-lymphocyte antigen 4 (CTLA-4), anti–programmed cell death protein 1 (PD-1) and anti–PD-1 ligand molecules (PD-L1 and L2), reactivate the immune system against tumor cells and trigger a myriad of autoimmune side effects, including several important endocrine side effects.

This chapter summarizes the endocrine complications of cancer therapy and discusses screening and surveillance of these complications in patients with cancer and survivors.

METABOLIC DISORDERS

Glucose Metabolism Disorders

Diabetes Mellitus

Serum glucose is under continuous complex regulation and affected by many processes, such as gut absorption, cellular uptake, gluconeogenesis, and glycogenolysis. Multiple hormones play important roles in overall glucose homeostasis, including insulin, glucagon, growth hormone (GH), cortisol, somatostatin, and incretins.

Glucocorticoids are used with many chemotherapy protocols and can have transient or permanent effects on glucose levels by increasing insulin resistance. They can unmask preexisting prediabetes or worsen glycemic control in patients with stable diabetes, sometimes leading to hyperglycemic emergencies such as diabetic ketoacidosis or nonketotic hyperosmolar coma. Most patients with hyperglycemia secondary to glucocorticoids, especially in high doses, require insulin therapy to achieve blood glucose control. Despite concerns for mitogenic effects of insulin, large-scale studies have shown that insulin therapy is safe in patients with cancer.[1,2] Traditional basal bolus insulin protocols for diabetes may cause hypoglycemia in the setting of glucocorticoid induced hyperglycemia[3] because patients typically require higher prandial insulin doses in the setting of high-dose steroids.[4] Neutral protamine Hagedorn insulin concurrently administered with prednisone was as effective as long-acting insulin at controlling blood glucose concentrations, had a lower risk of hypoglycemia, and required a lower total daily insulin dose.[5] Cost-effective and well-tolerated alternatives to insulin include metformin and dipeptidyl peptidase 4 (DPP-4) inhibitors.[6]

A number of antineoplastic agents, including signal transduction inhibitors, L-asparaginase, streptozocin, interferon-α (IFN-α), and immune checkpoint inhibitors, have also been associated with impaired glucose homeostasis and frank diabetes mellitus (Table 60–1).

Inhibition of the phosphoinositide 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathway results in peripheral insulin resistance, increased gluconeogenesis, and hepatic glycogenolysis.[7] Disruption of glucose homeostasis is considered an on-target effect of inhibition of this pathway. As such, hyperglycemia was a frequent adverse event in trials of the mTOR inhibitors everolimus and temsirolimus as well as the isoform specific PI3K inhibitors idelalisib and alpelisib.[1,2,8] Hyperglycemia was the most common grade 3 or 4 adverse event leading to dose reduction or discontinuation of the drug in phase 3 studies of alpelisib.[9–11]

The risk of developing hyperglycemia was about 20% in children with acute lymphoblastic leukemia treated with either pegylated *Escherichia coli* asparaginase or native asparaginase.[12] A combined insulin deficiency and insulin resistance syndrome is thought to occur, but the exact mechanism is unknown.[13] Long-term insulin therapy may not be needed in some cases of L-asparaginase–induced diabetes mellitus.[13] L-asparaginase-associated pancreatitis, with resultant islet cell destruction, can result in hyperglycemia and may necessitate insulin therapy.[14] Diabetic ketoacidosis has also been reported during L-asparaginase therapy. Another potential complication is hypoglycemia after cessation of L-asparaginase; thus, close monitoring of blood glucose is recommended.

Streptozocin is associated with a 6% to 60% incidence of glucose intolerance with most cases mild or moderate in severity and reversible upon discontinuation of the drug.[15]

IFN therapy has broad antiproliferative and immunomodulatory activity and was previously more widely used in conditions such as melanoma and chronic myelogenous leukemia (CML) but now has largely been supplanted by newer targeted therapies. Certain patients taking IFN may experience earlier development of type 1 diabetes with anti-islet autoantibodies detectable at onset.[16,17]

Several tyrosine kinase inhibitors (TKIs) are associated with alterations in glucose homeostasis. Nilotinib is the most frequently implicated, but hyperglycemia has been noted with pazopanib, sunitinib, and imatinib.[18] Improvement in glycemic control and even frank hypoglycemia have been noted with pazopanib and sunitinib.[18,19]

We recommend monitoring fasting serum glucose levels before initiating and during these therapies. Additionally, it might be helpful to determine the levels of anti-islet autoantibodies before starting IFN therapy in patients with family history of type 1 diabetes mellitus.[16]

Immune Checkpoint Inhibitors and Diabetes

Since the approval of ipilimumab by the Food and Drug Administration (FDA) in 2011 for the treatment of melanoma, immune checkpoint inhibitors have become an integral part of treatment regimens for a range of malignancies, including lung cancer, kidney cancer, bladder cancer, head and neck cancer, and Hodgkin lymphoma. These agents have multisystem complications, and endocrinopathies are the most common immune-related adverse events (irAEs). Of the immune-mediated endocrinopathies, the most common is immune-mediated thyroid disease, hypophysitis, and primary adrenal insufficiency. More recently, a form of type 1 diabetes mellitus has become apparent as a rare consequence of immune checkpoint inhibitor therapy. Immune-mediated thyroid, pituitary, and adrenal pathology are discussed later in this chapter.

TABLE 60–1 Antineoplastic Drugs That Cause Hyperglycemia

Therapy Type	Drug	Mechanism	Main Indications
PI3K/Akt/mTOR inhibitors	Everolimus	Inhibits mTOR	Advanced hormone receptor positive, HER2-negative breast cancer PNET of pancreatic origin Advanced renal cell carcinoma
	Temsirolimus	Inhibits mTOR	Advanced renal cell carcinoma
	Idelalisib	Inhibits PI3 kinase (delta isoform)	Relapsed CLL Relapsed follicular B-cell non-Hodgkin lymphoma Relapsed small lymphocytic lymphoma
	Alpelisib	Inhibits PI3 kinase (α isoform)	Advanced or metastatic breast cancer
Tyrosine kinase inhibitors	Nilotinib	Inhibits Bcr-Abl, c-KIT and PDGFRA	Ph+ CML
	Pazopanib	Inhibits VEGFR-2, Kit, and PDGFR-β	Advanced renal cell carcinoma Advanced soft tissue sarcoma
	Sunitinib	Inhibits VEGFR2, PDGFRB, c-KIT and FLT3	Advanced renal cell carcinoma GIST PNET
	Imatinib	Inhibits Bcr–Abl, c-KIT and PDGFRA	CML Chronic eosinophilic leukemia Ph+ ALL GIST
Cytotoxic enzyme	L-Asparaginase	Deamination and depletion of serum asparagine	ALL
Nitrosourea	Streptozocin	DNA alkylation and inhibits DNA synthesis	Metastatic islet cell carcinoma of pancreas
Cytokine	Interferon alfa	Broad range of immunoregulatory and antiproliferative effects	Melanoma Renal cell carcinoma CML
Somatostatin analogs	Octreotide Lanreotide Pasireotide	Bind somatostatin receptors to inhibit peptide secretion	Unresectable, locally advanced or metastatic gastroenteropancreatic-neuroendocrine tumors
Histone deacetylase inhibitor	Vorinostat	Inhibits class I, II, and IV histone deacetylases	Cutaneous T-cell lymphoma
Immune checkpoint inhibitors	Pembrolizumab	Inhibits PD-1	Metastatic melanoma Metastatic NSCLC HNSCC
	Nivolumab	Inhibits PD-1	Metastatic melanoma Metastatic NSCLC Advanced renal cell carcinoma
	Avelumab	Inhibits PD-L1	Metastatic Merkel cell carcinoma Locally advanced or metastatic urothelial carcinoma Advanced renal cell carcinoma
	Durvalumab	Inhibits PD-L1	Locally advanced or metastatic urothelial carcinoma Unresectable stage III NSCLC

ALL, acute lymphocytic leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; F LT3, fms-like tyrosine kinase 3; GIST, gastrointestinal stromal tumor; HER2, human epidermal receptor 2; HNSCC, head and neck squamous cell carcinoma; mTOR, mammalian target of rapamycin; NSCLC, non–small cell lung cancer; PD, programmed cell death protein 1; PDGFRA, platelet-derived growth factor receptor alpha; PD-L1, programmed death ligand 1; Ph, Philadelphia chromosome; PI3K, phosphatidylinositol-3-kinase; PNET, progressive well-differentiated neuroendocrine tumor; VEGFR, vascular endothelial growth factor receptor.

It is thought that immune checkpoint inhibitors trigger immune-mediated damage of pancreatic islet cells (insulitis), leading to a form of drug-induced type 1 diabetes mellitus. This effect has been reported even after a single treatment with immunotherapy.[20] Immune-mediated diabetes is most common with the PD-1 antibody pembrolizumab but has also been reported in patients treated with other PD-1 and PD-L1 antibodies: nivolumab, avelumab, and durvalumab.[21] Patients are typically older and have a higher body mass index than patients who develop spontaneous type 1 diabetes mellitus.[22,23] Patients may already have diabetes-associated autoantibodies at the time of diagnosis and can present in diabetic ketoacidosis.[21,23]

Initial treatment is discontinuation of the immune checkpoint inhibitor and addition of insulin and other diabetes medications to address the hyperglycemia. The role of steroids to treat acute insulitis remains controversial. There is at least one case report of immune-mediated diabetes being successfully treated with infliximab.[24] Spontaneous resolution of diabetes is unlikely even after stopping immune checkpoint inhibitor therapy, and most patients have long-term dependence on insulin therapy.[21]

Glucosuria

Some antineoplastic drugs (eg, ifosfamide, mercaptopurine) cause a proximal tubular defect and lower the renal threshold for glucosuria without affecting glucose metabolism. Delayed onset glucosuria was detected in the majority of adults and children treated with high-dose ifosfamide, cisplatin, and high-dose methotrexate compared with the early postchemotherapy assessment in a prospective study of renal function after treatment.[25]

Lipid Disorders

Lipid disorders are seldom evaluated during active anticancer therapy because patients are often encouraged to maintain a positive metabolic balance via liberal oral intake. However, association between dyslipidemia and malignancy has drawn increasing attention. Several anticancer agents are known to cause dyslipidemia ranging from clinically insignificant changes to severe hypertriglyceridemia causing pancreatitis and other complications. A recent study investigated the association between hyperlipidemia and colorectal cancer (CRC) metastasis and concluded that hyperlipidemia promotes stimulates CRC cells to leave the vasculature and metastasize. Thus, hyperlipidemia is an independent risk factor tumorigenesis and has negative prognostic implications.[26]

Agents Known to Cause Lipid Disorders

Lipid disorders are among the main side effects of vitamin A derivatives, such as bexarotene, which is used in malignancies such as cutaneous T-cell lymphoma (CTCL), acute promyelocytic leukemia, and head and neck cancer. Binding of bexarotene to retinoid X receptors upregulates not only lipid metabolism but also interferes with thyroid hormone synthesis, resulting in hyperlipidemia and central hypothyroidism.[27] Hypercholesterolemia is the second most common side effect of bexarotene (reported in 48% of treated patients), and it is important to check baseline lipid levels and thyroid function in patients before bexarotene therapy. Dietary modifications are recommended if triglyceride levels are 200 to 400 mg/dL, and omega-3 fatty acids with fibrates or nicotinic acid should be started for levels of 400 to 1000 mg/dL. Lipid levels should be monitored on therapy because triglyceride levels greater than 1000 mg/dL increase the risk of acute pancreatitis.[28,29] The British Association of Dermatologists has recommended starting prophylactic levothyroxine and fenofibrate for all patients receiving bexarotene because a significant proportion of patients develop central hypothyroidism and hypertriglyceridemia.[30]

Despite these measures, in some patients with genetic polymorphisms of apolipoprotein genes such as APOA5, APOC3, and APOE, there is a higher likelihood to develop severe hypertriglyceridemia, which can require combination treatment with omega-3 fatty acids and fenofibrate.[31] One study showed that patients carrying at least one minor allele were less likely to develop severe hypertriglyceridemia, which makes screening of APOA5 and APOC3 genotypes a useful tool to identify the best candidates for bexarotene therapy.[32] The long-term significance of drug-induced hypercholesterolemia is unclear; however, atorvastatin has been successfully used to treat bexarotene-associated hypercholesterolemia in patients at the University of Texas MD Anderson Cancer Center (MDACC).[33]

Mitotane, an analog of the insecticide dichlorodiphenyltrichloroethane, is used in treatment of adrenocortical carcinoma as adjuvant therapy and has a potential side effect of hypercholesterolemia. Possible mechanisms include inhibition of sterol-O-acyl transferase 1 (SOAT 1), which is important for adrenal cytotoxicity, resulting in an increase in lipid-mediated endoplasmic reticulum stress and apoptosis in adrenocortical carcinoma cells.[34] Another study also showed that mitotane directly interacts with lipid membranes and alters membrane properties depending on lipid composition.[35]

A study from MDACC showed that mitotane increases high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels.[36] Patients with adrenocortical carcinoma usually have a poor prognosis, making the clinical significance of mild to moderate elevation of cholesterol uncertain. However, in long-term survivors on

adjuvant mitotane therapy, hyperlipidemia can lead to early development of atherosclerotic disease.

mTOR inhibitors have metabolic side effects that include hypercholesterolemia and hypertriglyceridemia. Possible mechanisms include rapamycin-induced reduction of gene expression of lipogenesis enzymes, reduction in lipoprotein lipase activity, and increase in adipose tissue fatty-acid release by increasing the action of hormone-sensitive lipase and reduction of LDL-apoB100 catabolism.[37–39] In addition, mTOR inhibitors reduce LDL-receptor expression, resulting in reduced LDL uptake and then in reduction in lipid clearance from the bloodstream.[40]

Another mTOR inhibitor that is widely used for treatment of patients with progressive pancreatic neuroendocrine tumors, advanced renal cell cancer, and breast cancer, as well as for antirejection agent for transplantation is everolimus. Hyperglycemia is a common side effect of everolimus, and this medication is also used in the management of patients with insulinoma-induced hypoglycemia.[41]

Before starting mTOR inhibitor therapy, baseline fasting glucose, LDL cholesterol, and triglyceride levels should be checked. The lipid profile should be monitored with every treatment cycle. The goals of lipid-reducing therapy are targeting fasting LDL cholesterol of 190 mg/dL or less and triglycerides of 300 mg/dL or less in patients with a life expectancy longer than 1 year. Therapeutic lifestyle changes are the first appropriate approach for patients with hyperlipidemia. If these fail to reduce LDL cholesterol to 190 mg/dL or less, pravastatin is used as first-line therapy followed by fluvastatin or rosuvastatin 5 to 20 mg/day in patients with poor tolerance or inadequate response; atorvastatin and simvastatin are contraindicated because enzymatic induction of cytochrome P450 interferes with the metabolism and potentially reduces the activity of mTOR inhibitors, especially everolimus. Statin monitoring under mTOR inhibitor therapy is the same as in nononcologic contexts. The goals of LDL cholesterol reduction vary with patients' cardiovascular risk factors. Fibrate, omega-3 acid esters, niacin, and combination therapy are the treatment options for hypertriglyceridemia. Efficacy should be assessed on lipid profile after 2 months' treatment, repeated every 3 months until lipid targets are reached, and then repeated twice yearly. In uncontrollable hypertriglyceridemia exceeding 1000 mg/dL, mTOR inhibitor treatment should be interrupted, and specialist opinion should be sought.[5,42]

Dyslipidemia is also caused by other chemotherapeutic agents, including capecitabine. Transient dyslipidemia has been reported with paclitaxel and other platinum-based chemotherapy.[43,44] Neoadjuvant chemotherapy exerted an adverse temporary effect on lipid levels (manifested as increased triglyceride and LDL cholesterol levels and decreased HDL cholesterol levels) during the chemotherapy periods. However, this influence was not sustained because the lipid profiles levels were generally restored to baseline levels 6 months after chemotherapy completion.[45]

In addition to dyslipidemia, case reports have also described a new complication of cancer therapy, which is acquired generalized lipodystrophy as a complication of immunotherapy including pembrolizumab and nivolumab.[46,47] Although the mechanism is unclear, there is evidence of fat destruction in lipodystrophy, which may involve antiadipocyte antibodies.

WATER AND ELECTROLYTE DISORDERS

Serum osmolality is tightly regulated by hypothalamic osmoreceptor-controlled antidiuretic hormone secretion from cells in the paraventricular and supraoptic nuclei, the hypothalamic thirst center, and the kidneys. Disruption of these regulators leads to disturbance in free water clearance and subsequent abnormalities in serum sodium levels.

Syndrome of Inappropriate Antidiuretic Hormone Secretion and Hyponatremia

Hyponatremia, defined as serum sodium below 130 mEq/L, is a relatively common electrolyte abnormality in patients with cancer, and the incidence of this condition varies; it can be as high as 76% in patients with certain malignancies.[48] The development of hyponatremia in patients with cancer is a poor prognostic indicator and associated with an increase in 90-day mortality rate,[49] poor performance status,[50] and increased length of stay.[51]

Causes of hyponatremia in patients with cancer are categorized based on the patient's volume status. In hypervolemic patients, causes include heart failure from malignant pericardial disease or anthracycline-induced cardiac dysfunction, liver failure caused by metastatic liver disease or hepatotoxicity from chemotherapy, or kidney failure caused by nephrotoxicity from chemotherapy or malignancy-related nephrotic syndrome. In hypovolemic patients, treatment-related vomiting and diarrhea, platinum-based tubular damage resulting in renal salt wasting or intracranial tumor–related cerebral salt wasting could contribute to hyponatremia.[52]

Of the various causes, in euvolemic patients, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) is one of the most common underlying causes. SIADH is a diagnosis of exclusion after ruling out hypothyroidism and adrenal insufficiency as underlying causes. In patients with cancer, SIADH is most commonly caused by ectopic production of

arginine vasopressin (AVP) by a variety of tumors. Small cell lung cancer (SCLC) cells are the only known tumor type to produce AVP in tumor cell lines, and 70% of patients with SCLC are found to have elevated AVP levels.[53] Less frequently, SIADH has also been associated with several other cancers, including head and neck cancer, gastrointestinal cancers, gynecologic malignancies, and hematologic malignancies (including Hodgkin and non-Hodgkin lymphoma, multiple myeloma [MM], chronic lymphocytic leukemia, and malignant histiocytosis).[54]

Anticancer drugs can also cause SIADH through a variety of mechanisms. Chemotherapy-induced lysis of antidiuretic hormone (ADH)–containing cancer cells leads to severe hyponatremia at the time of chemotherapy induction. Cyclophosphamide increases AVP secretion and its effect on the kidney, and aggressive hydration to prevent cyclophosphamide-induced hemorrhagic cystitis can worsen hyponatremia. Vincristine- and vinblastine-induced neurotoxicity alter the delicate regulation of AVP secretion in the hypothalamic pituitary axis. Cisplatin treatment increases ADH production and renal response to ADH with hyponatremia caused by renal salt wasting syndrome.[55]

Other key factors causing SIADH in patients with cancer include symptoms such as nausea or pain and use of medications such as narcotics, nicotine, antidepressants such as selective serotonin reuptake inhibitors, thiazide diuretics, antipsychotics, and antiepileptics.[55]

Symptoms of hyponatremia include headache, lethargy, nausea, vomiting, drowsiness, and in extreme cases, seizures and obtundation. There are certain essential criteria that must be met for diagnosis of SIADH in a clinically euvolemic patient with normal adrenal and thyroid function. These include elevated urine osmolality (>100 mOsm/kg), which is typically higher than plasma osmolality, and urine sodium greater than 30 mEq/L in a patient with normal sodium intake.[48]

Standard treatment of hyponatremia includes fluid restriction based on urine solute content and increase in oral salt intake in the form of salt tablets in asymptomatic patients. In the presence of severe symptoms (seizures or obtundation), hypertonic saline infusions (3%) are used with close and frequent monitoring of sodium levels. Demeclocycline (600–1200 mg/day) can also be used in cases when hyponatremia does not respond to strict fluid restriction. Vasopressin receptor (V2) antagonists (tolvaptan and conivaptan) have been approved for treatment of patients with clinically significant hypervolemic or euvolemic hyponatremia associated with heart failure or SIADH.[56] It is important to avoid fluid restriction after patients are started on these agents to prevent rapid overcorrection. Other less commonly used treatment options include f loop diuretics with sodium supplementation, urea, lithium, and fludrocortisone.[57]

Treatment of hyponatremia in patients with cancer poses a unique challenge, especially in patients in whom the underlying stimulus cannot be removed. In addition, fluid restriction may not be an option in patients with cancer who need aggressive hydration to prevent chemotherapy-induced toxicities. Clinical factors need to be taken into careful consideration to determine what treatment option is best for the patient.

Diabetes Insipidus and Hypernatremia

Hypernatremia, defined as a serum sodium greater than 145 mEq/L, occurs in patients with cancer either because of lack of ADH production caused by pituitary surgery or inflammation from medication side effects, resistance of ADH response at the level of the kidney, or reduced free water intake for patients on parenteral or tube feeding regimens. Central diabetes insipidus can occur after surgery for brain tumors and occasionally in cases of tumors near the sella or the hypothalamus that invade the neurohypophysis or disrupt the pituitary stalk. Central diabetes insipidus caused by treatment with immune checkpoint inhibitors has been described in case reports but remains very rare.[58,59] These cases are often recognized by a clinical presentation of polyuria or polydipsia and are usually treated with vasopressin to control the symptoms and correct the associated hypernatremia.

Nephrogenic diabetes insipidus can also occur in patients with cancer, and multiple antineoplastic agents have been described in association with this syndrome. Ifosfamide is well known to induce damage to the proximal renal tubule and, to a lesser extent, the distal renal tubule, and thereby induce nephrogenic diabetes insipidus. There are case reports of nephrogenic diabetes insipidus occurring with bendamustine and streptozocin.[60,61]

Hypernatremia is also classified based on volume status. In hypovolemic patients, the caused can be diuretics, diarrhea, vomiting, or decreased free water intake, and treatment includes hydration with normal saline. In patients with euvolemic hypernatremia, treatment includes hypotonic fluids and vasopressin for patients with central diabetes insipidus and diuretics and nonsteroidal antiinflammatory drugs for patients with nephrogenic diabetes insipidus. For patients with hypervolemic hypernatremia, treatment is free water administration with loop diuretics to help with natriuresis.[57]

DISORDERS OF BONE AND BONE MINERAL METABOLISM

Osteoporosis

Normal bone remodeling requires a delicate balance between bone formation by osteoblasts and bone

resorption by osteoclasts. Antineoplastic therapy may affect this balance by increasing the activity of osteoclasts eg, interleukin-2) or from direct toxic effects on osteoblast function. Hormones and cytokines (ie, parathyroid hormone [PTH], PTH-related peptide, and interleukin-1) can also affect overall bone turnover.

Bone mineral loss is one of the side effects of cancer treatment. Hormone-suppressive therapies, chemotherapeutics, and corticosteroids can cause osteoporosis in patients with cancer.[62] Additionally, bone loss is of big concern in patients with transplant or MM and those receiving radiation therapy or multikinase inhibitors. Improved oncologic treatments and patient longevity have focused attention on skeletal health in patients with cancer, leading to emergence of cancer treatment-induced bone loss with growing evidence about the protective effect of bisphosphonates and denosumab therapy in this setting.[63]

Patients with breast cancer are at high risk for osteoporosis after hormone-suppressive therapy.[64] Whereas aromatase inhibitors, including anastrozole and letrozole, decrease bone density and increase the rate of fractures in postmenopausal women, tamoxifen, a selective estrogen receptor modulator, has a similar effect in premenopausal women. This is in sharp contrast to the positive effect on bone (both bone mineral density [BMD] and fracture rates) seen with tamoxifen in postmenopausal women (Fig. 60–1). In the ATAC (Arimidex [anastrozole], Tamoxifen, Alone or in Combination) trial, 9366 postmenopausal women with invasive operable breast cancer who had completed primary therapy were randomly assigned to receive anastrozole, tamoxifen, or both. More fractures were seen in patients who received anastrozole than those who received tamoxifen.[65] It has been shown that fracture risk in postmenopausal women during aromatase inhibitor treatment, in real-life conditions, was more than 40% compared with tamoxifen, corroborating previous randomized controlled trial (RCT) results.[66]

Patients with breast cancer and patients with prostate cancer are at risk for two types of bone diseases: fragility fractures related to osteoporosis and skeletal-related events. Patients should undergo BMD testing before treatment with aromatase inhibitors, and annual follow-up should be conducted thereafter. Antiresorptive therapy is usually added if a patient's bone density is within the osteoporotic range (T score ≤–2.5) before treatment or if a significant decline in BMD was seen during follow-up because studies have shown significant benefit of antiresorptive therapy in this setting.[66]

Osteoporosis can also occur in patients with prostate cancer with hypogonadism secondary to androgen deprivation therapy (ADT) or treatment with gonadotropin-releasing hormone (GnRH) agonists, nonsteroidal antiandrogens, bilateral orchiectomy, or androgen blockers.[67] Hypogonadism can also causes

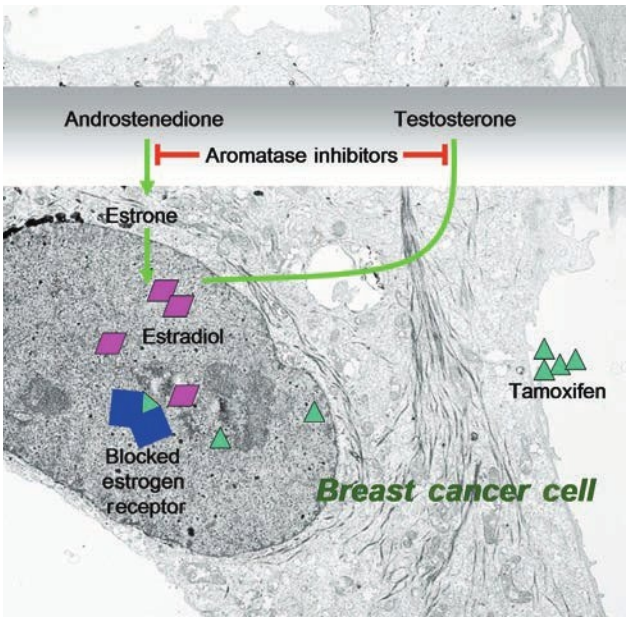

FIGURE 60–1 Mechanism of action of selective estrogen receptor modulators and aromatase inhibitors. Aromatase inhibitors, including anastrozole and letrozole, inhibit conversion of androstenedione or testosterone to estrone, which causes a decrease in bone mineral density. Tamoxifen, a selective estrogen receptor modulator, has a positive effect on bone.

muscle loss (sarcopenia), leading to increased falls and fractures.[68] Bone-seeking radiopharmaceuticals such as radium-223 dichloride should not be used with abiraterone and prednisone because of the high incidence of fracture and death.[69,70]

Patients with prostate cancer should be evaluated with BMD testing before starting ADT. Patients with fragility fractures or osteoporosis should be offered antiresorptive treatment and nonpharmacologic approaches such as exercise, along with calcium and vitamin D supplementation.[71]

Antineoplastic agents can cause chemotherapy-associated osteoporosis.

Prolonged therapy with oral methotrexate for acute lymphoblastic leukemia causes distal extremity pain, severe osteoporosis, and associated fractures, with significant improvement after cessation of methotrexate therapy.[72] Other agents reported to reduce bone density include cisplatin and carboplatin. In addition, many chemotherapy protocols include corticosteroids, which are known to decrease bone density and increase the risk of fractures.

Patients who have undergone bone marrow transplantation have been reported to have low bone mass. The reduced bone density is likely to be secondary to the long-term side effects of bone marrow radiation, chemotherapy, corticosteroids, and hypogonadism.

Bone is the predominant organ involved in MM and usually causes osteolytic bone disease in the axial and longitudinal skeleton, increasing the susceptibility to pathologic fractures. Bisphosphonates such as zoledronic acid and pamidronate reduce the proportion of patients with MM who experience skeletal morbidity.[73] It has been noted that combined treatment with a transforming growth factor β inhibitor (1D11) and bortezomib (a component of most MM first-line treatment regimens) improves bone architecture in a mouse model of myeloma-induced bone disease. However further studies are needed to validate that effect in humans.[74]

Osteoblasts and osteoclasts are under the influence of many hormonal and signaling pathways, including tyrosine kinase receptors for platelet-derived growth factor (platelet-derived growth factor [PDGF] receptors α and β) and c-Abl. Activation of the PDGF pathway improves BMD in ovariectomized rats and accelerates fracture healing. The absence of c-Abl is associated with impaired osteoblast maturation, leading to an osteoporosis phenotype.[75] Multikinase inhibitors, such as sorafenib, sunitinib, and imatinib, inhibit pathways that affect bone remodeling. Inhibition of bone resorption appears to be a class effect and is likely contributed by TKI effects on the hematopoietic and mesenchymal stem cells.[76,77] More studies are needed to determine the effects of TKIs on bone and bone mineral metabolism and the clinical implications of that effect. After 2 to 4 years of treatment with imatinib in patients with CML, a significant increase in the volume of the trabecular bone in the iliac crest has been observed.[78] Preosteoblast cells exposed to imatinib undergo suppression of PDGF-induced PI3 kinase/Akt activation with upregulation of genes associated with osteoblast differentiation and bone formation. In subsequent prospective investigation, imatinib-treated patients have also been confirmed to manifest a decrease in calcium levels with an associated increase in PTH levels unrelated to vitamin D deficiency or chronic renal insufficiency.[79,80]

The goals of management with regard to skeletal health are to prevent fragility fractures in patients without bone metastasis and to prevent symptomatic skeletal events (SSEs), which include pathologic fractures and spinal compression. Fragility fractures and SSE are both correlated with worse overall survival.[70]

Role of Antiresorptive Therapy in Prevention and Treatment of Cancer-Induced Bone Loss

There is significant benefit of antiresorptive therapy in setting of cancer-induced bone loss (CIBL). For example, in patients with breast cancer treated with aromatase inhibitors who are at high risk of fracture, treatment with bisphosphonate lowered fracture risk by 30% compared with patients who were not treated.[66] Bisphosphonates and denosumab are also beneficial in reducing the risk of bone loss and fractures in patients with prostate cancer treated with ADT.[81]

In addition, adjuvant bisphosphonates may have benefits on disease-free survival, especially with regard to bone recurrences, in postmenopausal women with nonmetastatic breast cancer.

A systematic review and meta-analysis of RCTs in patients with prostate and breast cancer showed that denosumab, when administered at dose of dose of 60 mg every 6 months led to a reduction of the BMD loss up to 36 months both at the lumbar and femoral levels and a BMD increase at both 24 and 36 months. There was also a reduction in the number of new vertebral and femoral fractures at 24 and 36 months.[82]

Bisphosphonates may have benefit in chemotherapy-induced bone loss. There is evidence that adding zoledronic acid to cisplatin ameliorated cisplatin-induced bone and muscle abnormalities in young mice.[83] For glucocorticoid-induced osteoporosis, denosumab was superior to bisphosphonates in its effects on lumbar spine and total hip BMD with no difference in the incidence of infections or adverse events. However, studies were underpowered to detect differences in the risk of fracture.[84]

Antiresorptive therapies have limitations because they lead to a low turnover state in which bone formation decreases with the decrease in bone-remodeling activity. Other drugs are currently widely used for the management of nonmalignant bone disease but are not specifically recommended in the oncologic setting; these include calcitonin (the clinical investigation of which in cancer patients has been very limited) and teriparatide, a recombinant human PTH analog. Teriparatide has been associated with an increased risk of osteosarcoma in patients receiving bone radiotherapy and is contraindicated for the treatment of CIBL.[85,86]

Osteomalacia and Rickets

Osteomalacia is characterized by hypomineralization of the bone matrix. In children, abnormal mineralization and maturation of the growth plate at the epiphysis is called rickets. Nutritional deficiency (especially vitamin D deficiency) and renal wasting of phosphorus leading to hypocalcemia or hypophosphatemia are among the common causes of osteomalacia. Other contributing factors include drugs such as anticonvulsants or aluminum and systemic acidosis. Antineoplastic agents can also cause or worsen osteomalacia.

Cisplatin and ifosfamide-induced tubular damage lead to renal phosphate wasting, hypophosphatemia, and rickets. Although renal and skeletal consequences of ifosfamide therapy have been well described in

children, only four adult patients with osteomalacia have been reported.[87] Another antineoplastic agent, the estrogen derivative estramustine, used in prostate cancer metastatic to bone, can cause hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, and osteomalacia with normal vitamin D levels.[88]

Tumor-induced osteomalacia (TIO) is a rare paraneoplastic metabolic syndrome that is characterized by severe hypophosphatemia, hyperphosphaturia, and osteomalacia secondary to renal loss of phosphate. It is caused by overproduction of fibroblast growth factor 23 (FGF23) from tumors of mesenchymal origin. However, it has been also reported in patients with solid malignancies, including breast cancer.[89]

Treatment of patients with TIO consists of surgical resection of the tumor, though locating the responsible tumor is often challenging. Before surgery or when surgery is not indicated, medical treatment with phosphate repletion and active vitamin D is needed. Use of a monoclonal antibody against FGF23 (burosumab) is still under review for TIO, though it is FDA approved for X-linked hypophosphatemia rickets. Data on management of TIO in the metastatic setting are scarce. In these cases, treatment of cancer can potentially lead to the normalization of the electrolytic disturbances and reduction of the activity of FGF23. The use of antiresorptive therapy in patients with bone metastases can potentially trigger FGF23 overexpression, and further studies are needed are to evaluate the use of antiresorptive therapy in this setting.[89]

Hypercalcemia

Calcium homeostasis is normally maintained by the interplay of PTH, calcitonin, phosphorus, and vitamin D metabolites in several target organs, including bones, parathyroid glands, intestines, and kidneys. In patients with cancer, multiple factors can affect this delicate balance, including nutritional status, medications, and tumor secretion of cytokines, hormones, or other humoral factors.

Hypercalcemia can occur in 20% to 30% of all patients with malignancy.[90] Recent studies report a lower incidence, probably reflecting better cancer care. A retrospective study used the Oncology Services Comprehensive Electronic Records warehouse of electronic health records to evaluate the prevalence of hypercalcemia of malignancy in the United States. It estimated the prevalence of hypercalcemia of malignancy to affect approximately 2% of patients with cancer. The rates were highest for patients with MM (7.5%–10.2%) and lowest for those with prostate cancer (1.4%–2.1%).[91] In addition to MM, squamous carcinoma, renal cell carcinoma, non–small cell lung carcinoma, breast carcinoma, leukemia, and non-Hodgkin lymphoma are among the most common malignancies associated with hypercalcemia. Retinoic acid derivatives have been reported to induce hypercalcemia and are used for treatment of patients with acute promyelocytic leukemia.[92]

Evaluation should include PTH level to differentiate between PTH-dependent or -independent hypercalcemia. PTH level more than 20 in setting of hypercalcemia is considered unsuppressed and should raise suspicion for hyperparathyroidism. For patients with low PTH, further evaluation is needed and should include PTH-related peptide, 25 hydroxy-vitamin D, and 1,25 hydroxy- vitamin D.[93] Hyperparathyroidism occurs 2.5 to 3 times more often in patients treated with low-dose (2.0–7.5 Gy) external radiation to the head and neck area than in the age-matched control population. Hyperparathyroidism after high-dose irradiation is uncommon. Radiation exposure from radioactive iodine treatment has also been reported in association with hyperparathyroidism.[94]

Management of hypercalcemia includes fluid resuscitation, calcitonin (4–8 U/kg intramuscularly or subcutaneously every 12 hours) and intravenous (IV) zoledronic acid at a dose of 5 mg. Denosumab can has been shown to be effective in cases of hypercalcemia that is refractory to bisphosphonate treatment. Denosumab is administered subcutaneously (120 mg every 4 weeks, with loading doses on days 8 and 15). Steroids can be beneficial in hypercalcemia caused by increased levels of 1,25-dihydroxy vitamin D.[95]

Hypocalcemia

Many factors can increase a cancer patient's risk of hypocalcemia. These factors include the patient's nutritional status, antineoplastic agents used, and type of surgical procedures performed eg, neck dissection). Cytotoxic chemotherapy can result in tumor lysis syndrome and its resultant hypocalcemia, as commonly seen in treatment of hematologic malignancies. Hyperphosphatemia, hyperkalemia, hypocalcemia, and hyperuricemia can occur after induction chemotherapy; it is of vital importance to prevent the complications of tumor lysis by hydration, alkaline diuresis, inhibition of uric acid synthesis, and administration of oral calcium or aluminum-based compounds to bind intestinal phosphate and enhance calcium absorption. IV calcium administration can potentially cause calcium phosphate precipitation in the presence of severe hyperphosphatemia and should be used with extreme caution. Dialysis may be needed in cases of symptomatic hypocalcemia and with refractory hypophosphatemia with and elevated calcium phosphorus product greater than 70 mg^2/dL.[4,96]

Cisplatin has been associated with hypocalcemia. One proposed mechanism of cisplatin's ability to induce hypocalcemia is through hypomagnesemia

resulting in decreased PTH secretion.[97] Other theories include inhibition of 1,25-dihydroxy-vitamin D formation by hypomagnesemia or cisplatin inhibition of mitochondrial function in the proximal renal tubule. Other agents reported to induce hypocalcemia include dactinomycin, carboplatin, doxorubicin, and cytarabine. Hypocalcemia has been seen after administration of bisphosphonates (zoledronic acid and pamidronate) or denosumab (a monoclonal antibody that inhibits receptor activator of nuclear factor-κB ligand [RANKL]), both used to reduce skeletal complications in treatment and prevention of advanced malignancies involving the bone.[98] Serum calcium levels and 25-hydroxy-vitamin D levels should be checked before and during therapy with bisphosphonates or denosumab.[99]

More recently, there are emerging data regarding immunotherapy-induced hypoparathyroidism resulting in hypocalcemia. There have been case reports describing hypoparathyroidism caused by combination anti–PD1 and CLA4 in two patients with malignant melanoma. Both patients manifest with acute severe symptomatic hypocalcemia. The exact pathophysiology remains unknown but may be caused by immune-mediated destruction of calcium-sensing receptor or inflammation mediated. Because immunotherapy is being commonly used in treatment of various malignancies, clinicians should be aware of the potential risk for hypocalcemia.[100,101]

Hypomagnesemia

Hypomagnesemia is common in patients with cancer. This may be caused by gastrointestinal (diarrhea) magnesium losses, malnutrition, decreased dietary intake, and certain chemotherapeutic agents. Hypomagnesemia is a well-known side effect in patients receiving platinum-based chemotherapy. Cisplatin has toxic effects on the kidneys, causing morphologic changes and necrosis in the proximal tubule, a major site of magnesium reabsorption. Hypomagnesemia is a frequent complication of cisplatin chemotherapy, affecting up to 90% of patients; 10% of these patients have symptoms of muscle weakness, tremulousness, and dizziness. A study showed that premedication with magnesium reduced cisplatin-induced nephrotoxicity in patients with thoracic cancers.[102]

Carboplatin, a second-generation platinum compound, was developed to reduce the side effects of cisplatin. However, hypomagnesemia has been seen with increasing frequency and severity at higher doses of carboplatin.

Oxaliplatin, a third-generation platinum derivative that has become an integral part of various chemotherapy protocols, particularly in advanced CRC, has dose-limiting cumulative sensory neurotoxicity like cisplatin. Oxaliplatin chelates to calcium and decreases magnesium levels. Hypomagnesemia was seen in 11% of patients with advanced epithelial ovarian cancer treated with oxaliplatin in a phase II trial.[103] Oxaliplatin is considered to carry a lower risk for hypomagnesemia than cisplatin and carboplatin.

Cetuximab and panitumumab, monoclonal antibodies against the epithelial growth factor receptor (EGFR), are used to treat metastatic colon cancer and can cause supplement-resistant hypomagnesemia. Because EGFR is common in the loop of Henle, cetuximab and panitumumab block reabsorption of magnesium in the kidneys. Magnesium levels should be checked before and during cetuximab or panitumumab therapy and should be treated. Interestingly, a recent meta-analysis showed that metastatic cancer colon patients who developed hypomagnesemia because of anti-EGFR monoclonal antibodies demonstrated better progression-free survival, overall survival, and objective response rate than those who did not develop hypomagnesemia because of therapy.[104]

Erlotinib, which is a TKI that acts on the EGFR receptor, was found in mouse model to cause mild hypomagnesemia, oxidative stress, and cardiac dysfunction. Further studies are needed to investigate if a similar effect is produced in humans.[105]

PITUITARY AND HYPOTHALAMIC DISORDERS

Hypothalamic–pituitary damage leading to hormonal deficiencies can occur in patients treated with cranial or craniospinal irradiation or intracranial surgery. Cranial radiation therapy is often used to treat leukemia and lymphoma, nonpituitary brain tumors, pituitary tumors, nasopharyngeal carcinoma, and skull base tumors.[106] The hypothalamus appears to be more radiosensitive than the pituitary gland and may be damaged by low radiation doses (<40 Gy), but high radiation doses are likely to damage both hypothalamic and pituitary functions. Deficiency in one or more pituitary hormones occurs after irradiation (>40 Gy) of the hypothalamic–pituitary area in about 90% of patients 5 years after radiation treatment (Fig. 60–2).[107]

Ipilimumab, an immunoglobulin G1 antibody that blocks CTLA-4, is used in the treatment of melanoma, renal cell carcinoma, CRC, and non–small cell lung cancer. In a retrospective review of patients with metastatic melanoma treated with ipilimumab, 11% developed autoimmune hypophysitis, with increased risk seen in older men.[108] In comparison, hypophysitis is rare with other immune checkpoint inhibitors, with only a handful of cases reported with anti–PD-1 or PD-L1 monotherapy (Table 60–2).[109] Combination

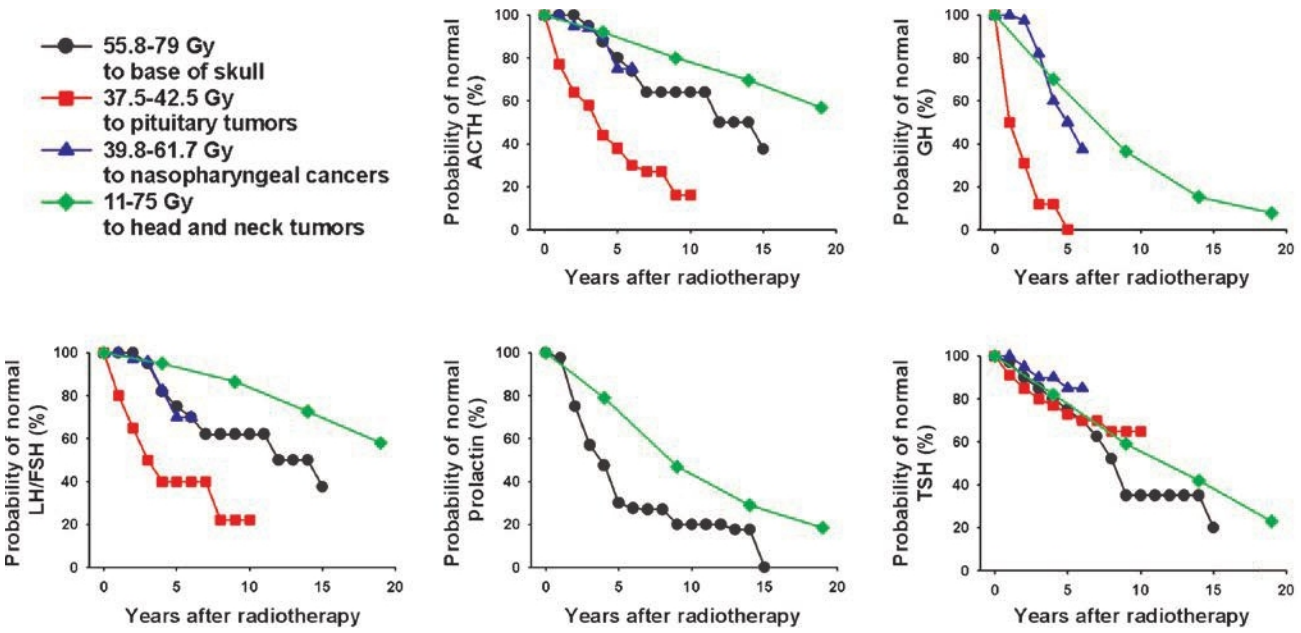

FIGURE 60–2 **Probability of normal pituitary hormone secretion over time after irradiation of the hypothalamic–pituitary area. The data are from four studies: Pai et al,[124] in which 55.8 to 79 Gy was administered to the base of the skull; Shalet et al,[107] in which pituitary tumors were treated with 37.5 to 42.5 Gy; Appelman-Dijkstra et al,[123] in which nasopharyngeal carcinoma was treated with 39.8 to 61.7 Gy; and Samaan et al,[125] in which 11 to 75 Gy was administered to treat head and neck tumors. ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.**

TABLE 60–2 Novel Immunotherapeutic Agents with Endocrine Adverse Effects

Drug	Type	Mechanism	Endocrine Adverse Effects
Ipilimumab Tremelimumab	IgG1 monoclonal antibody	Block CTLA-4 receptor	Hypophysitis Thyroiditis Graves disease Primary adrenal insufficiency
Pembrolizumab Nivolumab	IgG4 monoclonal antibody	Block PD-1 receptor	Hypothyroidism Thyroiditis Hypophysitis Autoimmune diabetes Primary adrenal insufficiency Lipodystrophy
Atezolizumab Durvalumab Avelumab	IgG1 monoclonal antibody	Bind PD-L1 and block its binding to PD-1 receptor	Hypothyroidism Thyroiditis Autoimmune diabetes

CTLA-4, cytotoxic T-lymphocyte-associated antigen 4; Ig, immunoglobulin; PD, programmed cell death protein 1; PD-L1, programmed death ligand 1.

therapy with anti–CTLA-4 and anti–PD-1 increases antitumor efficacy but also the frequency of irAEs, including hypophysitis.[110]

The typical clinical presentation includes headache, fatigue, and nausea. Magnetic resonance imaging may reveal pituitary enlargement. Visual deficits are uncommon because the degree of enlargement tends to be mild. Adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), and gonadotropin deficiencies are the most common hormonal deficiencies at presentation.[111] Diabetes insipidus, GH deficiency, and hyperprolactinemia are very rarely seen in immune checkpoint inhibitor–induced hypophysitis.[112] After cessation of the drug, pituitary morphology returns to normal (Fig. 60–3), but recovery of anterior pituitary hormone function is variable.[113] Adrenal axis recovery has only rarely been reported; thyroidal and gonadal axis recovery is more common.[114]

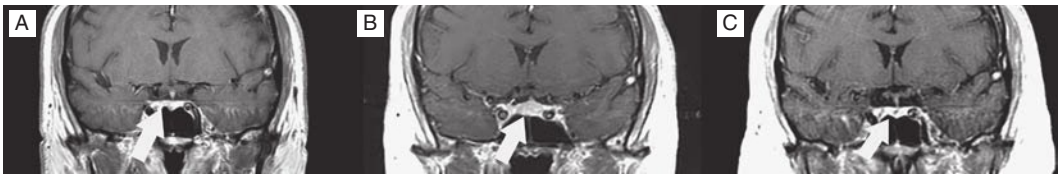

FIGURE 60–3 Magnetic resonance images of a patient before (A), during (B), and 8 weeks after (C) ipilimumab therapy.

Secondary Adrenal Insufficiency

Prolonged glucocorticoid treatment is the most common cause of adrenal dysfunction in patients with cancer. Secondary (central) adrenal insufficiency may develop up to 2 years after discontinuation of glucocorticoids and can persist for months. Irradiation of the hypothalamic–pituitary region causes ACTH deficiency with resultant secondary adrenal insufficiency in 19% to 42% of patients. The median time to development of adrenal insufficiency after radiation therapy is 5 years, but onset can occur in as little as 2 years.

Prolonged therapy with busulfan was initially reported to cause a reversible clinical syndrome resembling central adrenal insufficiency as evidenced by metyrapone testing. No recent reports have corroborated this finding. Long-term intrathecal opioid therapy for intractable nonmalignant pain resulted in central adrenal insufficiency in 15% of patients tested for insulin-induced hypoglycemia.[115]

Megestrol acetate is an appetite stimulant, but prolonged use can lead to a Cushing-like syndrome, and sudden withdrawal after prolonged treatment may result in adrenal insufficiency. Megestrol shows glucocorticoid-like effects with an acute suppressive effect on the hypothalamic–pituitary axis and can lead to central adrenal insufficiency.[116,117]

Secondary adrenal insufficiency can be diagnosed by a variety of tests with varying sensitivity and specificity, but in our practice, we frequently use a combination of basal (8:00 AM) serum cortisol and ACTH measurement as well as1-µg cosyntropin stimulation testing. Rarely, insulin-induced hypoglycemia is used to assess the overall cortisol and GH response to hypoglycemia when evaluating patients for panhypopituitarism.

Growth Hormone Deficiency

GH deficiency is frequently noted after cranial irradiation. In children, isolated GH deficiency can occur after low radiation doses, but high doses may produce panhypopituitarism. Hypopituitarism appears to be dose dependent. At low doses (20–24 Gy), the only effect may be an altered pulsatile secretory pattern. At doses higher than 30 Gy, deficient GH secretion and growth retardation are observed in more than one third of patients (Fig. 60–4). Children who receive cranial irradiation require long-term follow-up.[118]

GH deficiency is also common in adults who have undergone cranial radiation therapy. Manifestations may include decreased bone and muscle mass, fatigue, impaired sense of well-being, lowered exercise capacity,

FIGURE 60–4 A patient with short stature caused by growth hormone deficiency resulting from radiation treatment of a brain tumor.

increased volume of adipose tissue, altered myocardial function, higher occurrence of atherosclerotic plaques, and increased risk for cardiovascular diseases. GH replacement in these patients can restore normal adipose tissue composition, bone metabolism, quality of life, sense of well-being, lipid profile, and cardiac function.[119] Despite the apparent benefits, data on the effect of GH replacement in long-term cancer survivors are still lacking. GH replacement is contraindicated in all patients with an active malignant condition, but it can be initiated in an adult in whom malignant disease has been absent for at least 5 years. Another treatment reported to result in GH deficiency is long-term intrathecal opioids. Patients receiving this treatment have about a 15% elevation in the risk of developing GH deficiency.[115]

Central Hypothyroidism

Cranial and craniospinal radiation therapy can cause immediate and long-term effects with alterations in the hypothalamic and pituitary regulation of TSH, resulting in secondary and tertiary hypothyroidism, especially with doses of 40 Gy or higher. In one study, central hypothyroidism was detected 1 year after the end of radiation treatment in 6% of patients.[120] In that study, 15% to 20% of patients who had undergone cranial irradiation had diminished TSH secretion 5 years after the end of treatment, and approximately 35% of those patients had it after 10 years. Because of the combined effect of irradiation on the thyroid gland and the hypothalamic–pituitary axis, we suggest measuring serum free thyroxine and TSH concentrations yearly or sooner if the patient is having symptoms suggestive of hypothyroidism and to replace thyroid hormone when necessary.

Chemotherapy may enhance the deleterious effect of radiation. Children with brain tumors (not involving the hypothalamic–pituitary axis) who receive vincristine, carmustine, lomustine, or procarbazine in combination with brain irradiation have a 35% incidence of hypothyroidism compared with a 10% incidence in children who undergo brain irradiation alone.[121]

Bexarotene was found to cause central hypothyroidism in 40% of patients with CTCL.[29] Reversible, retinoid X receptor–mediated suppression of TSH secretion is one explanation for this side effect. Bexarotene patients often require higher levothyroxine dosing compared with patients with other causes of hypothyroidism because of bexarotene-related increase in thyroid hormone metabolic clearance.[122]

Hypogonadotropic Hypogonadism

Brain surgery and irradiation of the skull carry the potential for hypothalamic–pituitary damage, including hypogonadotropic hypogonadism.

FIGURE 60–5 Loss of axillary hair in a patient who developed secondary hypogonadism after cranial irradiation.

Hypogonadism occurs within 7 years after cranial irradiation for nonpituitary neoplasia in 25% of patients. Hypogonadism is transient in the presence of hyperprolactinemia and is treated with antidopaminergic therapy.[123] Hyperprolactinemia is the most commonly reported hormonal abnormality in patients who have undergone head and neck irradiation, occurring in more than 66% of patients.[124,125] Hyperprolactinemia inhibits gonadotropin secretion from the pituitary gland and decreases the responsiveness of the pituitary gland to GnRH, causing secondary hypogonadism. In children, inadequate sexual development, delayed puberty, and absent menarche are significant problems, whereas in adults, gonadotropin deficiency may cause sex steroid hormone deficiency, infertility, and loss of axillary and pubic hair (Fig. 60–5). Sex steroid hormone deficiency lowers libido and may have deleterious effects on bone and lipid metabolism.

Early or even precocious puberty has also been reported in patients with acute lymphoblastic leukemia treated with combined chemotherapy and cranial irradiation and in patients with brain tumors treated with cranial irradiation. This phenomenon occurs more often in girls along with coexisting GH deficiency. In a recent study of male cancer survivors (excluding those who had undergone treatment that may have otherwise affected gonadal function), chronic opioid therapy, given in morphine-equivalent daily doses of at least 200 mg/day, was associated with secondary hypogonadism.[126]

THYROID DISORDERS

Thyroid Neoplasms

Ionizing radiation is implicated in the etiology of thyroid cancer. Irradiation of the thyroid, especially in children and young adults (eg, young patients with Hodgkin disease), increases the risk of papillary thyroid carcinoma.[127]

Hyperthyroidism

Radiation-induced hyperthyroidism has been described but is far less common than radiation-induced hypothyroidism. In a 2018 report from the Childhood Cancer Survivor Study, the incidence of hyperthyroidism was found to be significantly higher in patients who received radiation therapy with an elevated risk lasting more than 25 years after exposure.[128] External and internal high-dose radiation is associated with development of Graves disease after exposure. Patients with lymphoma treated with radiation constitute the largest number of patients who have developed Graves disease after radiation therapy. Patients treated with radiation for nasopharyngeal, breast, or laryngeal carcinomas may also develop Graves disease. Radiation-induced silent thyroiditis with transient thyrotoxicosis has also been reported. Thyroiditis-induced thyrotoxicosis occurs within a few months of radiation therapy in most cases; hypothyroidism occurs several months later.

Cytokines have also been reported to lead to Graves disease. IFN is known to induce the production of autoantibodies and can lead to autoimmune thyroid disease, such as autoimmune primary hypothyroidism, transient thyrotoxicosis, or more rarely, Graves disease. Women have a higher risk than men of developing autoimmune thyroid disease upon starting IFN treatment.[129] It is important to distinguish the cases in which IFN induces transient thyrotoxicosis followed by hypothyroidism from the cases in which IFN induces Graves disease. Thyroid scans showing increased homogeneous uptake in the presence of hyperthyroidism are highly suggestive of Graves disease and warrant treatment with antithyroid medications (eg, methimazole).

Targeted therapies can also be linked to hyperthyroidism. The anti–CTLA-4 agents ipilimumab tremelimumab and anti-CD52 antibody alemtuzumab are associated with painful thyroiditis and Graves disease.[130] Pembrolizumab treatment caused hyperthyroidism in 1 of 135 patients in a safety study.[131] Interleukin-2 (denileukin diftitox) treatment alone causes transient hyperthyroidism followed by hypothyroidism, which may last months in about 50% of patients with disruption of self-tolerance postulated as a mechanism.[132]

Hypothyroidism

Multiple factors increase the risk for hypothyroidism during the course of cancer treatment, including certain systemic therapies, high doses of radiation to the head and neck, combined radiation and surgical treatments (eg, thyroid resection during laryngectomy or disruption of the vascular supply to the thyroid), time interval since radiation therapy, and failure to shield midline structures during radiation (Table 60–3).

Radiation can induce primary hypothyroidism when given in doses higher than 25 Gy to the region near the thyroid gland with a dose-related risk (Fig. 60–6). Cumulative incidence of hypothyroidism after thyroid irradiation is estimated to be 20% to 30%, with the greatest risk in the first 5 years after treatment, but elevated risk persists up to 20 years later.[133,134]

A significant number of patients develop subclinical hypothyroidism (elevated TSH with normal thyroxine levels), not overt hypothyroidism, when less than 40 Gy of radiation is administered. Subclinical hypothyroidism (20%) is more frequent than overt hypothyroidism (5%) 5 years after chemotherapy and radiation therapy.[135]

The use of iodine-131 (^{131}I) may result in thyroid dysfunction. The use of ^{131}I-metaiodobenzylguanidine in treatment of metastatic pheochromocytoma carries the possibility of inducing primary hypothyroidism and requires routine use of potassium perchlorate to block the thyroid ^{131}I uptake.

IFN therapy is associated with primary hypothyroidism in about 10% of treated patients, especially those with pretreatment antithyroid antibodies, and is not dose related.[136] The absence of thyroid autoantibodies at the end of IFN treatment was found to be a protective factor against development of thyroiditis up to 6 years after treatment, whereas positivity for thyroid antibodies at high titers at the end of IFN treatment was significantly related to chronic subclinical hypothyroidism.

Patients treated with multiple antineoplastic agents (with or without radiation) also have a higher-than-normal incidence of primary hypothyroidism. Fifteen percent of patients who received a combination of cisplatin, bleomycin, dactinomycin, vinblastine, and etoposide developed elevated TSH levels with normal free triiodothyronine (T_3) and free thyroxine (T_4), compatible with subclinical primary hypothyroidism, in contrast to the control group.[137]

Targeted therapy has also been linked to development of a variety of thyroid abnormalities. For example, autoimmune thyroid disease has been seen in 23% of patients receiving alemtuzumab.[138] Thyroid dysfunction is a known potential adverse effect of TKIs, specifically those that target angiogenic receptors such as sunitinib, sorafenib, and vandetanib. Reported rates

TABLE 60–3 Antineoplastic Agents Associated with Hypothyroidism

Therapy Type	Drug	Effect on the Thyroid
Synthetic retinoid	Bexarotene	Central hypothyroidism Increased dose requirement in patients on thyroid hormone replacement
Steroidogenesis inhibitor and adrenolytic	Mitotane	Central hypothyroidism
Immune checkpoint inhibitors	Anti–CTLA-4 Tremelimumab Ipilimumab	Central hypothyroidism in the setting of hypophysitis Thyroiditis with transient thyrotoxicosis followed by primary hypothyroidism Primary hypothyroidism
	Anti–PD-1 Pembrolizumab Nivolumab	Thyroiditis with transient thyrotoxicosis followed by primary hypothyroidism Central hypothyroidism in the setting of in hypophysitis
	Anti–PD-L1 Atezolizumab Durvalumab Avelumab	Primary hypothyroidism Thyroiditis with transient thyrotoxicosis followed by primary hypothyroidism
Nonspecific immunomodulatory cytokines	IL-2 IL-α	Thyroiditis with transient thyrotoxicosis followed by primary hypothyroidism Primary hypothyroidism
CD52 monoclonal ab	Alemtuzumab	Subacute thyroiditis Primary hypothyroidism
Tyrosine kinase inhibitors	Sunitinib	Destructive thyroiditis Primary hypothyroidism
	Sorafenib	Primary hypothyroidism May lead to increased or decreased dose requirement in patients on thyroid hormone replacement
	Imatinib	Increased dose requirement in patients on thyroid hormone replacement
Estrogen-containing drugs		Increased dose requirement in patients on thyroid hormone replacement
Selective estrogen receptor modulator	Raloxifene	Interferes with GI absorption of thyroid hormone

CTLA-4, cytotoxic T-lymphocyte-associated antigen 4; GI, gastrointestinal; IL, interleukin; PD, programmed cell death protein 1; PD-L1, programmed death ligand 1.

FIGURE 60–6 Mapping of radiation ports on a patient with squamous cell cancer of the head and neck. The patient developed primary hypothyroidism 2 years after radiation therapy.

of thyroid dysfunction on sorafenib range from 21% to 68%, but fewer patients may require thyroid hormone replacement (6% in one prospective study).[139,140] Sorafenib-related thyroiditis has been suggested as a mechanism of thyroid dysfunction in some of the patients, but it is unclear if thyroid dysfunction represents an autoimmune process or a manifestation of vascular endothelial growth factor blockade affecting the thyroid blood supply. Sorafenib also frequently affects the thyroid hormone replacement dose requirement in patients with preexisting hypothyroidism.[141,142]

Similarly, thyroid dysfunction has been well documented in patients receiving sunitinib, with reported rates of 20% to 85%.[143] Some patients were reported to present with thyrotoxic phase preceding hypothyroidism supporting destructive thyroiditis as a cause. However, some patients became athyrotic on sunitinib after having normal thyroid function at baseline.[144] Another study showed that thyroid size was reduced to 59%

after 12 months of sunitinib use in patients with renal cell carcinoma.[145] Impaired iodine uptake and inhibition of peroxidase activity were also suggested as potential mechanisms to explain hypothyroidism.[146,147]

Thyroid dysfunction is a significant adverse effect of ICIs. Treatment with anti–PD-1 antibody confers a higher risk of hypothyroidism than with anti–PD-L1 and anti–CTLA-4 antibodies.[148] Combination therapy with two immune checkpoint inhibitors increases the risk of thyroid dysfunction as compared with monotherapy.

Primary hypothyroidism has been reported to occur in 8.3% of patients receiving pembrolizumab, with a median time to onset being 3.5 months (range, 0.7 weeks–19 months).[149] Ipilimumab-induced activation of T-cells results in not only antitumor activity but also immune infiltration of endocrine glands. The major endocrine glands affected by ipilimumab are the pituitary and thyroid glands. Although hypophysitis can involve central hypothyroidism as discussed earlier, ipilimumab-induced thyroiditis leads to primary hypothyroidism.[150] Primary and central hypothyroidism can present concomitantly. Because the timing of the onset of thyroid dysfunction varies widely, patients who have received immune checkpoint inhibitor therapy should be monitored closely for changes in thyroid function during treatment and in short- to medium-term follow-up.[151]

Abnormalities in Thyroid Hormone–Binding Proteins

Thyroid hormones are preferentially bound to thyroid hormone–binding globulin (TBG) (65%–70%), transthyretin (15%–20%), and albumin (10%–15%). Multiple factors in patients with malignancies, including changes in sex hormone levels, glucocorticoids, narcotics, nutritional status, and some antineoplastic agents, affect the levels of these binding proteins and the subsequent levels of bound thyroid hormones. Overall, the level of total T_3 and T_4 may be affected, but in general, the levels of free (biologically active) hormones are normal. The effect on TBG synthesis or clearance is usually reversible. Not only are estrogens known to increase TBG and total thyroid hormone levels, but tamoxifen also causes elevated plasma concentrations of TBG in postmenopausal women with breast cancer after 6 months of therapy. Letrozole, a nonsteroidal aromatase inhibitor, when given at 2.5 mg/day, was associated with a statistically significant decrease in total T_4 but not total T_3 levels.[152]

Glucocorticoids are frequently used in combination with chemotherapy and are known to suppress TSH secretion and inhibit TBG synthesis. L-Asparaginase can inhibit the synthesis of albumin and TBG, which affects serum thyroid hormone levels. 5-Fluorouracil increases total T_3 and T_4 levels and maintains a normal free thyroxine index, suggesting that this agent increases serum thyroid hormone–binding proteins, resulting in normal thyroid function.[153]

Mitotane increases the levels of hormone-binding globulins, but the increase in TBG is less remarkable than mitotane's effect on corticosteroid-binding globulin.

ADRENAL DISORDERS

Diagnosis of adrenal insufficiency in patients with advanced malignancy can be difficult. The symptoms of fatigue, weakness, loss of appetite, weight loss, nausea, hypotension, hyponatremia, and so on can be similar to progressive disease or secondary to cancer therapy. Treatment involves administration of glucocorticoids and mineralocorticoids.

Primary Adrenal Insufficiency

Adrenal glands are a common site for metastatic disease in patients with advanced malignancies of the kidney, lung, breast, or colon; non-Hodgkin lymphoma; and melanoma. Patients with bilateral adrenal metastases can develop adrenal insufficiency because of infiltration of the adrenal gland. There have been several reports of adrenal insufficiency as the presenting symptom of an occult malignancy.[154]

Antineoplastic agents can also cause destruction of the adrenal cortex. Mitotane has selective toxicity to both normal and malignant adrenocortical cells. Active form of mitotane irreversibly binds with adrenal molecules, including cytochrome P450 (CYP) enzymes such as CYP11A1 and CYP21B, causing altered serum hormone concentrations.[155,156] It directly interacts with lipid membranes and inhibits SOAT activity, resulting in an excess of free cholesterol and other fatty acids that are toxic to the hormone-producing adrenal cells.[34,35] In addition to inhibiting steroidogenesis by multiple mechanisms, it also induces CYP3A4 expression, leading to increased steroids clearance, and causes an increase in serum levels of cortisol-binding globulin.[157] Glucocorticoid replacement therapy is needed when mitotane is used; high doses are required because of the increased levels of binding globulin and enhanced metabolic clearance of corticosteroids by mitotane.

Animal studies found cases of adrenal necrosis associated with sunitinib use, leading the FDA to recommend monitoring adrenal function in patients receiving sunitinib. However, there was no evidence of adrenal hemorrhage or clinical evidence of adrenal insufficiency in subsequent clinical safety data.[158]

Primary adrenal insufficiency, though uncommon, has also been reported with immune checkpoint inhibitors by causing direct impairment of adrenal cortex. Primary adrenal insufficiency associated with

immunotherapy may be underestimated because of concomitant treatment with corticosteroids or the coexistence of secondary adrenal insufficiency.[159] It has been described in 0.3% to 1.5% of patients treated with anti–CTLA-4 (ipilimumab and tremelimumab) in addition to case reports describing primary adrenal insufficiency with nivolumab.[110,160]

Primary adrenal insufficiency can also by caused by novel anti–prostate cancer drugs (abiraterone or novel steroid-blocking agents, eg, ODM-208). These medications cause inhibition of steroid synthesis at multiple levels (eg, cholesterol side-chain cleavage enzyme, 17-hydroxylase, and 21-hydroxylase), which results in various degrees of decreased cortisol production.[161]

Elevated ACTH with low cortisol is often diagnostic of primary adrenal insufficiency. Confirmatory testing with 250-μg cosyntropin stimulation may be needed. Treatment requires replacement of glucocorticoids with daily hydrocortisone (~30 mg in divided doses), prednisone (5 mg), or dexamethasone (0.5–1 mg). Patients with primary adrenal insufficiency also need mineralocorticoid replacement with fludrocortisone 0.1 mg/day.

GONADAL DISORDERS

Direct radiation exposure and cytotoxic chemotherapeutic agents are common causes of hypogonadism and infertility in cancer survivors, with a variety of effects on fertility and gonadal functions in the two sexes. Compromised fertility is one of the most common long-term effects of cancer therapy.[162] Childhood cancer survivors should have routine monitoring that assesses their gonadal health and fertility potential as part of survivorship care.[163]

Female Gonadal Disorders

Because oogenesis occurs during embryonic life and is quiescent, oocytes are relatively resistant to the adverse effects of cytotoxic chemotherapy. However, because of their limited number, any damage can shorten a woman's reproductive period. Granulosa cells, on the other hand, are susceptible to cytotoxic drugs, as evidenced by the results of ovarian biopsies performed after chemotherapy (Fig. 60–7). Infertility can be caused by damage to either granulosa cells or oocytes.

With advances in cancer treatment, an increasing number of women survive malignancies to face reproductive disorders. It is of vital importance to discuss fertility issues before initiating radiation or systemic chemotherapy because of the long-term risks of ovarian dysfunction and infertility. Baseline ovarian reserve can be evaluated by levels of serum anti-Mullerian hormone level, antral follicle count, follicle-stimulating hormone (FSH) levels, inhibin-B levels, and ovarian volume.[162]

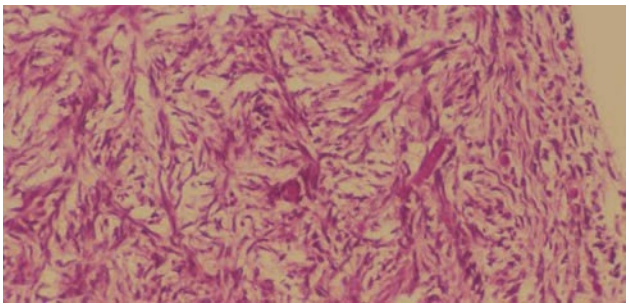

FIGURE 60–7 Hematoxylin and eosin staining of a biopsy sample showing atrophy of ovarian tissue after cytotoxic chemotherapy.

The effects of radiation treatment on the ovaries differ with patient age, radiation dose, and field of treatment. Radiation treatment that includes the pelvis increases the risk of infertility more than radiation treatment that includes only the abdomen.[164] Pregnancy rates decrease at doses between 5 and 10 Gy.[165] Fractionated radiation carries less risk for permanent sterility, and if done with appropriate shielding of the gonads, reduces the risk of ovarian failure. Before initiating pelvic irradiation, ovarian transposition (oophoropexy) via laparotomy or laparoscopy can preserve ovarian function in women younger than 40 years of age with cervical carcinoma less than 3 cm in diameter.[166] Patients require assisted fertilization after this procedure for future pregnancies.

Oocyte cryopreservation before cancer treatment has been proposed as a means of preserving fertility in women treated for cancer, but it has been less successful in humans than in animal models. The ethical issues behind these techniques are still being disputed, and there is still the concern of potential disease recurrence from residual disease in autografted ovarian tissues. Obtaining unilaminar follicles from cryopreserved, thawed tissue and growing them in vitro has been proposed to reduce the risk of recurrence.

GnRH agonists are also used to reduce ovarian susceptibility to chemotherapy based on the concept that the cytotoxic effects of chemotherapeutic agents are seen more in rapidly dividing cells than in cells at rest.[167] GnRH agonist–induced suppression of the hypothalamic–pituitary–gonadal axis has been shown in animal models to reduce cyclophosphamide-induced but not radiation-induced ovarian toxicity and has also shown encouraging results in women with breast cancer, leukemia, and lymphoma. Another study showed that GnRH agonist therapy may protect ovarian reserve but does not decrease the risk of premature ovarian failure in patients treated for lymphoma.[167] In mice, melatonin, which has antioxidant properties, has been shown to prevent primordial follicle loss in cisplatin-treated ovaries.[168]

In premenopausal women with breast cancer treated with regimens based on anthracyclines (5-fluorouracil,

epirubicin, and cyclophosphamide), the rate of chemotherapy-related amenorrhea is 93%. At the end of therapy, menstrual periods resume in 24% of patients.[169]

Alkylating agents, which are non–cell-cycle specific, are generally highly gonadotoxic. Mechlorethamine is usually used in combination with vincristine, procarbazine, and prednisone. Chlorambucil, melphalan, busulfan, and cyclophosphamide also carry a high risk of ovarian damage. Ovarian failure with alkylating agents was found to impose the highest risk with an estimated odds ratio (relative to no treatment) of 3.98.[170] Temporary amenorrhea developed in 2 of 12 female patients in whom cisplatin (0.4–0.6 g/m^2) was used in combination with bleomycin and vinblastine to treat ovarian germ cell tumors; the amenorrhea lasted from 12 to 15 months after the cessation of chemotherapy.[170]

Transient and permanent ovarian failure has been reported with etoposide use.[171]

Antimetabolites, which are cell-cycle specific, may exert few toxic effects on the ovaries. As a single agent, doxorubicin has few, if any, adverse effects on ovarian function, although a synergistic effect of the combination of doxorubicin and cyclophosphamide is a concern.

Vinblastine has been known to cause reversible and dose-related amenorrhea when combined with alkylating agents.[172]

Male Gonadal Disorders

Spermatogenesis occurs continuously and germ cells and spermatogonia, and in contrast to Leydig or Sertoli cells, sperm are much more sensitive to cytotoxic agents. If sufficient germ cells remain after cytotoxic chemotherapy, resumption of spermatogenesis usually occurs; the longer the duration of azoospermia, the lower the likelihood of spermatogenesis recovery.[173]

Radiation damage to the gonads is dose dependent. Low-dose testicular irradiation leads to a transient suppression of sperm counts with recovery time proportional to the radiation dose.[174] However, permanent infertility can occur with fractionated radiation doses of more than 2 Gy (Fig. 60–8), whereas clinically significant Leydig cell impairment occurs rarely with doses of less than 20 Gy.[175]

Therapy with alkylating agents such as cyclophosphamide or chlorambucil causes reversible but prolonged azoospermia. Chlorambucil causes azoospermia at cumulative doses of 400 to 800 mg, with recovery taking 3 to 4 years after a mean total dose of about 750 mg/m^2.[176] Cyclophosphamide affects spermatogenesis more than Leydig cell function, causing reduced sperm count with normal testosterone levels.

Antineoplastic agents causing azoospermia in humans can be classified in four groups. The first group consists of chemotherapeutics that cause prolonged azoospermia, which include chlorambucil, cyclophosphamide, procarbazine, melphalan, and cisplatin. In the second group, chemotherapy agents such as carmustine and lomustine cause azoospermia in adults treated with chemotherapy before puberty. In the third group, agents such as busulfan, ifosfamide, nitrogen mustard, and dactinomycin cause prolonged azoospermia when given with other sterilizing agents. The agents in the fourth group, which include doxorubicin, thiotepa, cytosine arabinoside, and vinblastine, have additive and temporary effects on azoospermia when combined with any of the agents from the other three groups.[177]

Multiple methods of preventing or reversing infertility in men treated for cancer have been suggested. In rats, suppression of testosterone production with use of GnRH agonists or antagonists before or after cytotoxic therapy can preserve fertility; although this approach does not protect survival of stem cells in the testes, it enhances the ability of the testes to maintain differentiation of type A spermatogonia.[178] Semen cryopreservation before starting gonadotoxic therapy followed by assisted fertilization is another strategy to preserve fertility in men with cancer.

SURVEILLANCE FOR COMPLICATIONS IN CANCER SURVIVORS

Primary care physicians and oncologists should be aware of the long-term consequences of cancer therapy for early detection and management of treatment-related side effects because many of the complications occur years after treatment and can have subtle clinical presentations.

Diabetes and Metabolic Disorders

For long-term cancer survivors who were treated with streptozocin, L-asparaginase, partial pancreatectomy, or immunotherapy, screening for delayed development of diabetes mellitus is recommended because they are at risk of development of 1 I diabetes, which can present as either new-onset diabetes or sudden worsening of previously well-controlled type 2 diabetes.

Recent data indicate that survivors of childhood cancer are at particularly increased risk of diabetes mellitus and metabolic syndrome and thus increased cardiovascular risk. Risk is even increased in patients exposed to abdominal or total-body irradiation.[179] According to 2013 Children's Oncology Group guidelines, these patients should have a fasting blood glucose or hemoglobin A1c checked every 2 years or more frequently if clinically indicated and clinicians should have a low threshold for performing oral glucose tolerance testing in suspected cases.

New data are emerging about increased diabetes risk in survivors of cancer colon for up to 5 years after the diagnosis.[180] Similarly, increased diabetes risk was also reported as a complication of hormonal therapy in breast cancer survivors (hazard ratio, 2.40; 95% confidence interval, 1.26–4.55; P =.008) with more risk reported with aromatase inhibitors than tamoxifen.[181] Thus, active screening and counseling regarding modifiable risk factors may be warranted in this high-risk group. Preventive strategies aimed at lifestyle modifications may minimize the risk.

Pituitary Dysfunction

In children with a history of cranial irradiation or craniospinal irradiation, the growth rate should be assessed at 6-month intervals. A more detailed evaluation, including measurement of the levels of GH and insulinlike growth factor 1 (IGF-1), thyroid function tests, and bone age assessments, should be performed when there is evidence of an abnormal growth pattern. The T_4 and TSH measurements should be performed annually for the first 5 years and less frequently thereafter. Central hypogonadism (or luteinizing hormone [LH] or FSHD) may emerge decades after cranial radiation and occurs in at least 35% of patients with an increased risk after doses greater than 30 Gy. Interestingly, a study of childhood brain tumor survivors showed that 12.2% of the patients had precocious puberty, indicating activation rather than reduction of pituitary function.[182] Discussions of fertility options, including oocyte or sperm cryopreservation, should be discussed early on to help keep the highest chances of fertility.

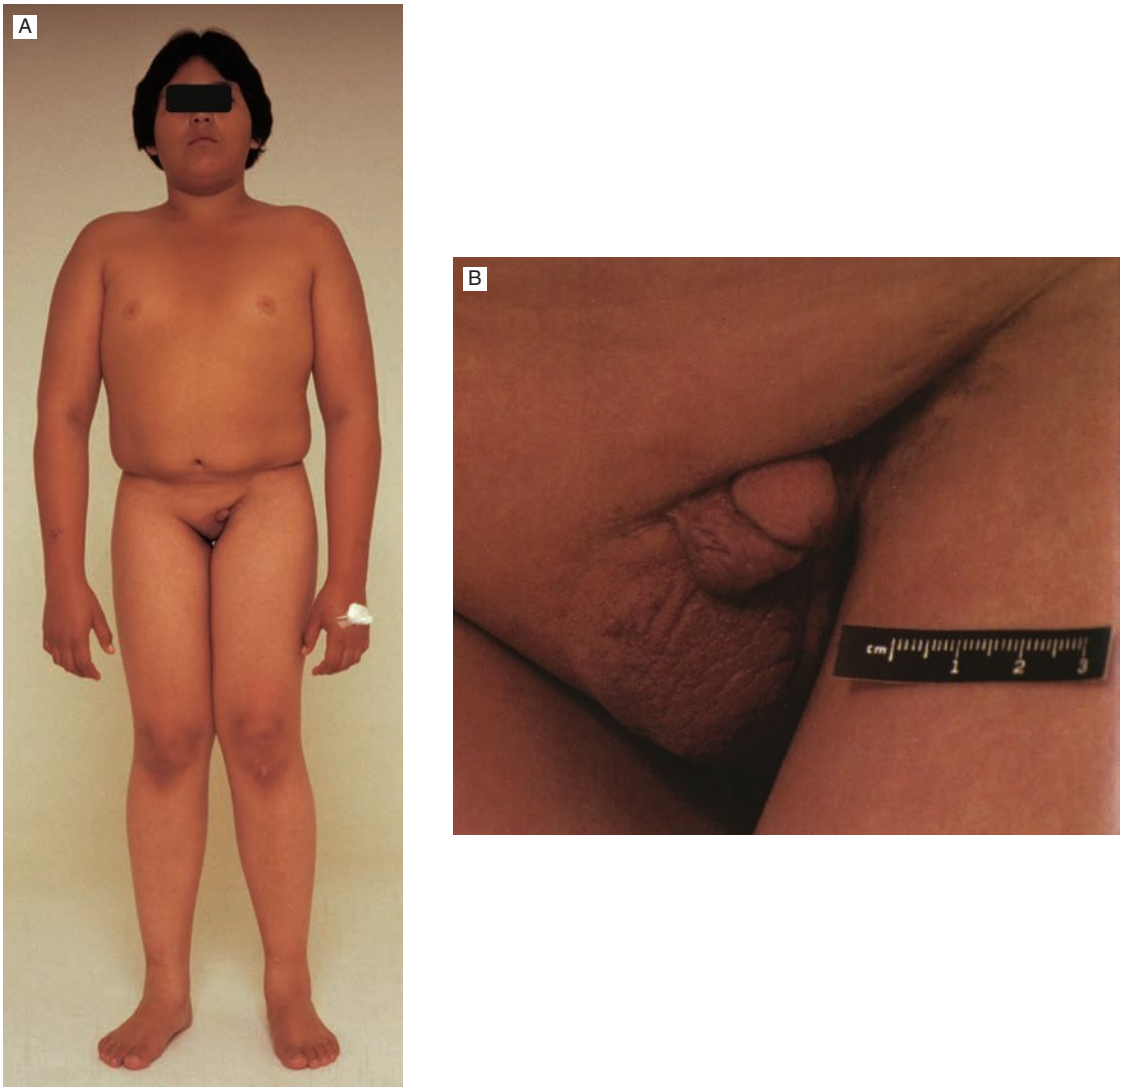

FIGURE 60–8 **A young male patient after therapeutic irradiation of the left testicle for a testicular tumor. Note the loss of body hair, hypogonadal facial puffiness, decreased muscle mass, and increased body fat (A). The left testicle was small and firm (B). The patient was infertile.**

In adults who have undergone cranial irradiation with more than 20 Gy, clinical monitoring with measurement of serum cortisol, ACTH, free T_4, IGF-1 (if the patient is a candidate for GH replacement), prolactin, LH, FSH, and serum testosterone and documentation of menstrual history should be undertaken annually for 15 years and then every 2 years for another 15 years.[123] The 1-µg cosyntropin stimulation test has been proposed to screen central adrenal insufficiency in cancer survivors who received more than 30 Gy of radiation to hypothalamic and pituitary areas.[183]

Thyroid Disorders

Careful physical examination should be performed annually for recipients of head and neck radiation to detect thyroid nodules, and if any are detected, a more detailed examination should be performed using ultrasound and, if necessary, fine-needle aspiration biopsy. Because multitarget TKIs can cause thyroid dysfunction, thyroid hormone levels should be checked before treatment begins. During treatment, thyroid hormone levels should be checked periodically to adjust thyroxine replacement. Multitarget TKIs can cause new-onset hypothyroidism or increase the levothyroxine requirements in patients on chronic thyroid hormone replacement.

Bone Health

In survivors of childhood malignancies, bone mass may be assessed in the early 30s, an age at which peak bone mass has been attained in most people. It is also important to consider the possibility of bone loss in androgen- or estrogen-deficient adults. If bone mass is normal, no further evaluation is needed beyond the usual recommendations for prevention of osteoporosis. In those with low bone mass, an active program of calcium and vitamin D supplementation, exercise, and occasionally, medical therapy (bisphosphonates or recombinant PTH) should be combined with assessment of bone mass every 12 to 18 months.

Patients who have been treated with chemotherapeutic agents that cause hypophosphatemia, hypomagnesemia, or hypocalcemia, such as ifosfamide, platinum compounds, fludarabine, or estramustine, are particularly at risk for osteomalacia and should undergo an evaluation of serum calcium, phosphorus, magnesium, alkaline phosphatase, and vitamin D metabolite levels. Those who have been treated with aromatase inhibitors should have BMD measurements before and during treatment and should be given calcium and vitamin D. Patients can be given bisphosphonates if deemed necessary.

MD ANDERSON PRACTICE TIPS

- Most endocrine glands are controlled by feedback systems. In a functional endocrine system, extreme hormone levels (deficiency or excess) should lead to extreme responses by negative feedback. Example, we see elevated TSH when the free T_4 levels are low. Abnormality in the feedback signal helps distinguish between primary and secondary endocrine dysfunction. Some hormones are secreted with circadian rhythmicity such as cortisol and testosterone with highest levels in the morning. For proper assessment, testing should be done at the appropriate time to include the complete axis. For example, cortisol along with ACTH should be done at 8 am.
- Many drugs can interfere with endocrine testing, resulting in an incorrect diagnosis. Steroids are frequently used in oncologic practice and can interfere with cortisol testing both as a result of endogenous hormone suppression and assay interference. Hence, cortisol testing is not recommended when the patient is being treated with steroids. The medications have to be held for an appropriate duration of time before testing.
- It is important to check C-peptide and glucose levels in patients with new-onset hyperglycemia and any signs and symptoms of insulin deficiency such as weight loss, polyuria, or polydipsia while on immune checkpoint inhibitor therapy and send urgent referral to endocrinology service for evaluation and management.
- It is important to screen patients for underlying adrenal insufficiency before initiating treatment for hypothyroidism in patients with immunotherapy-induced hypophysitis and multiple hormone deficits. If a patient has both secondary adrenal insufficiency and secondary hypothyroidism, steroid replacement therapy should be initiated first to prevent adrenal crisis that can occur with increased metabolism from initiating thyroid hormone.
- Bone targeting therapies such as bisphosphonates and denosumab can cause severe hypocalcemia in the setting of vitamin D deficiency. Hence, it is always recommended that the patient be screened for vitamin D deficiency and treated appropriately while receiving these agents.
- Patients with radiation-induced bone loss often have a delayed manifestation of bone loss, which can occur several years after completing radiation treatment. This is especially seen in women with gynecologic cancers who have had pelvic irradiation, which puts them at higher risk to develop sacral insufficiency fractures.

61 Oncologic Emergencies

Sai-Ching Jim Yeung
Ellen F. Manzullo
Patrick Chaftari

KEY CONCEPTS

- Oncologic emergencies can result from either the cancer or its treatment. This chapter discusses some selected emergencies.
- Nervous system emergencies include spinal cord compression, increased intracranial pressure, leptomeningeal disease, seizures, and altered mental status.
- Superior vena cava (SVC) syndrome, hyperviscosity syndrome, hyperleukocytosis, venous thromboembolism, hemorrhage, and disseminated intravascular coagulopathy are the vascular and hematologic emergencies discussed.
- Urologic emergencies such as hemorrhagic cystitis and obstructive uropathy are discussed.
- Pulmonary problems such as airway obstruction, massive hemoptysis, toxic lung injuries, pneumonitis, and pulmonary fibrosis can be caused by cancer or cancer treatments.
- Several classic metabolic oncologic emergencies include syndrome of inappropriate antidiuretic hormone secretion, tumor lysis syndrome, and hypercalcemia of malignancy.
- Gastrointestinal bleeding in patients with cancer and typhlitis in patients with neutropenic fever are potentially serious complications.
- Immune checkpoint inhibitors may cause immune-related adverse effects (irAEs) in practically any organ system. Urgent skin irAEs include grade 3 and 4 inflammatory dermatitis or rash, bullous dermatosis, drug reaction with eosinophilia and systemic symptoms, and Stevens-Johnson syndrome or toxic epidermal necrolysis. Gastrointestinal irAEs are common. The main pulmonary irAE is pneumonitis. Endocrine irAEs affect the thyroid, adrenal, and pituitary glands as well as the pancreatic islets (type 1 diabetes), which may be associated with acute diabetic ketoacidosis. Myocarditis is rare but may be life threatening. Pneumonitis may be associated with poor overall survival.

INTRODUCTION

Oncologic emergencies can result from either the cancer or its treatment. Patients with cancer often have immunologic, metabolic, and hematologic defects, which can lead to complex emergency conditions when they present to an emergency or urgent care center. In addition, emergencies resulting from comorbid conditions also occur in patients with cancer. It is important for practitioners who treat patients with cancer to be aware of the various oncologic emergencies so they can be recognized and treated promptly. This chapter discusses some selected emergencies, including their signs and symptoms, causes, and management.

NEUROLOGIC EMERGENCIES

Spinal Cord Compression

Spinal cord compression is a serious complication of cancer, affecting about 2.5% of patients with cancer overall.[1] It is not immediately life threatening unless it involves the first three cervical vertebrae, but compression of the spinal cord at lower levels of the spine leads to significant morbidity. The spinal cord is compressed by the cervical vertebrae in 10%, thoracic vertebrae in 70%, and lumbar vertebrae in 20% of patients. In 10% to 38% of cases, spinal cord compression occurs at multiple levels.[2] Compression is predominantly caused by metastatic tumors, with lung, breast, and prostate cancer accounting for 50% of cases. Other

tumors that commonly metastasize to the spine are multiple myeloma, renal cell carcinoma, melanoma, lymphoma, sarcoma, and gastrointestinal (GI) cancers. The mechanisms by which tumors can appear in the spine are hematogenous spread of tumor cells to the vertebral bodies, metastasis to the posterior spinal elements, epidural metastasis, and direct extension of paraspinal tumors. Spinal cord compression is caused by epidural metastases in about 75% and vertebral bony collapse in about 25% of cases.

The most common symptom of spinal cord compression is back pain, occurring in more than 90% of patients. Depending on the location of the tumor in the spinal canal, the pain can be unilateral or bilateral following dermatomal patterns. Patients typically report that their pain is exacerbated by coughing or a supine position. Motor weakness is the second most common complaint after pain; difficulty walking, buckling of the legs, and a feeling of heaviness in the legs are all frequent symptoms. Weakness of the upper extremities may be present when the spinal cord is compressed at the cervical levels. Some patients may have ataxia, which is caused by compression of the spinocerebellar tracts. The patient may have sensory symptoms, including numbness or tingling, which can progress proximally. Preexisting peripheral neuropathy must be differentiated from spinal cord compression by recognizing acute worsening and new distribution pattern of numbness or tingling. The last symptoms to appear are autonomic symptoms, such as an inability to urinate (urinary retention), and constipation. It is important to remember that the patient may present with intractable pain only, so a high level of suspicion for spinal cord compression is important in treating patients with cancer.

The physical examination usually reveals tenderness to percussion over the affected level of the spine, but the spine might not be tender if there is no bone involvement. Other possible findings are bladder distention, decreased rectal sphincter tone, and muscle weakness. The patient may have pain at a referred site; for instance, patients with T4 compression may have breast pain or chest pain, and those with L1 compression may have sacroiliac pain. Sensory changes are more difficult to diagnose than motor deficits and can either precede or accompany motor deficits. The patient might have decreased sensation in the lower extremities, which may ascend to the level of spinal cord involvement with dorsal column deficits, including loss of light touch sensation, vibration, and proprioception. When the cauda equina is compressed, the sensory changes are dermatomal with loss of sensation in the perineal area, posterior thigh, or lateral leg, depending on the spinal nerves involved.

Other than cancer, causes of spinal cord compression include degenerative spinal stenosis, spondylolisthesis (osteoarthritis), degenerative disk disease, spinal abscess, hematoma or bleeding, hemangioma, chordoma, meningioma, and neurofibroma. Magnetic resonance imaging (MRI) is the imaging technique of choice today for suspected spinal cord compression (Fig. 61–1).

Patients who are not able to undergo MRI (eg, patients with cerebral aneurysm clips, certain models of cardiac pacemakers, or magnetic implants) can undergo computed tomography (CT) myelogram, although this technique is more time consuming and tedious than MRI. Imaging study of the entire spine should be considered because spinal epidural disease is often multifocal. Findings for the whole spine can help the physician optimize the type and extent of therapy needed. For any patient with rapidly progressive neurologic symptoms, diagnostic imaging should be performed on an emergency basis.

Corticosteroid is a temporizing measure to stabilize or even improve neurologic function until definitive treatment. Conventionally, dexamethasone is initially given at 10 to 100 mg intravenously and then 4 to 24 mg intravenously or orally every 6 to 8 hours. The duration of therapy with high-dose glucocorticoids should be minimized to prevent complications of steroid use. Surgery is indicated for recurrent or progressive disease at an area with previous maximal radiotherapy, spinal mechanical instability, an unknown tissue diagnosis of malignancy, or compression of the spinal cord by bony structure or fragment. Patchell and colleagues[3] in 2005 reported the first phase III randomized clinical trial comparing the role of decompressive surgery and radiation to radiation alone. In this study, patients were initially treated with 100 mg of dexamethasone followed by 24 mg every 6 hours and then treated with radiation therapy (30 Gy in 10 fractions) alone or surgery (usually within 24 hours) followed by the same course of radiation within 2 weeks of surgery. The percentage of ambulatory patients was significantly higher in the group treated with surgery and radiation compared with radiation alone (84% vs 57%, respectively); so were their duration of ambulation (median, 122 days vs 13 days) and median survival time (126 days vs 100 days). Currently, anterior decompression with spinal stabilization is the surgery of choice, allowing removal of the affected vertebral body and stabilization above and below the vertebrae by metal hardware. For paraplegic patients with spinal cord compression, surgery with postoperative radiotherapy maximizes neurologic function and modestly prolongs survival.[4] Benefit from decompressive surgery is evident in ambulatory patients with poor prognostic factors for radiotherapy and in paralyzed patients with a single spinal area of compression, paraplegia less than 48 hours, nonradiosensitive tumors, and an expected survival period of more than 3 months. If surgery is not indicated, radiation therapy can be used for radiosensitive tumors; the most common dosage is 3000 cGy delivered in 10 fractions. The incidence of radiation-induced myelopathy

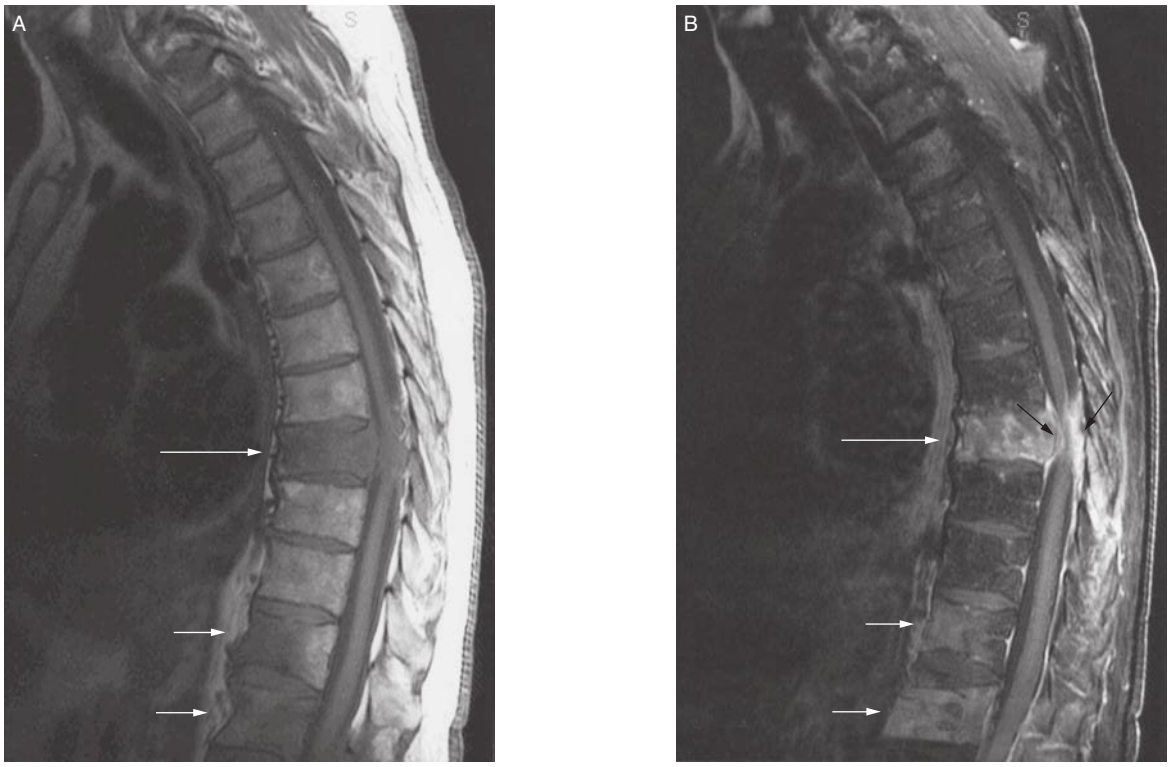

FIGURE 61–1 A. Precontrast T1-weighted magnetic resonance image (MRI) of thoracic cord compression at the T8 level produced by an epidural tumor from vertebral body metastasis (*large arrow*). *Smaller arrows* point to other sites of bony metastasis. The patient is a 67-year-old man with melanoma and back pain. B. Postcontrast T1-weighted MRI of the same patient. The epidural tumor is visualized better with contrast (*black arrows*). The white arrows are as described in A. (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)

increases with increasing total dosage of radiation and can appear from months to several years after radiotherapy. Palliative radiotherapy is recommended for those with paraplegia longer than 48 hours, expected to live for fewer than 3 months, unable to tolerate surgery, and multiple areas of compression. An ambulatory patient with a stable spine may be considered for radiation treatment only. The role of chemotherapy to treat spinal cord compression is not clear. Chemotherapy is occasionally used for chemosensitive tumors, such as Hodgkin disease, non-Hodgkin lymphoma, neuroblastoma, germ cell tumors, and breast cancer. Hormonal therapy can benefit some patients with hormone-responsive tumors, such as prostate and breast cancers. One of the most important prognostic factors at diagnosis is the patient's neurologic function. Of patients who are ambulatory at the time of presentation, approximately three fourths will be able to regain their strength with treatment. In contrast, only a small percentage of patients who are paralyzed at the time of diagnosis can walk again. This difference illustrates the importance of diagnosing spinal cord compression at an early stage. A scoring system based on tumor type, interval between tumor diagnosis and spinal cord compression, other bone or visceral metastases, ambulatory status, duration of paralysis, and so on can estimate survival.[5,6] Overall, the median survival after the first episode of spinal cord compression is about 3 months.

Increased Intracranial Pressure

Increased intracranial pressure (ICP) in patients with cancer is commonly caused by hemorrhage (from thrombocytopenia or tumor bleeding), brain metastasis with vasogenic edema and mass effect, or hydrocephalus because of obstruction of the flow of cerebrospinal fluid (CSF). Increased ICP can also be caused by tumor treatments, such as radiation therapy and surgery. The normal CSF pressure is less than 10 mm Hg. As ICP increases, herniation syndromes may develop, including uncal, central, and tonsillar herniation. Uncal herniation is caused by unilateral supratentorial lesions that push brain tissue through the tentorial notch. Signs and symptoms classically include ipsilateral pupil dilation, decreased consciousness, and hemiparesis, first contralateral and then ipsilateral to the mass. A false localizing sign dubbed the Kernohan-Woltman notch phenomenon may be a source of confusion because it manifests with hemiparesis ipsilateral to the primary brain

lesion.[7] Central herniation involves bilateral supratentorial lesions that displace tissue symmetrically and bilaterally. Signs and symptoms of central herniation include decreased consciousness leading to coma and Cheyne-Stokes respiration followed by central hyperventilation, midposition unreactive pupils, and posturing. Tonsillar herniation involves increased pressure in the posterior fossa, which forces the cerebellar tonsil through the foramen magnum, thereby compressing the medulla. Signs and symptoms of tonsillar herniation include decreased consciousness and respiratory abnormalities leading to apnea. Headache is the most frequent symptom reported in increased ICP. Headache is a common symptom in any patient population, but in patients with cancer, clinicians must always maintain a high index of suspicion for increased ICP. Headaches caused by increased ICP are typically present on waking in the morning, recur throughout the day, and are increased with Valsalva maneuver; they can be associated with nausea and vomiting, altered mental status, vision changes, seizures, or focal neurologic deficits. On physical examination, the patient may have papilledema, focal neurologic deficits, or altered mental status.

The diagnosis of increased ICP can be ascertained from a CT scan of the brain. Noncontrast CT imaging is superior to MRI in detecting acute hemorrhage (Fig. 61–2).

CT scans with contrast will usually reveal cerebral metastasis and occasionally leptomeningeal disease (LMD). Contrast-enhanced MRI is more sensitive than CT in revealing cerebral tumors as small as 3 mm (Fig. 61–3), LMD (Fig. 61–4), and early strokes (Fig. 61–5). Lumbar puncture should not be used to diagnose increased ICP because it can lead to brain herniation.

The differential diagnosis of increased ICP includes bleeding, tumor edema, hydrocephalus, postradiation effects, postradiosurgery effects, brachytherapy-induced changes, benign tumor effects, subdural hematomas, meningitis, encephalitis, and abscess formation.

Brain metastases may develop in 10% to 40% of patients with cancer and may be increasing as the survival of patients with cancer is improving.[8] LMD occurs in 5% of all patients with cancer.[9,10] Two thirds to three quarters of brain metastases are recognized as multiple lesions on MRI. Lung cancer is the neoplasm that most frequently metastasizes to the brain followed by breast cancer and melanoma. Other cancers that commonly metastasize to the brain are colorectal, kidney, prostate, testicular, and ovarian cancers and sarcomas, although any systemic cancer can metastasize to the brain. Tumors most commonly metastasize to the gray–white junction where the vessels are small and narrow, trapping tumor emboli. Eighty percent of tumors metastasize to the cerebral hemispheres, 15% to the cerebellum, and 5% to the brainstem. The tumors that are often hemorrhagic include melanoma, renal cell carcinoma, and choriocarcinoma.

FIGURE 61–2 Acute intracranial hemorrhage within the right frontoparietal lobe (*arrows*) with edema (E) in a 79-year-old woman with ovarian cancer. The hemorrhage was revealed by noncontrast computed tomography imaging. This modality is superior to magnetic resonance imaging in detecting acute hemorrhage. (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)

The treatment for increased ICP depends on the underlying cause. Infectious sources, such as meningitis, should be treated with antibiotics, and brain abscesses should be drained. Hydrocephalus should be treated with surgical shunting or ventriculostomy. Subdural hematomas should be either drained or, if small, monitored under the guidance of a neurosurgeon. Vasogenic edema associated with brain tumors is initially treated with oral or intravenous (IV) dexamethasone at a dosage of 16 to 28 mg/day in divided doses.[11] For patients with impending herniation, very large doses of IV dexamethasone can be used, initially 40 to 100 mg intravenously and subsequently 40 to 100 mg/day. Dexamethasone is the steroid of choice because of its lack of mineralocorticoid effect and therefore minimal effects on blood pressure and electrolytes. Steroid myopathy is a possible complication. Steroids may not be needed in asymptomatic brain lesions. If the ICP is increased by brain metastases and whole-brain radiation therapy (WBRT) or stereotactic radiosurgery (SRS) is planned,[12] corticosteroid therapy should be started before radiation treatment to avoid further increased in ICP.

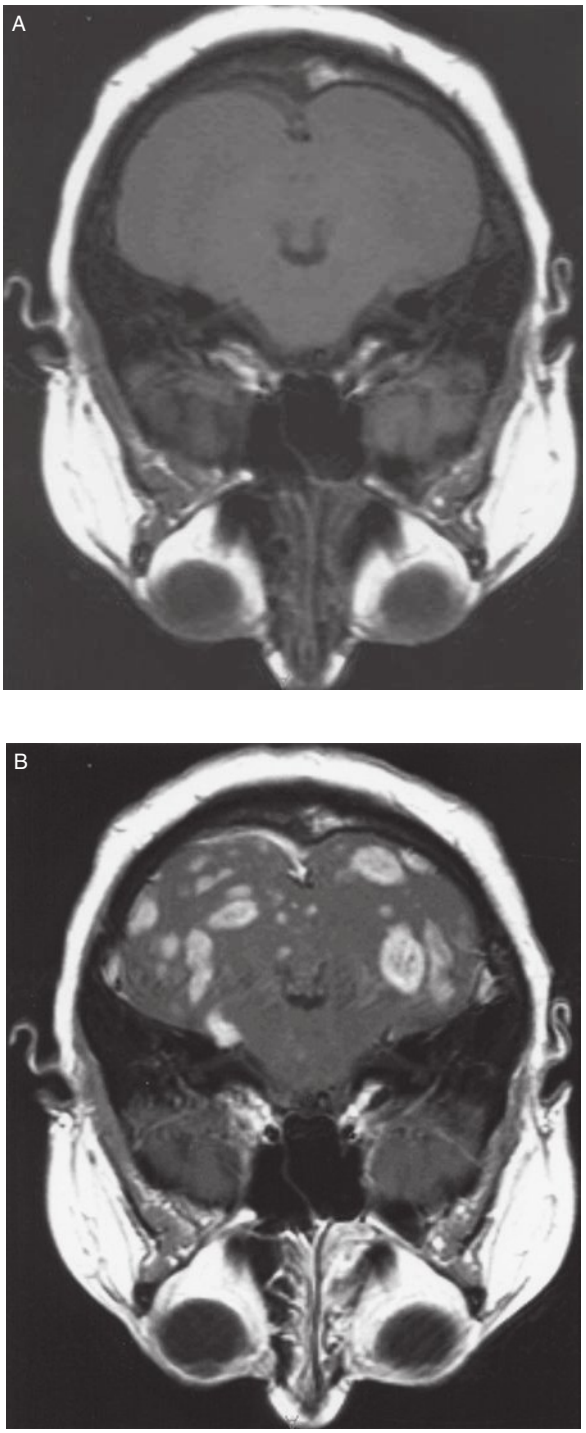

FIGURE 61–3 A. Precontrast T1-weighted magnetic resonance (images in a 40-year-old woman with breast cancer and multiple cerebellar metastases. **B.** Postcontrast images of the same patient reveal dramatic enhancement of the cerebellar metastases.

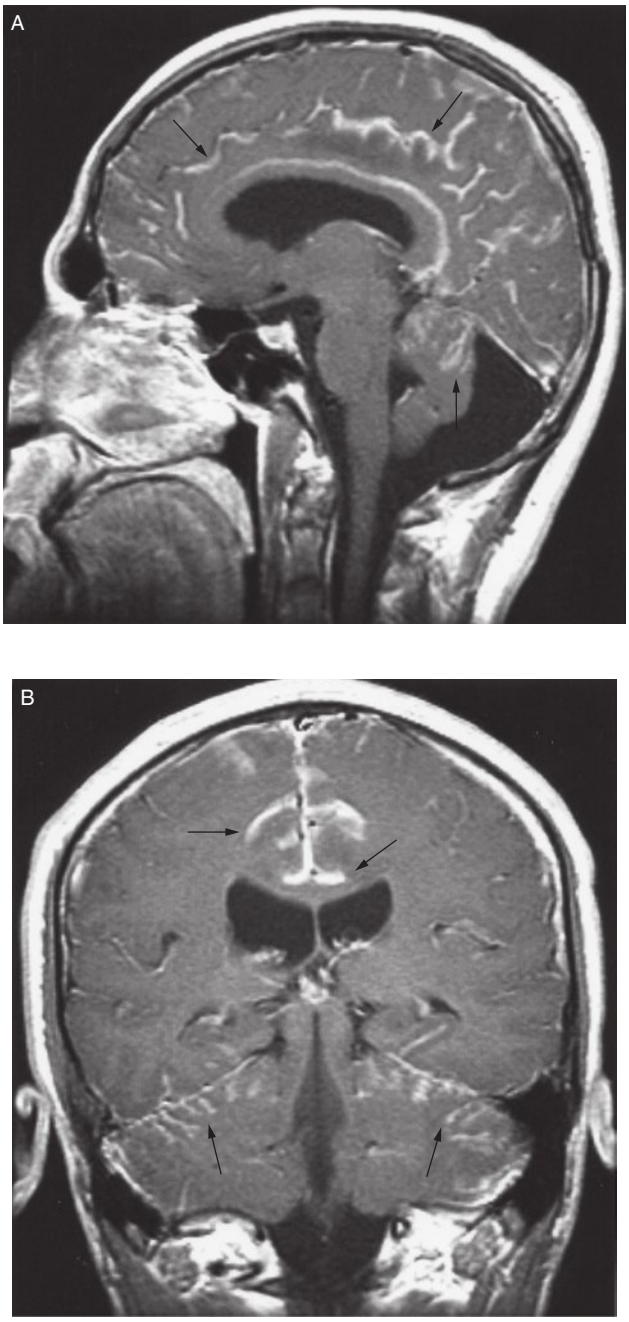

FIGURE 61–4 A. Sagittal postcontrast T1-weighted magnetic resonance image (MRI) showing subarachnoid spread of melanoma metastasis to the brain in a 29-year-old man. Abnormal enhancement of the cortical sulci (*large arrows*) and cerebellar sulci (*small arrows*) is noted. **B.** Coronal postcontrast T1-weighted MRI in the same patient. (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)

For life-threatening edema, mannitol can be used to decrease ICP in patients with an intact blood–brain barrier.[11] Mannitol is a hyperosmotic agent that can draw fluid out of the brain into the circulation; its effect can be augmented by diuretics. The recommended dosage of mannitol is a 20% to 25% solution at 0.5 to 2.0 g/kg administered IV over 10 to 30 minutes. Mannitol has a rapid onset of action and lasts for hours. Hypertonic saline IV infusion is another therapy for increased ICP. Hyperventilation can be used to decrease ICP, but it

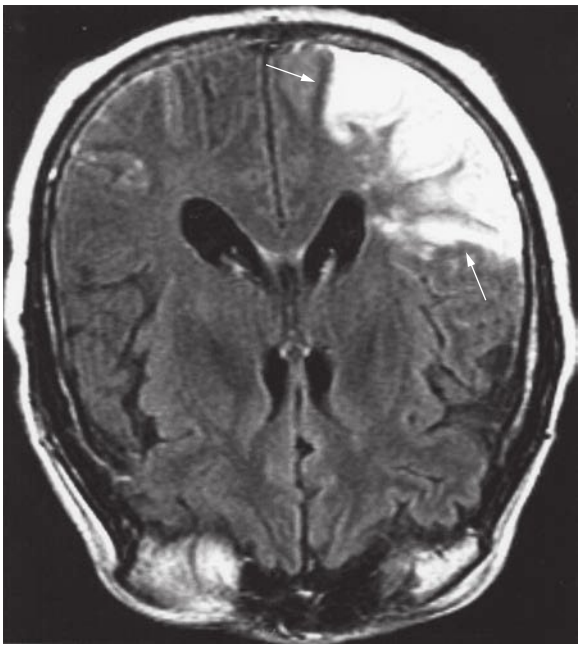

FIGURE 61–5 **Acute infarction involving the territory of the right middle cerebral artery in a 58-year-old patient with renal cell carcinoma. Magnetic resonance image (MRI; fluid-attenuated inversion recovery image) demonstrates abnormal thickening, with a T2-weighted increase in signal intensity (*arrows*) involving the right temporo-occipital lobe cortex and subcortical white matter. MRI is more sensitive than computed tomography in detecting early stroke. (Used with permission from Dr. Ashok Kumar, MD Anderson Cancer Center.)**

must be kept within the modest range of a PCO_2 of 25 to 30 mm Hg to prevent severe respiratory alkalosis.. For patients with brain lesions that are not amenable to surgery, SRS can be used in single doses as high as 1400 cGy. In a single SRS session, more than 10 brain lesions with a total volume of up to 25 mL can be treated. SRS plus WBRT may improve the overall survival in patients with brain metastasis compared with WBRT alone; however, this survival advantage may be limited to non–small cell lung cancer.[13]

Leptomeningeal Disease

LMD can involve invasion of the brain, the spinal parenchyma, the nerve roots, and blood vessels of the nervous system. LMD is commonly caused by metastatic breast and lung cancers, melanoma, non-Hodgkin lymphoma, and leukemia. Patients present with a variety of symptoms depending on the location of the leptomeninges affected, but they can include headache, altered mental status, cranial nerve palsies (in ~50% of patients), incontinence, back pain, sensory changes, seizures, isolated neurologic findings, and even a strokelike presentation.[9,14] Leptomeningeal metastases occur in 0.8% to 8% of all cases of cancer.

The diagnosis of LMD can be difficult to make. CT scans are occasionally suggestive of LMD. MRI scanning has better sensitivity than CT for detecting LMD, including leptomeningeal enhancement, hydrocephalus, and cortical nodules. However, MRI findings cannot definitively diagnose LMD because these imaging signs of inflammation of the meninges can also be found in cases of meningitis, trauma, infection, and hematoma formation. Lumbar puncture and evaluation of the CSF are the gold standard for diagnosing LMD, but multiple lumbar taps may be required to make the diagnosis because only 50% of patients have positive cytologic evidence of LMD on the first CSF evaluation. CSF findings consistent with LMD include a high opening pressure, low glucose and high protein levels, and a mononuclear pleocytosis.[9] Among patients with normal values for CSF protein, glucose, opening pressure, and cytology negative for LMD, fewer than 5% have LMD.

The treatment of patients with LMD can include chemotherapy through an implanted subcutaneous reservoir and ventricular catheter or through lumbar puncture instillation. Lumbar tap administration does not require placement of a catheter, but 10% to 15% of the subarachnoid space might be missed using this technique. Chemotherapeutic agents frequently used are methotrexate and thiotepa. Cytarabine can also be used in patients with leukemias and lymphomas, but it is generally not effective against solid tumors. Radiation therapy is commonly used for localized LMD or in areas of nerve root involvement where intrathecal chemotherapy is not likely to reach adequate concentrations.[14] Fixed neurologic deficits caused by LMD are not likely to improve with therapy, but encephalopathy may. The prognosis of patients with LMD is very poor, with a median survival time of 2 to 4 months and only a 15% to 25% chance of surviving more than 1 year.

Seizures

Seizures are the presenting symptom in 15% to 20% of patients with brain metastases. In patients with cancer presenting with seizures, metabolic, infectious, and coagulopathic causes should also be considered.[15] The initial laboratory work should include analysis of glucose level, electrolytes, blood urea nitrogen (BUN), creatinine, liver enzymes, calcium, urine analysis, lactic acid, prothrombin time (PT), activated partial thromboplastin time, and toxicology screening if indicated

Patients can have seizures during withdrawal from high-dose, short-acting benzodiazepines (eg, alprazolam), alcohol withdrawal, antibiotics (eg, the carbapenems), pain medicines (eg, meperidine), and many other medicines. The patient's family can be helpful in sorting out the etiology of seizures by providing

information about the patient's medications, social history, and preceding symptoms, such as fever or headache. CT without and with contrast is also helpful and can identify increased ICP, bleeding, or brain metastasis. Electroencephalography is also helpful in the evaluation of seizures and can determine whether an epileptic focus is present. Lumbar tap can be helpful if the seizures are believed to be secondary to infection or LMD, but this procedure should not be performed in patients with suspected increased ICP because of the risk of cerebral herniation.

Status epilepticus occurs when a patient has prolonged seizures lasting more than 30 minutes or recurrent seizures without full recovery of consciousness between seizures.[2,15,16] Initial care for patients with status epilepticus includes placing the patient in a safe environment, administering 100% oxygen by nonrebreather mask, monitoring with a continuous-pulse oximeter providing suction, and administering IV fluids (normal saline). Priority should be placed on protecting the airway and extinguishing the seizure, which can be treated initially with IV benzodiazepines (eg, diazepam, 0.2 mg/kg at 5 mg/min, up to 10 mg, or lorazepam, 0.1 mg/kg at 2 mg/min, up to 4 mg). For persistent seizures, fosphenytoin or phenytoin can be administered intravenously. Fosphenytoin can be given more rapidly and causes less hypotension than phenytoin, but continuous cardiac and blood pressure monitoring should be instituted during IV administration of 15- to 20-mg phenytoin equivalents per kilogram. Patients with persistent seizures might require intubation and sedation with phenobarbital (20 mg/kg intravenously at 100 mg/min) or other agents, such as pentobarbital or a midazolam drip. At this point, the patient requires careful monitoring and intensive care unit (ICU) care.

It is the general consensus that routine use of prophylactic antiepileptic drugs (AEDs) for patients with brain metastases who have not experienced a seizure is not indicated.[17] After seizures have been controlled, the patient should be placed on an AED. Several drugs can be used; among them are phenytoin, carbamazepine, clonazepam, gabapentin, lamotrigine, phenobarbital, primidone, topiramate, and valproate. For many of the newer AEDs, the serum drug levels do not need to be monitored. For medicines in which effective and safe levels have been defined, such as phenytoin, carbamazepine, phenobarbital, and valproate, the levels should be monitored carefully to limit toxic effects and maintain an effective preventive drug concentration.

Altered Mental Status

Altered mental status is a common neurologic complaint in patients with cancer, with metabolic encephalopathy being the most common cause.[18] Altered mental status can range from a slight decrease in normal intellectual functioning to coma. The patient's mental status may change in response to several factors, such as infections, metabolic derangements, bleeding, medications, hypoxemia, cancer therapies, paraneoplastic neurologic syndromes, and intracranial events, such as brain metastases.[19] Organ failure, whether hepatic, renal, adrenal, thyroid, or pulmonary, can also produce fluctuations in mental status. The most common metabolic deficiencies causing such alterations are hyponatremia, hypercalcemia, hypoglycemia, and vitamin B1 deficiency. The causes of altered mental status are numerous; an extensive history and physical examination can help to identify the underlying cause and determine appropriate therapy. The differential diagnosis and diagnostic evaluation are beyond the scope of this chapter, but a few entities are unique to patients with cancer.

For instance, cancer therapy is a common cause of altered mental status. Many neurologic manifestations, such as dementia, cognitive decline, and encephalopathy, can result from chemotherapy. Cancer immunotherapy can cause immune-mediated complications in the central nervous system (CNS). Table 61–1 highlights some of the common neurologic complications of chemotherapy.

Radiation therapy can also cause complications, among them leukoencephalopathy, radiation necrosis, and decreased memory and mental functioning. (The preceding section on increased ICP provides a fuller discussion of the cognitive side effects of radiation therapy.) Other possible causes of cognitive decline are narcotics (commonly prescribed for pain), infections (pneumonia, sepsis, urinary tract infection), and cerebral infarction.

CARDIAC EMERGENCIES

Cardiac Tamponade

Tumors involving the heart are much more frequently metastatic than primary. The tumors that most often metastasize to the heart are lung, breast, and GI tract cancers; leukemia; lymphoma; melanoma; and sarcoma. Metastatic involvement of the heart has also been noted in patients with leukemia and lymphoma. Certain therapies can also affect the myocardium and cause pericardial disease, such as cyclophosphamide and ifosfamide at high doses, all-*trans* retinoic acid (ATRA), and doxorubicin. Cardiac tamponade occurs when pericardial fluid accumulates and presses on the heart, increasing diastolic pressure in the ventricles and thereby decreasing stroke volume. The patient develops decreased cardiac output and systemic arterial pressure and can present with a shocklike syndrome. Most patients with pericardial

effusions report no symptoms, but patients with cardiac tamponade present with shortness of breath, cough, hoarseness, epigastric pain, or chest pain that is made worse by lying down or leaning forward. On examination, the patient typically has distended neck veins, low systemic blood pressure, and decreased heart sounds (Beck's triad) with a low pulse pressure. Patients can also have a pericardial rub. The presence of pulsus paradoxus, which is an inspiratory decline in systolic blood pressure of more than 10 mm Hg, should be ruled out. Pulsus paradoxus can also occur in chronic obstructive pulmonary disease, pulmonary embolism (PE), right ventricular infarction, and shock. Chest radiographs often reveal a "water bottle" configuration if the effusion has accumulated slowly, but the cardiac silhouette can appear normal if the effusion accumulates rapidly. Prior chest radiographs can be useful in determining changes in the size of the cardiac silhouette. The electrocardiogram (ECG) might reveal electrical alternans (a variation of voltage in individual QRS complexes) and low-voltage or ST-segment and T-wave changes. Transthoracic echocardiography is the best test to determine whether tamponade exists. If cardiac tamponade is present, echocardiography can help determine whether the effusion is localized or loculated, and it can also aid in planning pericardiocentesis. On echocardiograms, tamponade can be evidenced by collapse of the right ventricle and atria in diastole (Fig. 61–6).

Treatment of patients with tamponade includes the administration of oxygen, IV fluids, and vasopressors if necessary. Pericardiocentesis can be performed under ultrasound guidance and is relatively safe. At MD Anderson Cancer Center (MDACC), a drainage catheter is commonly placed in patients with tamponade, with drainage performed daily. When the total volume of fluid drained is less than 50 mL/day, the catheter can be removed. A pericardial window can also be created to prevent reaccumulation of fluid. Radiation therapy and chemotherapy can also be used to prevent reaccumulation of fluid, as can sclerosis of the pericardial sac.

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome is characterized by low blood flow from the SVC to the right atrium. Malignancy is by far the most common cause of SVC syndrome, although nonmalignant causes, such as indwelling central venous catheters, aneurysms, and goiters, can also cause this syndrome. Lung cancer is the most common malignant neoplasm causing SVC syndrome, but lymphoma, breast and GI cancers, sarcomas, melanomas, prostate cancer, and any mediastinal tumor can also cause this disorder. Among mechanisms that can lead to this syndrome are extrinsic compression by tumor, intrinsic compression by tumor or clot, or fibrosis. Patients may present with headache; dizziness; confusion; swelling of the upper extremities, face, and neck; shortness of breath; and dysphagia. Physical examination often reveals engorgement of veins and collaterals in the upper extremities caused by elevated pressure in the venous system.

Diagnosis of SVC syndrome requires imaging. Routine chest radiographs often reveal mediastinal widening, a right-sided chest mass, or a mediastinal mass. CT scanning of the chest using IV contrast is an excellent means of delineating the cause of the obstruction and any associated finding (Fig. 61–7). MRI, Doppler ultrasound, and radionuclide venography can be used to exclude the presence of a clot.

The treatment of SVC syndrome depends on the nature of the obstruction. Patients might respond to elevation of the head, corticosteroids if the ICP is increased, and occasionally diuretics. If thrombosis is present, local lytic therapy or anticoagulation can be used. It is important to obtain a tissue specimen of the tumor if its type is not known, so that it can be treated adequately. For patients with tumors that are chemosensitive, such as small cell lung cancer, chemotherapy can be instituted. Patients with non–small cell lung cancer often respond to radiation therapy. Intravascular stenting is effective and can provide prompt symptom relief.[20]

Myocardial Ischemia

Patients with cancer may present to the emergency center with myocardial ischemia.[21] A full discussion of ischemic heart disease is beyond the scope of this chapter, but there are special considerations in patients with cancer that should be mentioned.

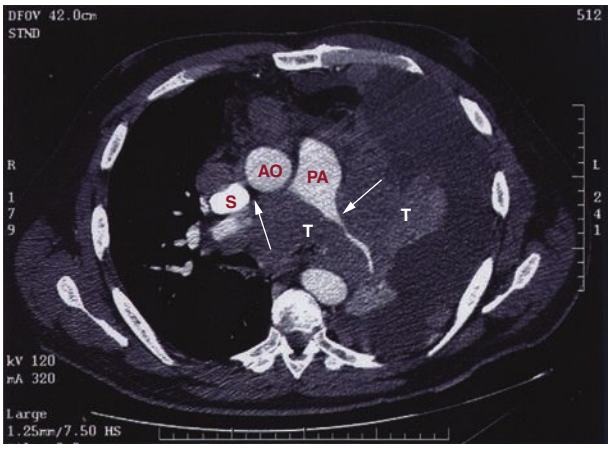

FIGURE 61–7 **Computed tomography scan revealing superior vena cava (SVC) syndrome from extrinsic compression of the SVC in a patient with non–small cell lung cancer. The *large arrow* indicates compression of the left pulmonary artery; the *small arrow* indicates obliteration of the right pulmonary artery. AO, aorta; PA, main pulmonary artery; S, superior vena cava; T, tumor. (Used with permission from Joel Dunnington, MD Anderson Cancer Center.)**

Many patients with cancer have thrombocytopenia caused by chemotherapy, radiation therapy, or bone marrow infiltration with tumor. Despite platelet counts in the single or double digits, these patients can still present with acute cardiac syndrome. Although the practitioner might feel uncomfortable giving aspirin to these patients, cardiologists at MDACC have found that patients with platelet counts less than 50,000/μL who have cardiac ischemia and are treated with aspirin have a better 24-hour survival rate than those who are not given aspirin.[22]

Certain chemotherapeutic agents can predispose patients to myocardial ischemia, including 5-fluorouracil (5-FU) and presumably capecitabine, which is a metabolite of 5-FU.[23] Radiation therapy can also be a predisposing factor for coronary artery disease. It is important to consider myocardial ischemia in patients who have undergone any of these therapies, especially those who otherwise have no risk factors for ischemic heart disease.

The cardiac markers troponin, creatine phosphokinase (CPK), and CPK-MB (creatine phosphokinase myocardial band) are useful in diagnosing myocardial infarction. Cardiac troponins are more sensitive and specific markers for ischemic heart disease than CPK-MB, which can be influenced by skeletal muscle injury; however, cardiac troponin levels can also be raised by chronic renal insufficiency, cardiomyopathy with severe congestive heart failure, myocarditis, and PE. For patients with PE, increased cardiac troponin is associated with increased right ventricular dilation (right ventricular–to–left ventricular ratio >1.2) and increased severity of hemodynamic consequences.[24] In patients with small increases of troponin, PE can be the cause rather than ischemic heart disease; this possibility should be considered in patients presenting with chest pain.

HEMATOLOGIC EMERGENCIES

Hyperviscosity Syndrome

Hyperviscosity syndrome is caused by abnormally high concentrations of paraproteins in the serum, which increase viscosity and cause red blood cell (RBC) sludging and low oxygen delivery to the tissues. This disorder occurs in 15% of patients with Waldenstrom macroglobulinemia, which is characterized by the presence of high molecular-weight (immunoglobulin [Ig] M) macromolecules and thus predisposes patients to this syndrome. Aggregation of IgG macromolecules and polymerization of IgA macromolecules, as well as purely light-chain myeloma are also capable of causing this syndrome.[25] Other conditions that can cause hyperviscosity syndrome are polycythemia vera, dysproteinemias, and occasionally leukemias.

Hyperviscosity syndrome can present with either bleeding because of abnormal platelet functioning or thrombosis caused by hyperviscosity. Visual complaints, headache, dizziness, alterations in mental status, and mucosal bleeding are all symptoms of hyperviscosity syndrome. Patients can also develop retinal hemorrhages, congestive heart failure caused by increased plasma volume, peripheral neuropathy, weakness, and fatigue.[25] Funduscopic examination can reveal venous dilatation, retinal vein occlusion, or papilledema (Fig. 61–8).

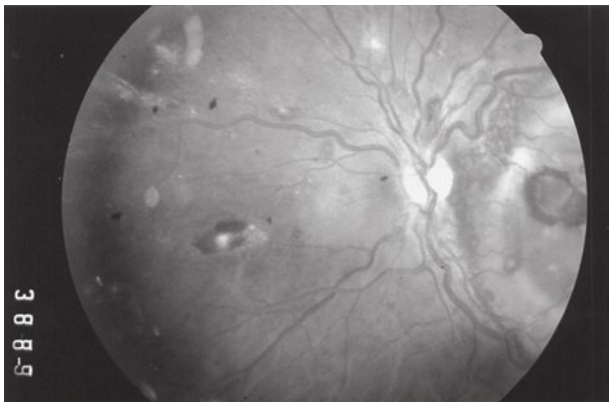

FIGURE 61–8 **Funduscopic examination revealing a Roth spot (the white-centered retinal hemorrhage). The Roth spot is the hallmark of leukemic retinopathy. (Used with permission from Dr. Bita Esmaeli, MD Anderson Cancer Center.)**

The diagnosis is made on the basis of a high serum viscosity. Normal serum viscosity ranges between 1.4 and 1.8 Ostwald units (relative to water, at 1). Patients start to develop symptoms when serum viscosity exceeds 4.0 Ostwald units.[26] The treatment for hyperviscosity syndrome includes the administration of IV fluids followed by diuresis. Plasma exchange can decrease symptoms quickly and can be followed by chemotherapy.[26]

Hyperleukocytosis

Hyperleukocytosis is typically defined as a white blood cell (WBC) count in the peripheral blood higher than 100,000/μL.[27] Acute myelogenous leukemia (AML), chronic myelogenous leukemia, and less frequently (because of the smaller size of the lymphocytes) acute and chronic lymphocytic leukemia are associated with leukostasis. From 5% to 30% of adult patients with acute leukemias present with leukostasis that requires prompt recognition and initiation of therapy to prevent respiratory failure or intracranial hemorrhage. The WBC count in patients with acute lymphocytic leukemia typically must be greater than 400,000/μL before leukostasis develops. The highest rate of mortality is in patients with AML who have high blast counts.

Symptoms of hyperleukocytosis are headache, dizziness, vertigo, shortness of breath, altered mental status, and hemoptysis. WBCs are poorly deformable and can become lodged in the microvasculature of the kidneys, lungs, brain, and other organs. The pulmonary and neurologic systems are most critically affected in hyperleukocytosis syndrome. In the lungs, WBCs can get caught in the pulmonary circulation, causing adult respiratory distress syndrome (ARDS), or can mimic PE because of WBC stasis in the pulmonary vasculature, thereby causing a ventilation/perfusion mismatch. Patients with the latter condition should not be given diuretics because they further increase stasis. Most patients with leukemia are anemic; this condition can offset the WBC elevation, so hyperviscosity is not as common in these patients. It is important not to give these patients blood transfusions unless absolutely necessary because this treatment can exacerbate hyperleukocytosis and increase the blood cell mass without changing the total blood volume. Patients can present with altered mental status, which can be caused by endothelial leakage from the small vessels of the brain or hemorrhage, but other causes of altered mental status should also be considered, including infection, LMD, and metabolic sources. Imaging studies, such as CT or MRI, as well as lumbar tap should be performed when indicated.

The treatment of patients with hyperleukocytosis involves lowering the WBC count, which can be accomplished with leukapheresis or chemotherapy. Leukapheresis can lower the WBC count by 30% to 60% from pretreatment levels. These effects can be transient; therefore, repeat leukapheresis might be necessary. Patients undergoing leukapheresis should also be monitored closely to prevent tumor lysis syndrome (TLS).

Thrombosis

Venous thromboembolism (VTE) is influenced by Virchow triad: venous stasis, higher-than-normal coagulability, and intimal injury. Patients with cancer have a high risk of VTE, and up to 15% of patients develop VTE because of hypercoagulability, the use of central venous catheters (vascular injury), and venous stasis (Virchow's triad).[28] Patients with cancer can have increased serum viscosity because of dehydration or, less frequently, hyperviscosity syndrome (described previously). Stasis and intimal injury can be caused by numerous events—for example, tumor encroachment on blood vessels or indirect effects of cancer, such as spinal cord compression, brain metastasis, dehydration, or impaired ambulation. Some chemotherapeutic cancer agents can also induce VTE; among them are tamoxifen, cisplatin, cyclophosphamide, methotrexate, and 5-FU.

Symptoms of PE include chest pain, shortness of breath, palpitations, and syncope. ECG findings can include T-wave inversion in the precordial leads, sinus tachycardia, right bundle branch block, or rightward shift of the QRS axis. Chest radiographs can be normal or might reveal a pleural effusion or elevation of the diaphragm on the involved side. Physical examination can reveal tachypnea, tachycardia, and leg edema or erythema in the case of associated deep vein thrombosis (DVT).

Diagnosis of PE can be made by spiral CT angiography (currently the most commonly used method), radionuclide perfusion/ventilation (V/Q) scan, pulmonary angiography, or MRI (Fig. 61–9).

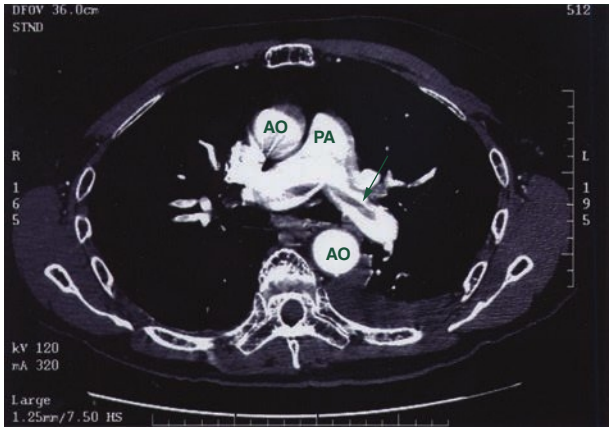

FIGURE 61–9 **Spiral computed tomography angiogram in a patient with a saddle pulmonary embolism (*arrow*). AO, aorta; PA, main pulmonary artery. (Used with permission from Joel Dunnington, MD Anderson Cancer Center.)**

Table 61–2 Heparin Dosage Schedule for Venous Thromboembolism

Low-molecular-weight heparin	
Enoxaparin	1 mg/kg SC every 12 hours or 1.5 mg/kg SC every 24 hours
Dalteparin	200 IU/kg SC every 24 hours or 100 IU/kg SC every 12 hours; maximum dosage, 18,000 IU
Tinzaparin	175 anti-Xa activity IU/kg SC every 24 hours
Unfractionated heparin	80-IU/kg IV bolus, with a maintenance IV dose of 18 IU/kg/day (adjusted to keep PTT at 1.5–2.5 times the normal range)

PTT, partial thromboplastin time; SC, subcutaneously.

Clinical suspicion based on the patient's risk factors and results of other tests can guide the clinician regarding the patient's pretest probability of PE. Spiral CT scanning and MRI can detect segmental PE but not necessarily subsegmental PE. Both of these tests are useful in that they give further information about the condition of the lung, such as whether pneumonia is present, tumor size, and impingement on the bronchial airways; this additional information is helpful in determining the cause of the patient's symptoms. Pulmonary angiography remains the gold standard in detecting PE, although it requires more dye than other contrast methods and a greater risk of renal complications. The alveolar-arterial gradient (A-a gradient) from an arterial blood gas (ABG) can serve to corroborate the diagnosis of PE. In the PIOPED (Prospective Investigation of Pulmonary Embolism Diagnosis) study, ABG results were normal in 14% of patients with preexisting cardiopulmonary disease and in 38% of patients with no underlying cardiopulmonary disease despite the presence of pulmonary emboli.[29]

The diagnosis of DVT can be made by Doppler ultrasound, impedance plethysmography (IPG), venography, nuclear venogram, or magnetic resonance venography

The D-dimer test can also be used in the evaluation of VTE; normal results are associated with a significantly lower likelihood of VTE than high value, but are not helpful in patients with leukemia or lymphoma.[30] D-Dimer has a high negative predictive value for PE in patients with cancer, and a normal D-dimer can be used to exclude PE in patients with cancer. Because D-dimer is commonly high in patients with cancer, an elevated D-dimer is not useful in diagnosing VTE. The American College of Physicians guideline for PE has good sensitivity for detecting PE in patients with cancer, and using these guidelines in patients with cancer with suspected PE may reduce unnecessary imaging and laboratory tests.[31]

First-line treatment for VTE consists of either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH). LMWH has the advantage that factor Xa levels usually do not have to be monitored because protein binding is low. LMWH also has a longer half-life than UFH and thus can be given less frequently (once or twice per day). The LMWHs enoxaparin, tinzaparin, and dalteparin are all different and cannot be used interchangeably. Monitoring may be required for patients with obesity and renal insufficiency because LMWH is cleared by the kidneys. When monitoring is necessary, the Xa level should be measured 4 hours after the injection, with a target level ranging from 0.6 to 1.0 IU/ mL for twice-daily dosing. For daily dosing, the Xa level should range between 1.9 and 2.0 IU/mL. For patients who will be transitioned to warfarin treatment, there should be an overlap of at least 5 days with LMWH. Although VTE can often be treated on an outpatient basis, patients not eligible for outpatient treatment are those with active bleeding, major comorbid illnesses, a history of heparin-induced thrombocytopenia, hypertensive emergencies, major surgery or trauma within the previous 2 weeks, recent GI bleeding, stroke or transient ischemic attack, severe renal dysfunction, or a platelet count below 50,000/μL. Table 61–2 shows the dosing schedule.

Most patients are treated for at least 3 to 6 months. Patients from whom the central venous catheter has been removed can undergo repeat testing using such techniques as Doppler ultrasound or nuclear venous flow study to determine whether the clot has resolved, so that cessation of anticoagulation therapy may be considered. For patients with small clots at the distal tip, manifested by the inability of the central line to work, tissue plasminogen activator can be given carefully provided that there are no contraindications.

Inferior vena cava (IVC) filters can be used for patients who cannot tolerate anticoagulation therapy or poor response or failure of optimal anticoagulation therapy. IVC filters do not decrease peripheral edema from DVT and, in fact, can serve as a nidus for further clot formation. Although IVC filters can prevent life-threatening PE, long-term complications can be significant in cancer survivors and end-stage patients with cancer may gain little benefit. Patients with massive PE may require thrombolysis or embolectomy. See Table 61–3 for a synopsis of the relative and absolute contraindications for thrombolytic therapy and Table 61–4 for thrombolytic doses.

Patients with cancer and VTE should be treated indefinitely if the cancer remains active or for at least 3 to 6 months after resolution of the VTE if the cancer is no longer active.[32] Patients who are treated with warfarin but who experience warfarin failure

Table 61–3 Absolute and Relative Contraindications to Thrombolysis

Absolute Contraindications to Thrombolysis
Major intracranial surgery or trauma within prior 2 months
Cerebrovascular hemorrhage within prior 3–6 months
Active intracranial neoplasm
Major internal hemorrhage within prior 6 months
Severe bleeding diathesis, including those associated with severe liver or renal disease
Relative Contraindications to Thrombolysis
Prolonged cardiopulmonary resuscitation
Pregnancy or postpartum period within prior 10 days
Nonhemorrhagic stroke within prior 2 months
Major trauma or surgery (excluding that of the central nervous system) within prior 10 days
Thrombocytopenia (platelet count <100,000/mm^3)
Hemorrhagic retinopathy
Allergies to thrombolytic agents
Minor surgery to noncompressible vessels within prior 10 days
Tissue biopsy within prior 10 days
Peptic ulceration within prior 3 months
Infective endocarditis or pericarditis
Uncontrolled hypertension (systolic BP ^{3}200 mm Hg or diastolic BP ^{3}110 mm Hg)
Aortic aneurysm

BP, blood pressure.

as evidenced by the recurrence or progression of clot formation can be switched to LMWH.[32] Direct oral anticoagulants (DOACs) reduce the risk of venous and arterial thromboembolism in large randomized clinical trials and provide oral alternatives for anticoagulation in patients with cancer. Apixaban, edoxaban, and rivaroxaban are efficacious in patients with cancer, but DOACs are associated with increased risk of bleeding, especially in GI tract or urinary tract patients with cancer. For starting anticoagulation using DOACs in the emergency department, rivaroxaban (15 mg orally twice daily for 21 days; then 20 mg daily) or apixaban (10 mg orally twice daily for 7 days; then 5 mg twice daily) are two options. The choice of anticoagulant for patients with cancer should consider individualized bleeding and thrombotic risks, drug interactions, and patient preferences.[33]

Aspiration mechanical thrombectomy is likely an efficacious treatment for patients with massive and submassive PE and contraindications to thrombolysis.[34] Surgical thrombectomy should be used for patients with massive PE who are hemodynamically unstable and who either have contraindications for thrombolytic therapy or have previously failed thrombolytic therapy. Catheter-based embolectomy methods and surgical thrombectomy both can improve hemodynamics, and the clinical outcomes may be comparable. The choice of therapy will need to consider the local expertise and experience, potential need for periprocedure support, and surgical risk of the patient.[35]

Table 61–4 Dosages of Thrombolytics

Streptokinase	250,000 IU IV load over 30 min; then 100,000 IU/hr for 24 hours for pulmonary embolism or 72 hours for DVT
Urokinase	4400 IU/kg IV load over 10 min; then 4400 IU/kg/hr for 12 hours
Alteplase	100 mg IV infusion over 2 hours; initiate heparin at the end of alteplase infusion

DVT, deep venous thrombosis; IV, intravenous.

Bleeding

Bleeding in patients with cancer is most commonly caused by thrombocytopenia induced by chemotherapy, marrow infiltration, disseminated intravascular coagulopathy (DIC), extensive radiation therapy, splenic sequestration, peripheral destruction, or infection. Thrombocytopenia usually manifest as mucocutaneous bleeding, such as gum oozing, epistaxis, and

gynecologic or GI bleeding. At MDACC, all patients generally receive platelet transfusions if their platelet count falls to 10,000/μL or below in patients without active bleeding or less than 50,000/μL with active bleeding. The American Society of Clinical Oncology (ASCO) recommends prophylactic platelet transfusions for patients being treated for leukemia and those receiving bone marrow transplants if their platelet counts are below 10,000/μL. A patient will also receive a platelet transfusion if an invasive procedure is planned and his or her platelet count is below 50,000/μL. Transfusion thresholds may be higher for patients with fever, hyperleukocytosis, a rapid fall in platelet count, coagulation abnormalities, or active bleeding. ASCO recommends that patients with chronic stable thrombocytopenia who are not undergoing active treatment, such as those with aplastic anemia and patients with myelodysplastic syndrome, be monitored and given platelets only for active bleeding even if their platelet counts are below 10,000/μL. For patients with solid tumors, prophylactic platelet transfusions should be given if the platelet counts are below 10,000/μL unless the tumor is necrotic or is located in the bladder and undergoing treatment; in those cases, the threshold for transfusion should be 20,000/μL. According to ASCO's guidelines, platelet counts of 50,000/μL should be sufficient for invasive procedures, such as surgery. For lumbar puncture, the platelet count should be above 20,000/μL. Patients with AML commonly receive multiple transfusions and can develop alloimmunization against human leukocyte antigens (HLAs). Approximately 25% to 35% of patients with AML will become alloimmunized and refractory to nonhistocompatible platelet transfusions, predominantly through their exposure to leukocytes. Random-donor platelets are derived from pooled platelet concentrates from whole-blood donations, whereas single-donor platelets are obtained from one donor by platelet pheresis. The likelihood of alloimmunization can be decreased by using single-donor platelets, leukocyte-depleted platelets, leukocyte filters, and ultraviolet-irradiated platelets. ASCO recommends that patients who are platelet refractory not receive platelet transfusions unless they are hemorrhaging or HLA-compatible platelets are available.[36]

DIC can cause bleeding and thrombosis. DIC should be suspected in a patient who has an unexplained elevation in PT, partial thromboplastin time (PTT), or thrombocytopenia with associated bleeding or thrombosis. Although bleeding is most often noted in patients with DIC, the thrombosis of small (and occasionally large) blood vessels leads to the most serious complications. Collaborative laboratory findings are high d-dimer and fibrin split product levels, low levels of fibrinogen and thrombin-antithrombin III, or the presence of schistocytes. It is important to remember that DIC is a clinical diagnosis based on the entire clinical scenario, and results for these laboratory tests might not be abnormal. Patients can also have mildly abnormal test results in cases of subclinical DIC; these patients should be monitored closely for conversion to overt DIC.

Tumors can cause DIC, especially adenocarcinomas of the breast, prostate, stomach, lungs, and colon. In this instance, the disorder is believed to be stimulated by mucin produced from these cancers. Leukemia, especially acute promyelocytic leukemia (APL), is associated with DIC in up to 85% of patients because of a tissue factor in APL that has procoagulant activity. Other tumors associated with DIC are melanoma, lymphoma, and ovarian and pancreatic cancers. Other causes of DIC are sepsis, acidosis, extensive burns, the use of Denver catheters or LaVeen shunts in patients with malignant ascites, hemolytic blood transfusion reactions, polycythemia rubra vera, and amniotic fluid embolism.

Patients who have both DIC and bleeding can present with oozing from multiple sites, such as arterial or venous punctures or the mucous membranes, with GI, or with epistaxis. Thrombotic complications can be visible on the skin in the form of hemorrhagic bullae, acral cyanosis, or even gangrene. Microvascular thrombosis most commonly affects the lungs, brain, and kidneys. The patient may develop shortness of breath, pleuritic chest pain, and ARDS. The kidneys can become clogged with microemboli, in which case patients often present with oliguria, anuria, hematuria, or proteinuria. The small vessels of the brain also can receive microemboli, causing strokes, seizures, altered mental status, or coma. As the patient deteriorates, hypotension, acidosis, and hypoxia can develop.

The treatment of DIC should focus on reversing the underlying cause or trigger, such as treating an underlying infection.[37] Acidosis, high catecholamine release, vasoconstriction, and corticosteroid use can exacerbate thrombosis associated with DIC. Additional therapeutic measures for thrombosis can include heparin administration at 15 U/kg/hour by continuous infusion. When the patient is bleeding, blood components (including platelets) can be transfused to correct coagulation abnormalities. Platelet transfusions are indicated to maintain platelet counts of at least 50,000/μL. Cryoprecipitate should only be used for severe hypofibrinogenemia (<50 mg/dL; <100 mg/dL if patient is actively bleeding). Cryoprecipitate can be given at 0.2 bags per kilogram of body weight, and the fibrinogen level should be tested 20 to 60 minutes after the infusion and every 6 hours thereafter until the bleeding has stopped. Fresh-frozen plasma can be transfused at 10 to 15 mg/kg to correct abnormalities in PT. Other products that might be needed are prothrombin complex, antithrombin concentrates, or washed RBCs. For patients with persistent bleeding, fibrinolytic

inhibitors, such as ε-aminocaproic acid (EACA) and tranexamic acid, can be given. EACA should always be given with heparin to prevent thrombosis; because EACA can cause hypotension, ventricular arrhythmias, and hypokalemia, it should be used with caution. Tranexamic acid is a newer fibrinolytic inhibitor that has fewer side effects and has been used successfully in DIC associated with APL.

GENITOURINARY EMERGENCIES

Hemorrhagic Cystitis

Hemorrhagic cystitis is inflammation or bleeding of the bladder; it can be caused by radiation therapy, viral infection, or chemotherapy. Radiation-induced bladder bleeding can present as early as 3 months or as late as 5 years after the termination of radiation therapy. Chemotherapeutic agents associated with hemorrhagic cystitis are cyclophosphamide and ifosfamide (because of the liver metabolites secreted during use of these compounds, namely, acrolein and chloroacetaldehyde). The mechanism by which cyclophosphamide and ifosfamide metabolites are toxic to the urinary bladder is not known, but they have been implicated as the cause of hematuria.[38] Mesna is a thiol compound that binds acrolein, chloroacetaldehyde, and other metabolites of cyclophosphamide and ifosfamide; when it is administered before the patient receives the chemotherapeutic agents, the incidence of bladder toxicity can be decreased. Forced diuresis and adequate hydration (hyperhydration) complement mesna administration.[39]

In addition to radiation therapy and chemotherapy-inducing hemorrhagic cystitis, the BK virus (a polyomavirus) can become activated in immunocompromised patients undergoing bone marrow transplantation and cause hematuria.[40]

Treatment of hemorrhagic cystitis involves gentle bladder irrigation to remove any clots and decompress the bladder. Any coagulopathy, such as thrombocytopenia, should be corrected, as should manifestations of DIC, such as low fibrinogen levels or an elevated PT or PTT. For patients with persistent bleeding, prostaglandins E_2 or F_2, 1% alum, or formalin can be instilled. Formalin instillation is painful and requires general or spinal anesthesia. To correct continued bleeding, some patients require surgery, hypogastric artery embolization, or open surgical intervention.

Urinary Tract Obstruction

Obstructive uropathy can be secondary to outflow obstruction or impingement on the ureters or kidneys; it can also be caused by tumor invasion, radiotherapy-induced changes, or indirect effects of the tumor, such as ascites, lymphadenopathy, or fibrosis. A patient who is unable to urinate should have a Foley catheter placed. In patients with benign prostatic hypertrophy (BPH) and bladder outlet obstruction, a coudé catheter can often be inserted more easily. The catheter should not be forced, and, if the bladder cannot be accessed, a suprapubic catheter may be necessary. A lack of residual urine in the absence of severe dehydration usually indicates either obstruction at a more proximal level in the urinary system or acute anuric renal failure. Patients who have residual urine may be unable to urinate because of a mechanical cause, such as BPH, urethral stricture, tumor impingement, or stone obstruction. Other possible causes of acute urinary retention are infection, spinal cord compression, viral radiculomyelitis, postsurgical effects interrupting bladder innervation, or medicines such as pain medications, anticholinergics, or antihistamines.[39] In each case, the underlying disorder should be treated. Patients with BPH can undergo a trial of α blockers, such as terazosin, prazosin, doxazosin, or finasteride, a type II 5-α–reductase inhibitor. Transurethral resection of the prostate can be considered for patients who do not respond to medical treatments.

Laboratory values are also useful in differentiating prerenal, postrenal, and renal failure. Patients with prerenal failure typically have a high ratio of BUN to creatinine of more than 20 to 1, although upper tract GI bleeding, corticosteroid use, and high protein intake can also increase the BUN-to-creatinine ratio. Acute urinary obstruction can present as flank pain, whereas chronic obstruction is often painless, with patients presenting with anuria or decreased urine output. The tumors most likely to cause ureteral obstruction are cervical, prostate, bladder, ovarian, breast, and GI cancers as well as lymphoma.[39] Patients with infected urine and obstruction may also present with symptoms of urosepsis, including fever, confusion, and a high WBC count.

CT scanning of the abdomen is good for evaluating the cause of ureteral obstruction in that it can elucidate the nature of the obstruction. Other tests that can be used are MRI, renal ultrasound, IV urography, retrograde pyelography, and radionuclide renography. Helical CT scanning of the abdomen has the added benefit of avoiding the use of IV contrast. Urinary obstruction can be managed with ureteral stents or percutaneous nephrostomy tubes with or without internal stents; the stents or tubes are typically placed under guidance by interventional radiology. Many patients with stents develop infection, which often requires hospitalization, IV antibiotics, and stent replacement. Other possible complications are stent clogging and stent migration. The "double J" stent, which is now most frequently used, is anchored in the bladder and

the renal pelvis, so that stent migration is less common than it once was. Open surgical procedures are much less frequently performed now than in the past and are generally reserved for patients in whom endourologic procedures have failed.

RESPIRATORY EMERGENCIES

Airway Obstruction

Airway obstruction can be caused by intraluminal tumor growth or compression of the airway by an extraluminal tumor. Rigid or flexible bronchoscopy can be used to both diagnose and treat airway obstruction. Patients with severe respiratory distress and airway obstruction should undergo endotracheal intubation distal to the obstruction before the obstruction is treated. After the airway has been stabilized, the obstruction can be treated. The methods that can be used to provide expedient relief of airway obstruction include laser treatment, argon plasma coagulation (APC), electrocautery, endobronchial balloon dilation, and stent placement. APC can be achieved through flexible or rigid bronchoscopy at a relatively low cost and degrades the obstructive tissue by increasing its temperature. Electrocautery is also relatively inexpensive and can provide immediate relief of the obstruction, but side effects can include fire, hemorrhage, and electric shock. Rigid bronchoscopy can be used to treat extraluminal tumors by metal or silicone stent placement; this technique is most useful for tracheal or main bronchial disease. Metal stents can promote the growth of granulomatous tissue, whereas silicone stents are more likely to develop mucous plugging and to migrate. Laser therapy can also be used for endobronchial lesions, with the possible side effects of hemorrhage, pneumothorax, and pneumomediastinum. Laser therapy is more expensive than the other techniques and requires a skilled technician. Other methods that can be used for airway obstruction are cryotherapy, brachytherapy, and photodynamic therapy, although in many cases, these do not provide rapid relief (Table 61–5).

Table 61–5 Bronchoscopic Methods of Treating Dyspnea from Tumor Obstruction

Tumor Type	Tumor Location: Intraluminal (I) or Extraluminal (E)	Rate of Relief of Dyspnea Symptoms: Immediate (I) or Delayed (D)	Complications or Disadvantages	Advantages or Uses
Argon plasma coagulation	I	I		Low cost
				Ease of use
				Rapid coagulation
Brachytherapy	I	D	Fistula	Best used in small epithelial tumors
			Hemoptysis	
Cryotherapy	I	D		Less expensive
Electrocautery	I	I	Fire	Less expensive
			Hemorrhage	
			Shock	
Laser	I	I	Bleeding	Special training; expensive equipment
			Pneumothorax	
			Pneumomediastinum	
Photodynamic therapy	I	I	Phototoxicity	
			Hemoptysis	
			Bronchial obstruction caused by debris	
Stent placement	I or E	I	Migration of stent	Used in tracheal or main bronchial disease

Hemoptysis

Massive hemoptysis is defined as bleeding into the airway at a rate of greater than 100 mL/day, although any amount of blood that compromises the airway can be considered massive. Some 5% to 14% of hemoptysis cases are massive hemoptysis.[41] Up to about one fifth of patients with lung cancer experience hemoptysis at some point, and about 3% have massive hemoptysis.[42] In addition to structural abnormalities in the lungs, bleeding can be caused by chemotherapy or other medications, sepsis, fungal infections, and thrombocytopenia. Death from this type of hemorrhage usually results from asphyxiation rather than anemia or blood loss.

The most important aspect of managing massive hemoptysis is protecting the airway. If the right lung is affected, the left lung can be selectively intubated through bronchoscopy. Use of a rigid bronchoscope allows for removal of the tumor or clots, whereas flexible bronchoscopy allows access to the more distal airways. If the left lung is affected, the right lung should not be selectively intubated because inadvertent collapse of the right upper lobe can ensue. A single-lumen endotracheal tube is easier to place than a double-lumen tube and allows a larger area for evacuation of blood and clots. The patient should lie on the side of the bleeding lung to promote aeration of the unaffected lung. Any coagulopathy should be corrected, and cough should be suppressed with codeine or other agents. If a tumor is causing the bleeding and it can be localized, the patient can undergo bronchial artery embolization or tumor resection. If the tumor is unresectable, external-beam radiation therapy can be used. If only the location of the bleeding can be determined, a solution of 1:10,000 epinephrine can be injected. Other means of halting bleeding are laser treatment, electrocautery, APC, photocoagulation, balloon tamponade, and iced-saline lavage.

Toxic Lung Injury

ARDS is a serious condition that can be a complication of infection or chemotherapy. ATRA is a chemotherapy used in APL, and it has been found to cause ARDS in 26% of patients starting 2 to 47 days after treatment. Cytarabine (Ara-C) can cause diffuse lung injury, capillary leakage, and pulmonary edema, usually after 6 days of therapy. These effects can be treated with diuresis and corticosteroids. Bleomycin can cause pulmonary fibrosis and increased sensitivity to intraoperative oxygen administration. Other chemotherapeutic agents that can cause pulmonary edema are mitomycin C, gemcitabine, cyclosporine, interferon, tumor necrosis factor (TNF), and interleukin-2.

Interstitial lung disease can be caused by bleomycin, carmustine, lomustine, busulfan, cyclophosphamide, methotrexate, doxorubicin, and actinomycin D. Bleomycin toxicity is usually dose related and most often occurs when the cumulative dose is greater than 450 units. It can be treated with corticosteroids. Busulfan's toxic effects can occur after 3 weeks of therapy, but they sometimes emerge as late as 3 years after treatment. Busulfan toxicity is associated with a high mortality rate, but corticosteroids can be used with some response. Cyclophosphamide complications present differently depending on whether they are early or late. The early-onset effect is pneumonitis, which can be treated with corticosteroids. The late-onset symptoms include a progressive fibrosis that is not responsive to steroids. Methotrexate can also produce pulmonary fibrosis, which can appear from several days to years after treatment. Interstitial lung disease (pneumonitis) from taxane toxicity is rare and usually respond to steroid therapy.[43] Tyrosine kinase inhibitors against epidermal growth factor receptor (EGFR) can cause pneumonitis, perhaps by interfering with the function of EGFR in non-neoplastic cells involved in the repair mechanisms for the lungs.[44] Immune checkpoint inhibitors (ICPis) may induce an immune-mediated pneumonitis, which is further discussed later.

Patients receiving doxorubicin and actinomycin D can present with pulmonary fibrosis characterized by a "recall" effect after radiation therapy, even in areas of the lung not exposed to radiation. Radiation can cause pneumonitis or fibrosis, the occurrence of which is most closely related to the rate of delivery of radiation. Pneumonitis is an acute-phase reaction that occurs 2 to 6 months after irradiation and may respond to corticosteroids. The late-phase response to radiation toxicity, fibrosis of the lungs, does not respond to corticosteroids.

CHEMOTHERAPY-INDUCED EXTRAVASATIONS

Extravasation injuries caused by chemotherapy can produce a variety of symptoms ranging from skin irritation to skin ulceration, tissue necrosis, nerve damage, and (rarely) loss of limbs. Vesicant chemotherapy agents, including the alkylating agents (mechlorethamine, cisplatin, mitomycin C), DNA intercalating agents (doxorubicin, daunorubicin), and plant alkaloids (vinblastine, vincristine, vinorelbine), can cause the most severe reactions. Irritant chemotherapy extravasations are generally not severe, causing only pain, erythema, and inflammation at the extravasated site.[45]

The goal is to prevent chemotherapy extravasations. The patient should be told to inform the staff of any discomfort, swelling, or erythema over the infusion site. Nursing staff should evaluate the IV infusion site carefully by administering IV fluids before chemotherapy agents are infused, and they should monitor the

patient frequently for any evidence of extravasation. IV lines should be placed carefully; areas that have a poor blood supply or overlie a joint should be avoided. If an extravasation does occur, the infusion should be stopped immediately with the catheter left in place, and the staff should attempt to withdraw any remaining chemotherapy agents. Cold compresses should then be placed on the involved site except when the agents are plant alkaloids, in which case warm compresses should be applied. Topical dimethylsulfoxide (DMSO) 99% or in a 50% solution can relieve extravasations when applied topically to the site twice daily or every 6 hours for 7 to 14 days. DMSO is commonly used to treat extravasations caused by mitomycin C and the anthracyclines. For extravasations caused by plant alkaloids (vinblastine, vincristine, vinorelbine), taxanes and epidophyllotoxins (etoposide, teniposide), a solution of 150 units of hyaluronidase in 1 to 3 mL of saline can be injected subcutaneously in and around the extravasation site in about 0.2-mL aliquots. A 0.17-mol/L solution of sodium thiosulfate can be injected into mechlorethamine-induced extravasation sites. Sodium thiosulfate is thought to work by creating an alkaline-rich site to which the vesicant binds instead of the skin. The byproduct is then excreted in the urine. There is some evidence that sodium thiosulfate can also be used for extravasations caused by carmustine, cisplatin, carboplatin, cyclophosphamide, dacarbazine, and oxaliplatin. Table 61–6 lists selected chemotherapeutic agents and their antidotes. Dexrazoxane is an antidote for anthracycline extravasation.[46] Dexrazoxane is also used to reduce the risk of cardiomyopathy induced by anthracyclines. Dexrazoxane 1000 mg/m^2 is administered IV in a limb other than the limb affected by extravasation within 5 hours of extravasation and then for 2 more consecutive days.[45]

If local measures fail to contain symptoms in all patients with anthracycline-induced extravasations, a plastic surgeon should be consulted. Surgery can consist of debridement, excision of dead tissues, and, in severe cases, skin graft placement. In patients with doxorubicin-induced extravasation, the drug remains in the tissue for a long period, perhaps being released by dying or dead cells and spreading over time. Patients who have had previous extravasation reactions can also experience a "recall reaction" when the same chemotherapy is received later, causing ulcerations or burns to reappear at the previously affected area.

METABOLIC EMERGENCIES

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Hyponatremia is the most common electrolyte abnormality, present in approximately 2% of hospitalized patients. The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is a paraneoplastic syndrome in which antidiuretic hormone (ADH) is secreted inappropriately from the posterior pituitary gland despite lower serum osmolality. Typically, ADH is secreted in response to hypernatremia, hypotension, or hypoxemia to increase the permeability of the collecting ducts so that water can be reabsorbed and the blood pressure and sodium level restored to normal values. In patients with cancer, a protein similar to ADH, atrial natriuretic factor (ANF), is secreted by the cardiac atria, which increases the renal excretion of sodium. The pituitary gland does not respond to feedback from ANF. Thus, SIADH can be characterized by inappropriate ADH secretion despite normal blood volume, with hyponatremia, serum osmolality less than 260 mOsm/L, inappropriate sodium secretion in the urine of greater than 20 mEq/L, and high urine osmolality greater than 100 mOsm/kg.[47,48]

SIADH can be caused by various cancers, including small cell lung cancer, pancreatic cancer, and primary brain cancers. Other causes of SIADH are pulmonary infections, postoperative effects, CNS disorders (meningitis, stroke, hemorrhage), and chemotherapeutic agents (vincristine, cisplatin, and cyclophosphamide).

Symptoms of SIADH depend on the sodium level and the rate at which the sodium level declines. The patient can present with confusion, seizures, headache, or weight gain without edema. In evaluating hyponatremia, the patient's volume status should be addressed, and the plasma osmolality, urine osmolality, and urine sodium and chloride levels should be determined. Hyponatremia should be distinguished from pseudohyponatremia, in which plasma osmolality is normal (hyperlipidemia, hyperproteinemia) or even high (hypertriglyceridemia, hyperglycemia, and mannitol use).

Most patients with hyponatremia have low serum osmolality, which can be grouped by type: primary sodium loss, primary sodium gain, and primary water gain. Patients with sodium gain present with volume overload, which occurs in congestive heart failure, liver disease, and nephrotic syndrome. Patients with primary sodium loss present with dehydration; sodium deficits can be caused by GI loss (nausea, vomiting, diarrhea, bowel obstruction), renal loss (thiazide diuretics), and skin loss (severe burns). Patients with SIADH can also have primary water gain, although other sources of primary water gain (primary polydipsia, decreased solute intake, beer potomania, chronic renal insufficiency, adrenal or thyroid deficiency, or increased ADH secretion in response to pain, nausea, vomiting, or drugs) should be distinguished. Some patients appear to have SIADH based on laboratory test results but actually have a reset osmostat. This adjustment can occur in patients with quadriplegia,

Table 61–6 Chemotherapeutic Extravasations and Their Antidotes

Chemotherapy Agent	Irritant (I) or Vesicant (V)	Sodium Thiosulfate	DMSO	Hyaluronidase	Dexrazoxane	Cool	Warm

Vinorelbine	I or V			+			+

DMSO, dimethylsulfoxide.

tuberculosis, psychosis, chronic illness, volume contraction, encephalitis, malnutrition, or malignancy and in older or pregnant patients. Other rare causes of euvolemic hyponatremia are an incomplete pituitary stalk and increased sensitivity to ADH secretion.

Treatment of SIADH involves restricting water to 500 to 1000 mL/day from all sources and treating the underlying disorder. If this combination is not effective, demeclocycline (600–1200 mg/day) can be used in divided doses two to four times per day. Patients whose symptoms include coma or seizure can be treated by slow infusion of 3% normal saline; care must be taken not to increase serum sodium by more than 0.5 to 1 mEq/hours. Too-rapid correction of serum sodium level can lead to central pontine myelinolysis. Vasopressin receptor antagonists is very effective in managing hyponatremia. If acute treatment of hyponatremia is needed or parenteral administration is more appropriate, conivaptan (a V_1/V_2R antagonist) can be given intravenously. Oral selective V_2R antagonists such as tolvaptan and lixivaptan can be used to manage hyponatremia chronically. In addition, urea and loop diuretics are all useful to increase free water excretion.[48]

Tumor Lysis Syndrome

TLS is a result of excessive tumor breakdown, causing hypocalcemia, hyperphosphatemia, hyperkalemia, elevated uric acid, and occasionally acute renal failure. Risk factors for TLS include high tumor burden, chronic renal insufficiency, and certain tumor types (Burkitt lymphoma, lymphoblastic lymphoma, diffuse large cell lymphoma, undifferentiated lymphoma, and leukemia). TLS usually presents during chemotherapy, but it can also occur after radiation therapy, corticosteroid treatment for sensitive tumors, or administration of hormonal agents.

Patients with TLS can present with nausea and vomiting, diarrhea, constipation, low urine output, weight gain, acute renal failure, weakness, cramps, seizures, tetany, or arrhythmias.

Prophylaxis is very important in preventing TLS and consists of IV hydration and oral allopurinol (100–600 mg/day). Alkalinizing the urine with sodium bicarbonate to maintain a urine pH greater than 7.5 decreases uric acid crystallization in the kidneys but is generally not necessary. Because allopurinol use is now common before chemotherapy, hyperphosphatemia, rather than hyperuricemia, is now the predominant cause of acute renal failure in TLS. To prevent TLS, patients with leukemia and high WBC counts should be treated with leukapheresis or hydroxyurea before chemotherapeutic agents are administered. Some patients with refractory electrolyte abnormalities might require dialysis if conservative measures fail. A newer and effective alternative to allopurinol is rasburicase. Rasburicase is a highly soluble IV recombinant form of urate oxidase that can also be used to prevent or treat hyperuricemia and does not require simultaneous urine alkalinization. Rasburicase effectively decreases levels of uric acid, xanthine, and hypoxanthine by reducing existing pools and preventing further production of uric acid. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, methemoglobinemia, and pregnancy and has a known side effect of hemolytic anemia. The 2008 International Expert Panel on TLS provided rasburicase dosing guidelines based on the level of risk for TLS and uric acid levels.[49]

Hypercalcemia

Hypercalcemia is present in 10% to 20% of patients with advanced cancer. The most common cancers include squamous cell cancer of the lungs, breast cancer, multiple myeloma, and lymphoma. The two major mechanisms of hypercalcemia include the secretion of a parathyroid-related peptide and abnormal 1,25-vitamin D production (which occurs in Hodgkin disease and non-Hodgkin lymphoma).

Symptoms of hypercalcemia are altered mental status, polyuria, polydipsia, nausea, vomiting, anorexia, constipation, and seizures. Measured serum calcium levels should be adjusted according to the albumin level for accurate estimation. A low albumin level should be subtracted from 4, and the difference should be multiplied by 0.8. This product should be added to the serum calcium level to arrive at the estimated calcium. Alternatively, ionized calcium can be measured, which assesses the active calcium in the serum and is more accurate.

The choice of treatment for hypercalcemia depends on the patient's calcium level and symptoms. Calcium is a potent diuretic, and patients with mild hypercalcemia can be treated by IV fluids. Patients with a calcium level greater than 14 mg/dL should be treated with additional measures. Patients who have symptoms of hypercalcemia and a calcium level between 12 and 14 mg/dL should also receive additional treatment to lower the calcium level.

Bisphosphonates are the drugs of choice in treating hypercalcemia. Zoledronic acid 4 mg intravenously over 15 min is more convenient than pamidronate 60 to 90 mg, which is infused intravenously over 2 to 24 hours. Bisphosphonates do not work immediately but have an onset of action after 12 to 48 hours. Bisphosphonates are useful not only in reducing serum calcium levels but can also help to decrease bone pain and treat skeletal complications in patients with cancer with bone metastases. Denosumab, a monoclonal antibody against the receptor activator of nuclear factor κB ligand (RANKL), is effective for treatment of hypercalcemia of malignancy, even for bisphosphonate-refractory cases.[50] Calcitonin 4 units/kg subcutaneously can also be used to treat hypercalcemia; it has an onset of action of 2 to 4 hours, but its effects are transient because tachyphylaxis develops after 3 days. Patients may develop nausea, abdominal cramps, or hypersensitivity reactions to calcitonin, and this medication is very expensive.

Corticosteroids can be helpful in some patients with hypercalcemia—for instance, those with lymphoma and myeloma. Furosemide can be used, but only after the patient has been hydrated adequately. In acute renal failure, severe life-threatening or refractory hypercalcemia, hemodialysis can effectively decrease calcium to safe levels.[51]

GASTROINTESTINAL EMERGENCIES

Gastrointestinal Bleeding

Patients with cancer can present with GI bleeding caused by direct tumor invasion, effects of chemotherapy agents or corticosteroids, thrombocytopenia, coagulopathy, side effects of radiation therapy, or Mallory-Weiss tears from intractable nausea and vomiting. Other possible causes of GI bleeding are gastritis, peptic ulcer disease, duodenal ulcers, arteriovenous malformations, and diverticulosis. Patients who have undergone bone marrow transplantation can present with GI bleeding as a manifestation of graft-versus-host disease, which typically presents as ulcerations in the small intestine. Immune-mediated colitis from ICPi therapy may also result in hematochezia. Patients with small tumors rarely have significant bleeding, and patients with large tumors tend to ooze and bleed. However, relief of bleeding by endoscopic measures is usually temporary, and these tumors tend to bleed

repeatedly. Endoscopic interventions can include electrocoagulation, epinephrine injections, and argon plasma laser treatment. For patients with persistent bleeding, arteriography and embolization is occasionally successful. If all other interventions have failed, surgery can be considered. Patients with bleeding should have any coagulopathy corrected, including deficits in the platelet count, which should be greater than 60,000/μL. Somatostatin or vasopressin can be used to control bleeding of esophageal varices. The patient should receive either an H2 blocker or a proton pump inhibitor intravenously. Nausea should be controlled using IV antiemetics, and the patient should receive nothing by mouth. The patient should also receive maintenance IV fluid. If hypotensive, the patient should be volume resuscitated with IV crystalloid fluid, transfusion, or both.

Typhlitis

Typhlitis is a syndrome of bowel inflammation, edema, and wall thickening involving the proximal large bowel in patients with neutropenic fever. It commonly affects the cecum but can also affect the ascending colon and occasionally the transverse colon. Typhlitis can occur in conjunction with any cancer but is most common in patients with leukemia. The organisms most often isolated in cases of typhlitis are *Clostridium* spp. and gram-negative bacilli.

Patients with typhlitis present with fever, pain in the right lower quadrant of the abdomen, and sometimes diarrhea, which may be bloody. The patient with typhlitis is neutropenic, and plain abdominal x-ray films are often inconclusive. The diagnosis of typhlitis is made based on clinical suspicion and CT or MRI findings that reveal bowel inflammation, edema, wall thickening, and possibly gas formation in bowel wall (eg, pneumatosis intestinalis) or, in severe cases, intraabdominal free air (Fig. 61–10).

Typhlitis is managed by bowel rest and IV administration of broad-spectrum antibiotics, including anaerobic coverage. Patients rarely require surgery unless they develop intractable bleeding or bowel perforation or do not respond to conservative measures.

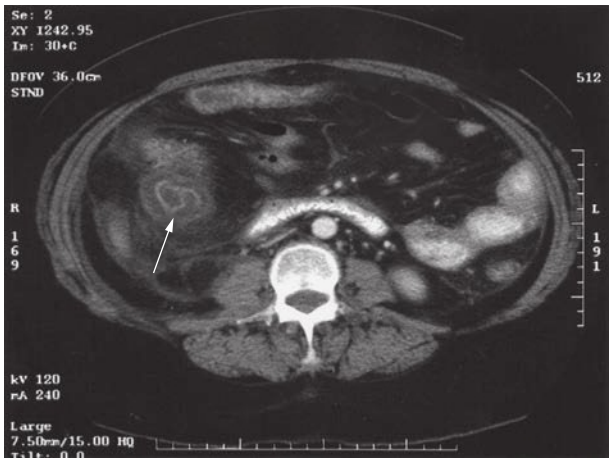

FIGURE 61–10 Inflammation of the cecum and ascending colon in a 45-year-old patient with typhlitis. The *arrow* points to inflammation and edema of the cecum. (Used with permission from Dr. Stephanie Mundy, MD Anderson Cancer Center.)

IMMUNOTHERAPY TOXICITY

The addition of ICPis to the arsenal of antineoplastic agents marked a breakthrough in cancer therapeutics. These drugs include monoclonal antibodies that target either the interaction between programmed cell death protein 1 (PD-1)on T-cells and programmed cell death ligand 1 (PD-L1) on tumor cells or immune cells in the microenvironment of the tumor (eg, nivolumab, pembrolizumab, atezolizumab, durvalumab, and avelumab), or the interaction between cytotoxic T-cell lymphocyte antigen-4 (CTLA-4) on T-cells and B7 on antigen-presenting cells (eg, ipilimumab, cemiplimab).[52]

However, these drugs unleash the immune system, and can lead to immune-related adverse events (irAEs) that practically can attack any organ system. Therefore, patients may present with a variety of symptoms depending on the organs involved and the degree of involvement. Toxicities are typically categorized into grades ranging from grade 1 to grade 4. ASCO has proposed some general recommendations for the management of irAEs irrespective of the organ involved.[53] For grade 3 irAEs, the ICPis should be withheld, and high-dose corticosteroids should be initiated (eg, prednisone 1 to 2 mg/kg/day or methylprednisolone IV 1 to 2 mg/kg/day) and then tapered over 4 to 6 weeks. If symptoms do not improve within 48 to 72 hours of corticosteroid therapy, infliximab may be considered. In general, grade 4 toxicities necessitate permanent discontinuation of ICPi therapy, except for endocrinopathies that have been controlled by hormone replacement.

Urgent skin irAEs include grade 3 and 4 inflammatory dermatitis or rash, bullous dermatosis, and severe cutaneous adverse reactions (SCARs) such as drug reaction with eosinophilia and systemic symptoms (DRESS), and Stevens-Johnson syndrome or toxic epidermal necrolysis. Rashes or inflammatory dermatitis associated with ICPis can be eczematous, lichenoid, psoriasiform, or morbilliform rashes. Possible reactions also include erythema multiforme minor, palmoplantar dysesthesia, and neutrophilic dermatoses (eg, Sweet syndrome). Grade 4 manifestations of these conditions are those that are severe, intolerable, and unmanageable with the regular interventions. They

require immediate admission with an urgent dermatology consultation. Bullous dermatosis includes bullous pemphigoid or other autoimmune and drug-related etiologies. Grade 3 and 4 bullous dermatosis involves more than 30% of the body surface area of a patient. In such cases, it is important to detect a secondary cellulitis or neutropenia, which would warrant an infectious diseases consultation. If bullous pemphigoid is diagnosed, alternative treatments such as rituximab may be explored. Grade 4 SCAR toxicity involves skin erythema and blistering or sloughing covering at least 10% of body surface area with associated signs or systemic symptoms and concerning associated blood work abnormalities (eg, liver function test elevation in DRESS). In such cases, it is important to urgently admit the patient to the ICU or burn unit. Intravenous immunoglobulin (IVIG) and cyclosporine may be considered in severe and corticosteroid-unresponsive cases.

GI irAEs are also common and include colitis and hepatitis, among others. Grade 3 colitis is characterized by an increase of seven or more stools per day over baseline, incontinence, hospitalization indicated, severe increase in ostomy output compared with baseline, or limiting self-care activities of daily living (ADLs). A grade 4 colitis is life threatening and warrants permanent discontinuation of the incriminated drug, with the possibility of early initiation of 5 to 10 mg/kg of infliximab if the symptoms are refractory to steroids within 2 to 3 days. A grade 3 hepatitis is defined by a 5- to 20-fold increase in transaminases (alanine aminotransferase or aspartate aminotransferase) from the upper limit of normal (ULN) or a 3- to 10-fold increase in the total bilirubin from the ULN. Grade 4 hepatitis on the other hand represents decompensated liver function (eg, ascites, coagulopathy, encephalopathy, coma) with more than a 20-fold increase in transaminases or more than a 10-fold increase in total bilirubin from the ULN. Both grade 3 and 4 hepatitis warrant permanent discontinuation of the ICPi; however, infliximab is typically avoided in patients with hepatitis, resorting to non–TNF-α immunosuppressants. In both grade 4 colitis and hepatitis, a corticosteroid taper may be attempted if symptoms improve to grade 1 or less.

The main pulmonary irAE is pneumonitis. A grade 3 pneumonitis typically requires hospitalization because of severe symptoms and involvement of all lung lobes or more than 50% of lung parenchyma, limiting self-care ADLs. A grade 4 toxicity represents life-threatening respiratory compromise. A grade 3 pneumonitis requires oxygen therapy, whereas in a grade 4 toxicity, urgent intervention such as intubation may be necessary. Otherwise, grades 3 and 4 pneumonitis are treated similarly with initial treatment involving permanent ICPi discontinuation and methylprednisolone 1 to 2 mg/kg/day intravenously. Empiric antibiotics for possible pneumonia may be indicated until infection has been excluded.

Endocrine irAEs affect the thyroid, adrenal, and pituitary glands as well as the pancreatic islets. Thyroid manifestations could include either hypothyroidism (primary) or hyperthyroidism. As these manifestations are common, testing for TSH and free thyroxine every 4 to 6 weeks is recommended for patients on ICPi therapy as part of routine monitoring. Grade 3 and 4 hypothyroidism is defined as having severe symptoms with medically significant or life-threatening consequences and inability to perform ADLs. Such a toxicity is treated by holding ICPi therapy and thyroid supplementation. Admission may be necessary for IV therapy if signs of myxedema exist; however, steroids have no major role in this toxicity. Most cases of thyrotoxic irAEs are caused by thyroiditis, but some can be caused by Graves disease, which is distinguished from thyroiditis by the presence of elevated thyroid-stimulating immunoglobulin. Similarly, grade 3 or 4 hyperthyroidism also presents with severe medically significant symptoms and an inability to perform ADLs. However, in addition to holding ICPi therapy, immediate therapy includes a β-blocker such as atenolol or propranolol for symptomatic relief. Severe symptoms or concern for thyroid storm warrant hospitalization and initiation of prednisone 1 to 2 mg/kg/day or equivalent tapered over 1 to 2 weeks. Other agents such as SSKI (potassium iodide) and thionamides (eg, methimazole or propylthiouracil (PTU)) can also be considered in the setting of Graves disease.

Another endocrinopathy is primary adrenal insufficiency, which typically leads to low morning cortisol, high morning ACTH, and hyponatremia and hyperkalemia with orthostasis and volume depletion caused by loss of aldosterone. Severe and significant symptoms affecting ADLs are considered grade 3 or 4 toxicities. These should be managed by holding ICPi therapy until the patient is stabilized on replacement corticosteroid hormone. At least 2 L of normal saline solution should be administered upon presentation, as well as an IV stress dose of 100 mg hydrocortisone or a 4 mg-dose of dexamethasone if the diagnosis is unclear and stimulation testing is expected. The corticosteroid dose should then be tapered to a maintenance dose over 7 to 14 days after discharge.

Hypophysitis is inflammation of the pituitary gland and can result in hypofunction of one or multiple hypothalamic–pituitary hormonal axes. Central hypothyroidism, adrenal insufficiency, diabetes insipidus, and hypogonadism are common findings. A grade 3 or 4 toxicity results in severe symptoms affecting ADLs and warrants immediate cessation of ICPi therapy until the patient is stabilized on replacement hormones. In addition, we may consider initial pulse

dose therapy with prednisone 1 to 2 mg/kg orally daily (or equivalent) tapered over at least 1 to 2 weeks. In addition to hypophysitis, ICPi therapy may result in type 1 diabetes from islet cell destruction and may be associated with acute diabetic ketoacidosis, which is a grade 3 or 4 toxicity with severe symptoms affecting ADLs or is life threatening. As for hyperglycemia, a grade 3 toxicity is also defined as having a glucose level greater than 250 to 500 mg/dL (>13.9–27.8 mmol/L), whereas a grade 4 toxicity would involve a glucose level greater than 500 mg/dL (>27.8 mmol/L). In grade 3 and 4 toxicities, ICPis must be held until glucose control is obtained on therapy with reduction of toxicity to grade 1 or less. Furthermore, insulin therapy should be initiated for all these patients.

Musculoskeletal irAEs include inflammatory arthritis, myositis, and polymyalgia-like syndrome. A grade 3 or 4 inflammatory arthritis manifests as severe pain associated with signs of inflammation, erythema, or joint swelling and can lead to irreversible joint damage. Because early recognition is critical to avoid erosive joint damage, such a toxicity warrants temporary holding of ICPi therapy with an initial oral prednisone dose of 0.5 to 1 mg/kg. Myositis is characterized by muscle inflammation with weakness and elevated muscle enzymes (CK). In addition to pain, severe myositis may be life threatening if respiratory muscles or the myocardium are involved. As such, a grade 3 or 4 toxicity, characterized by severe weakness limiting self-care ADLs, warrants immediate cessation of ICPi therapy. In addition to initiating corticosteroids, plasmapheresis, IVIG, and other immunosuppressants may be considered. Caution is advised with rechallenging, but ICPi discontinuation is typically permanent if myocardial involvement is evident. Polymyalgia-like syndrome is characterized by marked pain and stiffness in proximal upper or lower extremities and no signs of true muscle inflammation or true muscle weakness. A grade 3 or 4 toxicity manifests as severe stiffness and pain, limiting self-care ADLs. Initial management includes holding ICPi therapy and initiating 20 mg/day of prednisone or its equivalent. Admission for pain control is reasonable.

The major renal irAE is nephritis, which, although serious, may be asymptomatic. If the diagnosis is suspected, swift treatment of the autoimmunity is important. If no alternative causes of the acute kidney injury are identified, a kidney biopsy should be obtained, and the patient should be initiated on immunosuppressive treatment. A grade 3 toxicity is represented by creatinine more than three times baseline or greater than 4.0 mg/dL and warrants immediate permanent discontinuation of ICPi therapy with hospital admission. The recommended initial dosage of corticosteroid is 1 to 2 mg/kg/day of prednisone or its equivalent. A grade 4 toxicity is treated similarly but is characterized by severe life-threatening consequences and the need for dialysis. Tapering of corticosteroids can be attempted if toxicity improves to grade 1 levels.

Nervous system ICPi toxicities are of particular concern. They can be very debilitating and include a wide variety of conditions, notably myasthenia gravis (MG), Guillain-Barré syndrome (GBS), peripheral neuropathy, autonomic neuropathy, aseptic meningitis, encephalitis, and transverse myelitis. MG may be particularly difficult to differentiate from the Miller Fisher variant of GBS and from oculobulbar myositis because of overlapping symptoms. For MG and GBS, any grade toxicity requires workup and intervention given the potential of progression to respiratory compromise. Grade 3 or 4 MG is characterized by limited self-care, weakness that limits walking, any of dysphagia, facial weakness, respiratory muscle weakness, rapidly progressive symptoms, or Myasthenia Gravis Foundation of America (MGFA) severity class 3 or above. Management of patients with grade 2 MG includes pyridostigmine and corticosteroids (prednisone, 1.0–1.5 mg/kg orally daily). Grade 3 or 4 toxicity warrants permanent ICPi discontinuation and should be administered corticosteroids as well as IVIG 2 g/kg IV over 5 days (0.4 g/kg/day) or plasmapheresis for 5 days. Admission is warranted, and the patient may require ICU monitoring. Treatment of a GBS toxicity of any grade also warrants IVIG or plasmapheresis for the same duration and dose. Although corticosteroids are not recommended for idiopathic GBS, a trial of 2 to 4 mg/kg/day of methylprednisolone may be reasonable, with pulse dosing as another possibility.

Peripheral neuropathies can present as asymmetric or symmetric sensory, motor, or sensory motor deficits. Autonomic neuropathies result from damage to the nerves that control involuntary bodily functions, such as blood pressure, digestion, and bladder function. A grade 3 or 4 peripheral neuropathy leads to limited self-care weakness, limiting walking or respiratory problems (ie, leg weakness, foot drop, rapidly ascending sensory changes). If the changes are severe, they may represent GBS and should be managed as such. Otherwise, initial management of grade 3 or 4 peripheral toxicity includes permanent ICPi discontinuation with a 2- to 4-mg/kg dose of IV methylprednisolone followed by regular GBS management. A grade 3 or 4 autonomic neuropathy also warrants permanent ICPi discontinuation but with 1 g of methylprednisolone for 3 days followed by an oral corticosteroid taper.

Patients with aseptic meningitis may present with headache, photophobia, and neck stiffness. Patients are usually febrile, although they may be afebrile. Unlike encephalitis, mental status in patients with aseptic meningitis should be normal. In both conditions, it is important to rule out infectious causes. For

aseptic meningitis, a grade 3 or 4 toxicity is severe and limits self-care and is treated similarly to any grade. Management includes holding ICPi therapy and performing a lumbar puncture with the possibility of initiating empirical antiviral and antibacterial therapy pending results. If the results are negative for infection, the patient may be monitored closely without corticosteroids or may be administered oral prednisone 0.5 to 1 mg/kg or IV methylprednisolone 1 mg/kg for the management of moderate to severe symptoms. Encephalitis symptoms include confusion, altered behavior, headaches, seizures, short-term memory loss, depressed level of consciousness, focal weakness, and speech abnormality. A grade 3 or 4 toxicity is severe and limits self-care and is treated as any grade toxicity for encephalitis. As in aseptic meningitis, ICPi should be held ,and IV acyclovir may be administered pending polymerase chain reaction detection of herpes virus. Immediate treatment includes a trial of methylprednisolone 1 to 2 mg/kg. If the condition progresses, pulse corticosteroids and IVIG may be considered. The presence of autoimmune encephalopathy antibody warrants rituximab or plasmapheresis if there is no or limited improvement with regular treatment. Transverse myelitis typically presents with bilateral acute or subacute weakness or sensory changes, often with increased deep tendon reflexes. Treatment of all toxicity grades includes permanent ICPi discontinuation, 2 mg/kg of methylprednisolone or higher doses of 1 g/day for 3 to 5 days, and the possibility of using IVIG.

Hematologic irAEs also encompass a wide variety of conditions, including autoimmune hemolytic anemia (AIHA), acquired thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), aplastic anemia, lymphopenia, immune thrombocytopenia (ITP), and acquired hemophilia, which is discussed. AIHA symptoms include weakness, paleness, jaundice, dark-colored urine, fever, and heart murmur. A grade 3 toxicity is defined with a hemoglobin level below 8.0 g/dL, whereby transfusion is indicated. A grade 4 toxicity is characterized by life-threatening consequences and requires urgent intervention. The immediate management of both grade 3 and 4 toxicities warrant permanent ICPi discontinuation with RBC transfusion as per existing guidelines and 1 to 2 mg/kg/d of prednisone (oral or IV for grade 3; IV for grade 4). Acquired TTP is characterized by the presence of microangiopathic hemolytic anemia, thrombocytopenic purpura, fever, renal abnormalities, and neurologic abnormalities. A high index of suspicion and a timely diagnosis are crucial because delayed hematology consult is associated with increased mortality/morbidity. Grade 1 and 2 toxicities do not present with any clinical consequences. However, a grade 3 toxicity involves both laboratory findings and clinical findings such as thrombocytopenia, anemia, renal insufficiency. A grade 4 toxicity is one that presents with life-threatening consequences such as intracranial hemorrhage and renal failure. Grade 3 and 4 toxicities require immediate cessation of ICPi, initiation of plasma exchange (PEX) as per existing guidelines, and administration of 1 g of methylprednisolone IV daily for 3 days with the first dose typically immediately after PEX. HUS is characterized by a form of thrombotic microangiopathy with renal failure, hemolytic anemia, and severe thrombocytopenia. Symptoms vary but can include bloody diarrhea and high blood pressure. As in TTP, a G3 toxicity is one with clinical consequences and a G4 toxicity is a life-threatening one with consequences such as CNS thrombosis or embolism and renal failure. Both grade 3 and 4 HUS require permanent ICPi discontinuation with initiation of eculizumab therapy 900 mg weekly for four doses and 1200 mg for week 5 followed by 1200 mg every 2 weeks. RBC transfusion may be done as per existing guidelines.

Aplastic anemia is characterized by a deficiency in the production of new blood cells. During diagnostic workup, the patient should be typed and screened, and the blood bank should be notified that all transfusions need to be irradiated and filtered. A grade 3 or 4 toxicity presents with absolute neutrophil count less than 200/mm,^{3} platelet count less than 20,000/mm,^{3} reticulocyte count less than 20,000/mm,^{3} and hypocellular marrow less than 25%. ICPi therapy should be held, with a hematology consult and growth factor support. Initial treatment also includes horse antithymocyte globulin (ATG) plus cyclosporine. Lymphopenia is a specific hematologic disorder defined as an abnormally low level of lymphocytes in the peripheral smear (<1500/mm^3 for adults). Grade 3 lymphopenia is defined with a lymphocyte level of 250 to 499/mm^3 and warrants weekly complete blood count monitoring and cytomegalovirus (CMV) screening while continuing ICPi therapy. However, if the toxicity is G4 (lymphocyte count <250/mm^3), then ICPi should be discontinued, and prophylaxis should be initiated for *Mycobacterium avium complex* and *Pneumocystis jirovecii*. CMV, human immunodeficiency virus, and hepatitis screening should be done, and Epstein-Barr virus testing may be considered if signs or symptoms are consistent with lymphoproliferative disease.

ITP is another specific autoimmune disorder characterized by immunologic destruction of otherwise normal platelets. A platelet count below 50/μL is considered a grade 3 toxicity, whereas a count below 25/μL is considered grade 4. Both grade 3 and 4 toxicities require holding ICPi. Prednisone 1 to 2 mg/kg/day (oral or IV depending on symptoms) should be given,

and IVIG (1 g/kg as a one-time dose; can be repeated) may be added if a rapid rise in platelets is required.

Acquired hemophilia is a form of hemophilia caused by the development of autoantibodies (inhibitors) directed against plasma coagulation factors. The development of hemophilia A generally requires a specialist on-board with clinical and laboratory experience. A grade 3 or 4 toxicity is severe and leads to less than 1% of normal factor activity in blood or levels below 0.01 IU/mL of whole blood. ICPi should be discontinued, and the patient should be admitted. Treatment involves immunosuppressive agents and factor replacement based on Bethesda unit level of inhibitor. Prednisone is given as 1 to 2 mg/kg/day (oral or IV depending on symptoms) with or without rituximab (375 mg/m^2 weekly for 4 weeks) and/or cyclophosphamide (1–2 mg/kg/day). Bypassing agents may be used, and transfusion support is provided as required.

Cardiovascular irAEs are also of concern. These typically include VTE, which is managed in one way, and several other irAEs such as myocarditis, pericarditis, arrhythmias, impaired ventricular function with heart failure, and vasculitis, which are all managed similarly. For VTE, a grade 2 or 3 toxicity is one in which medical intervention is required. ICPi can be continued, and the patient should be managed as per CHEST, American College of Cardiology (ACC), or American Heart Association (AHA) guidelines. LMWH is the preferred agent for initial and long-term treatment, although IV heparin is an acceptable alternative for initial use, and oral anticoagulants are acceptable for the long term. A grade 4 VTE is life threatening and typically includes hemodynamic or neurologic instability and the need for urgent intervention. The management of a grade 4 toxicity also follows the aforementioned guidelines with preference for the use of LMWH but also includes permanent ICPi discontinuation with hemodynamic and respiratory support. For all other mentioned irAEs, signs and symptoms may include chest pain, arrhythmia, palpitations, peripheral edema, progressive or acute dyspnea, pleural effusion, and fatigue. A grade 3 toxicity is one that involves abnormal testing or symptoms with mild activity, whereas a grade 4 toxicity involves moderate to severe decompensation, the need for IV medication or intervention, or life-threatening conditions. All toxicity grades require workup and intervention given the possibility for cardiac compromise. In toxicities with grade greater than 1, ICPi should be permanently discontinued, and high-dose corticosteroids (1–2 mg/kg of prednisone) should be initiated rapidly (oral or IV depending on symptoms). Immediate transfer to a coronary care unit is required for patients with elevated troponin or conduction abnormalities, and management of cardiac symptoms should be according to ACC/AHA guidelines. In patients without an immediate response to high-dose corticosteroids, consider early institution of cardiac transplant rejection doses of corticosteroids (methylprednisolone 1 g every day) and the addition of mycophenolate, infliximab, or ATG. However, it is important to note that infliximab has been associated with heart failure and is contraindicated at high doses in patients with moderate to severe heart failure.

Ocular irAEs require a high level of clinical suspicion because symptoms may not always be associated with severity. These events include uveitis or iritis, episcleritis, and blepharitis and are often seen in the context of other irAEs. The workup for these disorders is the same, and patients are best treated after an ophthalmologist eye examination. Uveitis or iritis is inflammation of the middle layer of the eye (uvea or iris). A grade 3 toxicity includes posterior uveitis or panuveitis. This warrants permanent ICPi discontinuation with urgent ophthalmology referral and systemic corticosteroids and intravitreal, periocular, or topical corticosteroids. A grade 4 toxicity leads to visual deficits of 20/200 vision or worse. This also warrants permanent ICPi discontinuation with emergent ophthalmology referral. Corticosteroids should be administered systemically (IV prednisone 1–2 mg/kg or methylprednisolone 0.8–1.6 mg/kg) and intravitreal, periocular, or topical corticosteroids as per ophthalmologist opinion. In severe or refractory cases, TNF-α blockers can be considered. Episcleritis is defined as an inflammatory condition affecting the episcleral tissue between the conjunctiva and the sclera in the absence of an infection. A grade 3 toxicity is symptomatic and involves vision worse than 20/40 vision, whereas a grade 4 toxicity involves 20/200 vision or worse. Both grade 3 and 4 toxicities require permanent ICPi discontinuation, ophthalmology referral, and systemic and topical corticosteroids with cycloplegic agents. TNF-α blockers can also be considered in some cases. Blepharitis is characterized by inflammation of the eyelid that affects the eyelashes or tear production. As of yet, there is no formal grading system for blepharitis. However, treatment includes warm compresses and lubrication drops, with continuation of ICPi therapy unless the condition is persistent and serious.

It is important to have a high index of suspicion for irAEs while examining patients taking ICPis to facilitate early recognition and minimize any long-term damage. Experience and evidence are accumulating on the best possible approach to the diagnosis and management of irAEs. At this point, many recommendations are based on expert opinion, and more studies are needed in the future to determine evidence-based best practice for irAEs.

MD ANDERSON PRACTICE TIPS

- Spinal cord compression occurs at the cervical vertebrae in 10%, thoracic vertebrae in 70%, and lumbar vertebrae in 20% of cases. Up to about one third of cases have multilevel compression. Metastatic lung, breast, and prostate cancers account for 50% of cases. Early diagnosis before severe paraplegia is associated with more favorable clinical outcome.
- For life-threatening cerebral edema with increased ICP, mannitol, hypertonic saline IV infusion, and hyperventilation can be used to decrease ICP, in addition to high-dose glucocorticoids.
- Pericardial tamponade can be managed by emergent pericardiocentesis and placement of a drainage catheter followed by pericardial window, radiotherapy, chemotherapy, or sclerotherapy.
- Intravascular stenting usually can provide prompt symptom relief for SVC syndrome.
- Patients with massive PE may require thrombolysis or embolectomy.
- Interstitial lung disease (pneumonitis) from certain cytotoxic chemotherapy agents may occur. Tyrosine kinase inhibitors against EGFR can cause pneumonitis. ICPi may induce an immune-mediated pneumonitis.
- Rasburicase can effectively manage hyperuricemia in TLS but is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency,
- Beware of bullous lesions, the Nikolsky sign, and mucosal involvement in dermatologic irAEs.
- Multiple irAEs may occur concurrently. When one irAE is diagnosed, look for other irAEs.
- In patients with dyspnea or mental status change, arterial blood gases are informative in the diagnostic workup.
- Hyponatremia is a common metabolic abnormality in both hypoadrenalism and hypothyroidism.

KEY CONCEPTS

- Myocardial dysfunction related to chemotherapy can be classified as type 1 or type 2. Type 1 is typically irreversible and associated with myocyte death. Anthracyclines are the prototype drugs that cause type 1 cardiotoxicity, and this can manifest months to years later. Thus, lifelong cardiac monitoring is recommended. Type 2 myocardial dysfunction is associated with reversible myocyte contractile dysfunction. Trastuzumab is the prototype drug causing type 2 dysfunction, but other targeted agents such as tyrosine kinase inhibitors (TKIs) can also cause type 2 cardiotoxicity. Trastuzumab can be reinitiated after recovery of left ventricular (LV) systolic dysfunction. Myocardial dysfunction is less common with TKIs than with trastuzumab, but LV dysfunction reverses in only about half of these patients.
- Cancer can be associated with risks for cardiovascular ischemia beyond traditional risk factors. These risks include hypercoagulability associated with cancer, development of coronary or carotid vascular disease related to radiation therapy, tumor embolization, and arterial ischemia related to chemotherapies (L-asparaginase, cisplatin, 5-fluorouracil, capecitabine, and gemcitabine) and angiogenesis inhibitors (thalidomide and TKIs).
- QT prolongation with risk of torsades de pointes is an important consideration in patients with cancer. Many cancer drugs prolong the QT interval, and this can be exacerbated by concomitant use of antiemetics, methadone, antibiotics, antifungal agents, antiviral agents, antiarrhythmic agents, and antipsychotics, and by electrolyte abnormalities. QT prolongation is particularly prominent with vandetanib, nilotinib, vemurafenib, and arsenic.
- Pericardial effusions are common in patients with cancer. Two thirds of pericardial effusions are nonmalignant and related to loss of lymphatic drainage or certain drugs or infection or radiation. The 1-year survival rate is 55% in nonmalignant effusions and dismal, 16%, with malignant effusions.
- Hypertension is commonly caused by angiogenesis inhibitors. Onset of hypertension is typically in days to weeks and usually returns to baseline after the vascular endothelial growth factor (VEGF) inhibitor is discontinued. It is not yet clear if hypertension can be considered a marker of response to therapy.
- Atrial fibrillation is common in patients with cancer, particularly after thoracic surgery. It often requires pharmacotherapy for rate or rhythm control, and anticoagulation must be guided by the risk of bleeding versus the risk of thromboembolism.

Oncocardiology is a fast-growing medical subspecialty focused on the management of heart diseases in patients with cancer. Although cancer remains a leading cause of morbidity and mortality worldwide, the survival rate of patients with cancer has increased in the last 25 years. In the United States, the 5-year relative survival rate of patients diagnosed with cancer between 1975 and 1977 was 50%. For patients diagnosed between 1999 and 2005, the survival rate increased to 68%. The U.S. National Cancer Institute estimates that at least 13.7 million cancer survivors were alive in the United States in 2012.[1] More recent data show a continued decline in cancer-related death over the past three consecutive decades with a 27% decrease in cancer mortality between 1991 and 2016.[2]

Although survival from cancer is improving, there is evidence that cancer survivors have an increase in cardiovascular (CV) events and CV mortality compared with age-matched control participants.[3] A survey of 1807 cancer survivors with a 7-year follow-up period

found that 33% of the survivors died of heart diseases, and 51% died of cancer.[4] Cancer survivors living at least 5 years beyond diagnosis are reported to have a 3.6-fold increased risk of CV-specific mortality and up to an 18.5-fold increased incidence of CV disease risk factors such as hypertension, diabetes mellitus, and dyslipidemia compared with age-matched counterparts with no cancer history.[5–7] These increased CV risks are likely the results of normal age-related pathologies in association with direct (ie, radiation therapy, chemotherapy) and indirect (ie, deconditioning, weight gain, oncometabolites) effects of cancer therapies and may partially explain the increased incidence of certain CV syndromes in this population, including a 2-fold increase in risk of arterial ischemia and up to a 15-fold increased risk for cardiomyopathy and heart failure (HF).[8–10]

Historically, since the late 1970s, the interest in chemotherapy-induced cardiotoxicity was focused on cardiomyopathy related to a few chemotherapeutic agents. As the field of cancer therapies has expanded, so has the finding of other CV side effects such as transient left ventricular (LV) dysfunction, hypertension, cardiac arrhythmias, pericardial effusions, and arterial ischemia.

Oncocardiology has evolved to address the CV needs of these patients whose optimal outcome mandates close and collaborative efforts between cardiologists and oncologists in a multidisciplinary approach. Involvement of cardiologists in the care of patients with cancer has changed from a focus on management of CV complications of therapy to consultation in the care of these patients from the initial cancer diagnosis to survivorship as outlined in Figure 62–1.

PATHOPHYSIOLOGY

Clinical knowledge and basic science discoveries in oncocardiology have grown over the past decade. The molecular mechanisms of cardiac toxicity caused by cancer drugs is now better understood. For example, the Bruton tyrosine kinase receptor is expressed in the atria of human heart tissue.[11] This tyrosine kinase is the target of the novel drug, ibrutinib, used in certain hematologic malignancies, including chronic lymphocytic leukemia. Ibrutinib has been associated with a significant incidence of atrial arrhythmias, possibly mediated by its on-target effect but more specifically mediated by inhibiting the phosphoinositide 3-kinase (PI3K)–Akt signaling pathway.[11] Another drug, trastuzumab, targets ErbB2 in breast cancer cells and improves outcome and prolongs survival in HER2+/ErbB2 patients with breast cancer. These same receptors within the cardiac myocyte are responsible for normal cell function and myocyte repair and, when affected by ErbB2 inhibitors such as trastuzumab, can develop secondary mitochondrial dysfunction.[12] Other mechanisms of toxicities have recently been reported with older, conventional, chemotherapeutic drugs such as the anthracyclines; recently, the CV toxicity of this drug has been linked to inhibition of topoisomerase IIβ.[13] This enzyme is responsible for normal myocyte function, and its inhibition partially explains the CV toxicity associated with Adriamycin.

Other chemotherapeutic agents such as cisplatin, 5-fluorouracil (5-FU), monoclonal antibodies against VEGF (vascular endothelial growth factor [VEGF]

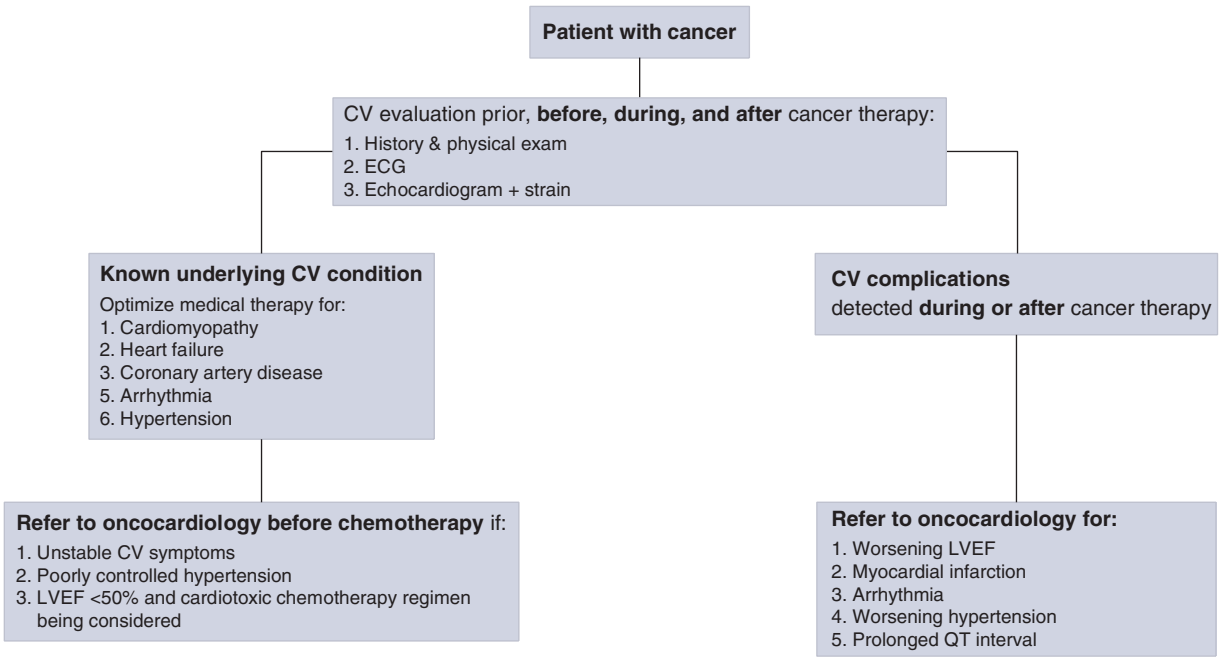

FIGURE 62–1 The general role of onco-cardiology algorithm. CV, cardiovascular; LVEF, left ventricular ejection fraction.

inhibitors), and several oral tyrosine kinase inhibitors (TKIs) (ie, ponatinib, sunitinib, sorafenib and others) are known to be associated with vascular toxicity. This toxicity is mediated via direct interference with normal physiologic endothelial function and alteration of the delicate balance of the coagulation factors, leading to a variety of vascular toxicities, including hypertension and arterial or venous thrombosis.

Certain TKIs such as crizotinib, ceritinib, and dasatinib can also cause QT prolongation because of interaction with myocardial human ether-a-go-go-related gene (hERG) Kþ channels, resulting in delayed repolarization.[14–16] They occur with variable frequency, which may be accentuated by drug interactions and genetic predispositions.[17]

Immune checkpoints inhibitors (ICIs) are a new category of targeted immunotherapy directed against mechanisms that cancer cells use to evade the immune system. They have been approved for the treatment of patients with metastatic melanoma, non–small lung carcinoma, and squamous cell carcinoma of the head and neck. They have been reported to cause myocarditis, pericarditis or pericardial effusion, cardiomyopathy, hypertension, and arrhythmia.[18,19] Data from animal models suggest that one potential mechanism of ICI-mediated cardiotoxicity involves modulation of the programmed cell death protein 1 (PD-1) pathway, which can lead to immune-mediated CV toxicity, primarily in the form of autoimmune myocarditis. Knockout of the PD-1 receptor in mice causes severe dilated cardiomyopathy characterized by high levels of immunoglobulin G autoantibodies that react specifically to cardiac troponin.[20]

Chest radiation used to treat patients with Hodgkin lymphoma, esophageal, lung, and breast cancers can cause injury to cardiac myocytes within or near the radiation field. This can result in vascular injury, direct myocyte damage, and alterations in cardiac conduction.[21] Radiation-induced arrhythmias are likely caused by microvascular damage to the sinoatrial and atrioventricular nodes, leading to bradycardia or heart block.

Infiltrative processes are another cause of cardiomyopathies commonly encountered in patients with cancer. Examples include amyloidosis and secondary hemochromatosis. In patients with myelodysplastic syndrome, myocardial iron overload develops from frequent blood transfusions (ie, >100 units).

In addition to the benefit of improving strategies to prevent drug toxicities, a better understanding of these biologic pathways that are important for cancer therapy may also provide a better understanding of certain heart diseases and their management. For example, the discovery of the key role of ERB2 in normal cardiac function and its relation to trastuzumab toxicity was followed by the discovery of the benefit of an ERB2 agonist called neuregulin-1 in the animal models of HF. Neuregulin-1 is currently being studied as a treatment of HF in humans.[22]

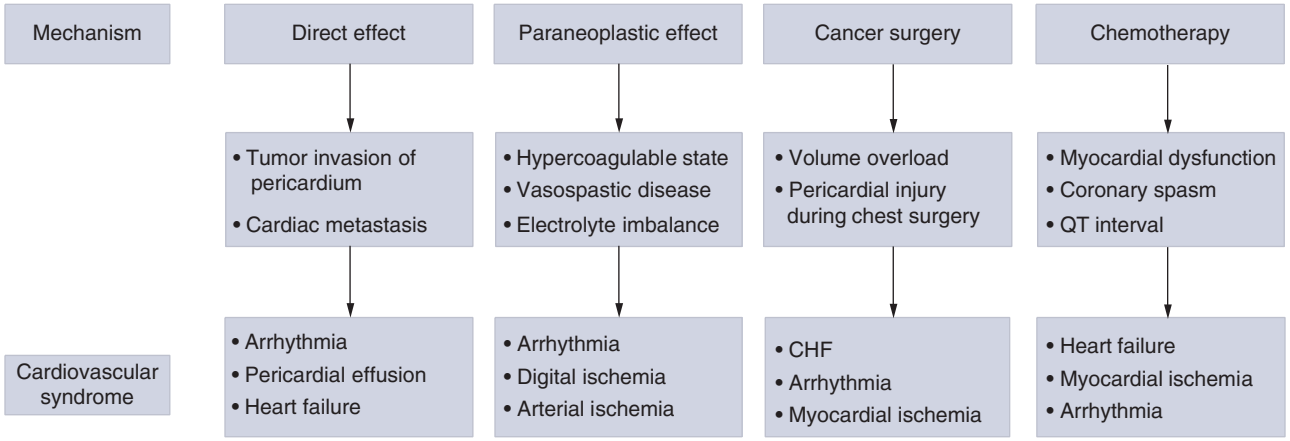

FIGURE 62–3 **Mechanisms and causes of some cardiovascular syndromes observed in patients with cancer. CHF, congestive heart failure.**

Cardiovascular Syndromes Observed in Patients with Cancer

In addition to the direct cardiac toxic effect of certain cancer drugs (Fig. 62–2), many aspects of the CV system can be affected by cancer or cancer therapy, resulting in a variety of CV syndromes (Fig. 62–3).

MYOCARDIAL DYSFUNCTION

Oncocardiologists are often asked to assess patients with cancer with clinical HF symptoms. Although the most feared etiology is the progressive, permanent, and irreversible myocardial damage related to anthracycline toxicity, this in fact constitutes only a small percentage of patients with cancer with clinical HF. The majority of these patients with new-onset HF in the setting of cancer and cancer therapy have symptoms triggered by mechanisms other than anthracycline toxicity. Despite some overlap, a clinically useful approach to evaluating and managing these patients is to divide them into two groups based on their initial clinical presentation as shown in Table 62–1. The first group includes patients presenting with sudden and new-onset acute HF with associated systolic dysfunction. These include cardiomyopathies related to sepsis, stress cardiomyopathy, and myocarditis (toxic or infectious). The second group includes patients presenting with subacute or chronic HF symptoms and includes those with underlying structural heart disease, those with chemotherapy-induced cardiomyopathy, and those with infiltrative myocardial conditions related to their underlying malignancies (ie, amyloidosis) or to cancer therapy (ie, iron overload). Evaluation of these patients typically includes a two-dimensional echocardiogram, cardiac biomarkers (brain natriuretic peptide and troponin), thyroid function tests, iron or ferritin level, ischemia assessment, and occasionally an endomyocardial biopsy.

Acute Cardiomyopathy

The majority of these cases are related to conditions referred to as reversible myocardial dysfunction, or more commonly, stress cardiomyopathy. This phenomenon is typically triggered by sepsis but also occurs in a wide range of acute illnesses (see Table 62–1). Myocardial dysfunction in fact has been documented in up to 40% of patients with sepsis and is a major predictor of mortality in this population.[23,24] During the course of malignancy management, patients with cancer are at risk of going through these acute illnesses, especially during chemotherapy with associated secondary neutropenic sepsis. Physiologically, both left and right ventricular systolic functions are diminished with variable degrees of myocardial depression. This function is typically reversed

TABLE 62–1 Causes of Left Ventricular Systolic and Diastolic Heart Failure in Patients with Cancer

Acute Left Ventricular Systolic Dysfunction (Acute Cardiomyopathy)	Subacute or Chronic Left Ventricular Dysfunction (Cardiomyopathy)
Stress cardiomyopathy	Preexistent cardiomyopathy
Sepsis	Ischemic heart disease
Myocarditis	Nonischemic cardiomyopathy
Viral	Hypertensive heart disease
Chemotherapy	Chemotherapy
Myocardial infarction	Infiltrative cardiomyopathy
Metabolic derangement	Amyloid heart disease
Hypocalcemia	Iron overload

within 7 to 10 days. The exact mechanism for myocardial dysfunction is not well defined, and multiple theories have been suggested including the possibility of altered microcirculatory flow, mitochondrial dysfunction, myofibrillary dysfunction, autonomic dysregulation, altered calcium cellular transportation, and others (Fig. 62–4).[23,25] Clinically, patients with reversible myocardial dysfunction or stress cardiomyopathy are recognized when evidence of new-onset LV dysfunction is documented in the appropriate clinical setting (see Table 62–1). It is frequently associated with repolarization abnormalities on electrocardiography (ECG) and a minimal rise in cardiac troponins. Echocardiographic findings of severe LV dysfunction are typically out of proportion to the ECG changes and the rise in cardiac troponins. The severity of LV dysfunction, however, correlates well with B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP)levels.[23,25] Management is focused on stabilizing blood pressure (BP) using vasopressors if shock is present and transitioning to cardioprotective drugs such as angiotensin-converting enzyme (ACE) inhibitors and β-blockers after the patient is weaned off of pressure support and after BP is stable for 24 to 48 hours.[23] Persistent LV dysfunction beyond 2 weeks should raise suspicion for possible underlying ischemic heart disease or possible viral myocarditis in the setting of immune-compromised patients. These two conditions are typically associated with significant rise in cardiac biomarkers such as troponin and CK-MB (creatine kinase myocardial band). Patients with suspected ischemic heart disease should undergo evaluation and management of coronary artery disease. The diagnosis of viral myocarditis is more challenging because viral cultures and antibody titers have limited diagnostic accuracy. Myocardial biopsy is the gold standard in the general population for diagnosis of viral myocarditis despite its limited diagnostic yield (60% sensitivity and 80% specificity)[26] and can be even more challenging and risky in patients with cancer because they often have coagulopathy with risk of procedural related complications (bleeding, myocardial perforation). The use of empiric therapy with intravenous immunoglobulin (IVIG) for antiviral and immunomodulatory effect in this setting is controversial, especially in view of limited data to supporting benefit of such intervention in the adult population.[27] IVIG is also typically associated with high volume fluid shift, which can exacerbate HF. A suggested algorithm for evaluation of new-onset cardiomyopathy and HF in patients with cancer is summarized in Figure 62–5.

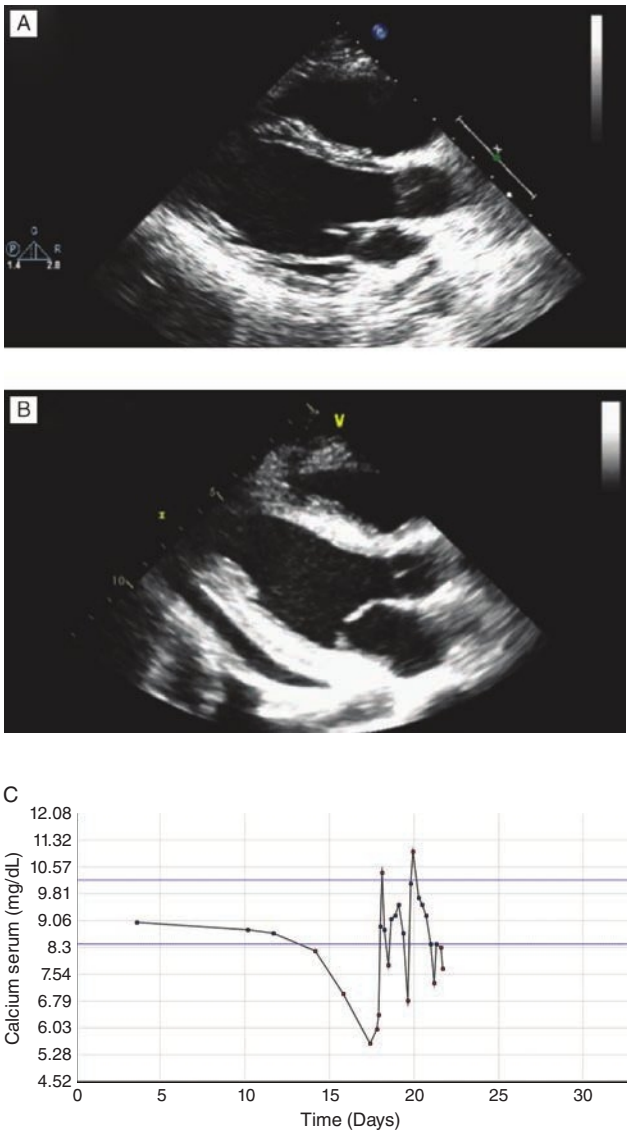

FIGURE62–4 Acute severe cardiomyopathy with shock after chemotherapy for ovarian cancer complicated by severe hypocalcemia. Echocardiographic studies show baseline normal left ventricular systolic function (A), severely depressed systolic function with small pericardial effusion 48 hours after developing severe hypocalcemia (B) after chemotherapy (C).

Cancer Therapy–Induced Cardiomyopathy

Chemotherapy-Induced Cardiomyopathy

Definition

A large number of chemotherapeutic agents have been linked to cytotoxic myocardial injury. Table-62–2 lists several groups of chemotherapeutic agents known to be associated with LV systolic dysfunction or HF. The ones most commonly associated with chemotherapy-induced cardiomyopathy include anthracyclines, alkylating agents, and TKIs. Despite a lack of consensus, cardiotoxicity generally is defined as a drop in left ventricular ejection fraction (LVEF) by 5% or more, to less than 55% in the presence of HF symptoms, or an asymptomatic drop in LVEF by 10% or more to less than 55%.[28] Myocardial toxicity is also classified into type I and type II based on the nature of myocyte injury.

Type I Myocardial Toxicity

Anthracyclines are the prototype drugs that cause type irreversible myocyte damage. Histologic findings include myofibrillar disarray, disruption of cellular organelles, myofibrillar loss, and myocyte death.[29] Myocardial toxicity is dose dependent with a less than 5% chance of cardiomyopathy observed at a cumulative dose of less than 400 mg/m^2 for Adriamycin (150 mg/m^2 for idarubicin and 900 mg/m^2 for epirubicin). This risk jumps to 26% at a cumulative dose of 550 mg/m^2.[30] Anthracycline-related cardiotoxicity has also been classified as acute or chronic. The acute form manifests as nonspecific ECG changes, arrhythmia, myopericarditis, and transient LV dysfunction. The more feared chronic form is marked by LV systolic dysfunction occurring many months to years after exposure and manifests as progressive HF. It is not clear if the acute form of anthracycline-induced cardiotoxicity is in fact the prodrome of the more delayed cardiomyopathy form because it has been shown that myocyte dysfunction can be present even after the first dose of the drug. It is plausible that myocardial reserve allows normal cardiac function despite initial injury until a second insult leads to further myocardial cell loss and subsequent systolic dysfunction. The long-term prognosis for patients with chemotherapy-induced cardiomyopathy is much worse than for those with other causes.[31] For years, the understood mechanism has been based on the free radical and iron hypothesis: the addition of an electron to the quinone moiety of anthracyclines within the cardiomyocytes leads to the generation of excess reactive oxygen species (ROS) and subsequent mitochondrial and intracellular protein damage. This toxicity is further increased when ROS interact with iron, generating a surge of oxidative stress.[32] More recently, the role of topoisomerase IIβ was found to be a key mediator of anthracycline-induced

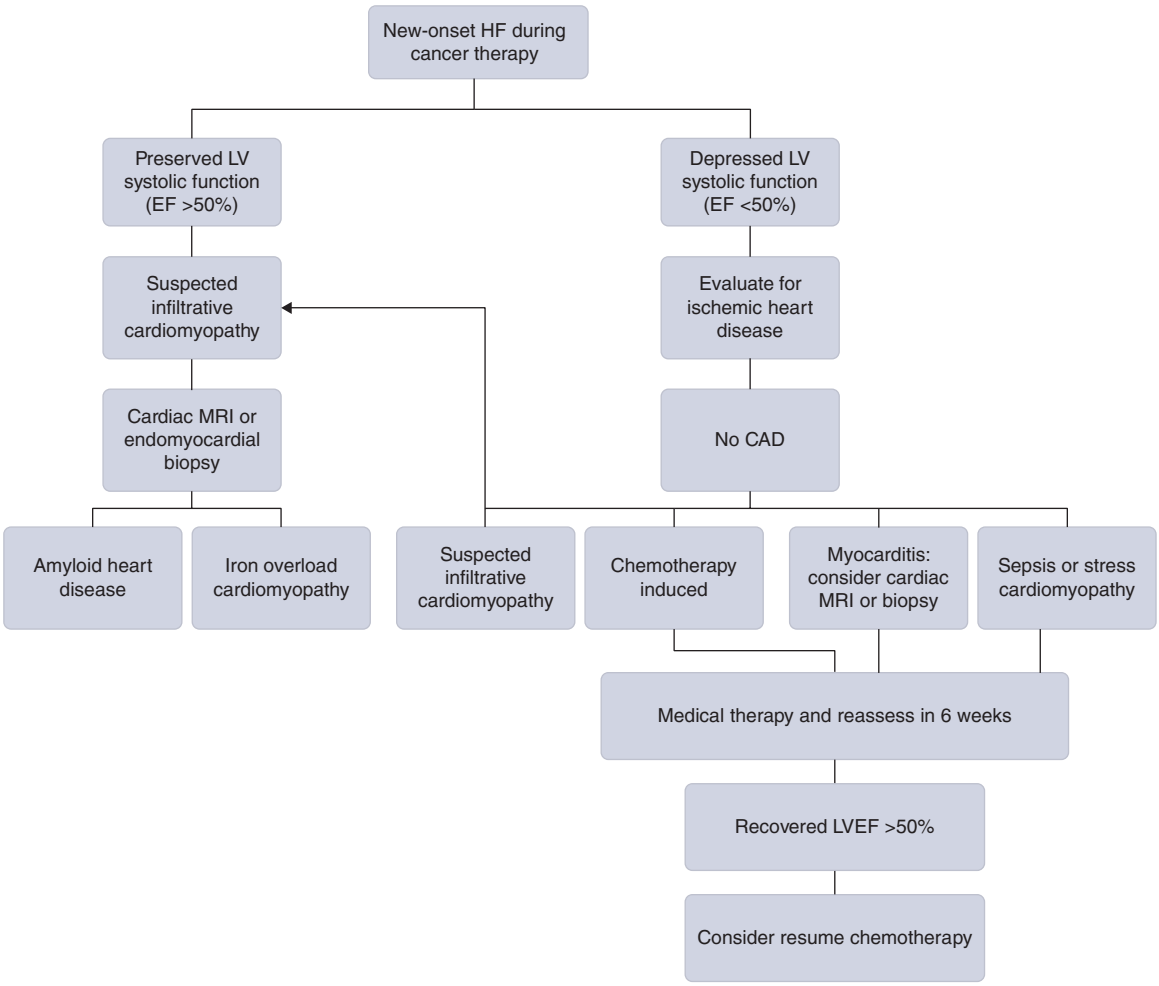

FIGURE 62–5 Algorithm for evaluation of patients with acute cardiomyopathy during cancer therapy. CAD, coronary artery disease; EF, ejection fraction; HF, heart failure; LV, left ventricular; LVEF, left ventricular ejection fraction; MRI, magnetic resonance imaging.

TABLE 62–2 The Most Commonly Used Chemotherapeutic Agents Known to Be Associated with Left Ventricular Systolic Dysfunction or Heart Failure

Chemotherapeutic Agent	Mechanism of Toxicity	Cardiomyopathy Incidence	Other Cardiovascular Toxicity
Anthracyclines			
Doxorubicin		5% at 400 mg/m^2 18% at 700 mg/m^2	Arrhythmia
Epirubicin	Oxidative stress		Pericarditis
Idarubicin	Inhibition of topoisomerase IIβ	4% at 900 mg/m^2 15% at 1 g/m^2 5%	Arrhythmia
Anthracycline analogue			
Mitoxantrone		2. 6%	Arrhythmia Hypertension
Monoclonal antibodies			
Rituximab	No direct toxicity		
Cetuximab	Hypomagnesemia related arrhythmia		Arrhythmia
Alemtuzumab	Infusion-related hemodynamic effect	<0.5%	Hypotension
Trastuzumab	ERB/2 receptor–mediated myocyte dysfunction	2%–28%	
Bevacizumab	VEGF inhibition Hypertension-mediated cardiomyopathy	1. 7%–3%	Arterial thrombosis Hypertension
Alkylating agents (at high doses)	Myocarditis	3%–25%	Tamponade
Cyclophosphamide (>1.5 mg/m^2)	Myocardial fibrosis	Rare	Pericardial effusion
Busulfan	Myocarditis	17%	Myocardial infarction, arrhythmia
Ifosfamide (>1 g/m^2)			
Antimetabolites			
Gemcitabine	Noncardiogenic pulmonary edema	7. 1%	
5-FU		2%	Ischemia
Antimicrotubule agents			
Vinca alkaloids (vincristine, vinblastine)	Impairment of myocardial metabolism	3%	Coronary spasm Hypertension
Oral TKIs			
Dasatinib	Mitochondrial toxicity	1%–4%: HF	Hypertension
Lapatinib	Dysregulation of cellular energy		QT prolongation
Pazopanib		Up to 10%–28%: LV systolic dysfunction	Arterial thrombosis
Sorafenib	Mitochondrial toxicity		Arrhythmia
Sunitinib			Fluid retention
Vandetanib			

5-FU, 5-Fluorouracil; FHF, heart failure; LV, left ventricular; tyrosine kinase inhibitor; VEGF, vascular endothelial growth factor.

cardiomyocyte toxicity. Topoisomerase IIβ is an enzyme present in heart tissue that modulates DNA. Anthracycline-mediated inhibition of topoisomerase IIβ causes double-stranded DNA breaks, which can lead to cardiomyocyte death.[13,33] In a small study by Vejpongsa and Yeh,[33] the level of topoisomerase IIβ was significantly higher in an anthracycline-sensitive group. In the future, use of the topoisomerase IIβ level in peripheral blood leukocytes could be of potential benefit for risk stratification and as a surrogate

biomarker for individual susceptibility to anthracycline- induced cardiotoxicity. Presently, there is not a way to predict which patients will be at higher risk of developing cardiotoxicity from anthracyclines. Close cardiac monitoring with early recognition and treatment of LV dysfunction using β-blockers and ACE inhibitors within the first 6 months of onset has been shown to be associated with a better chance of stabilization and even recovery of cardiac function.[34] These observations are the basis of the current recommendations for routine cardiac monitoring during anthracycline therapy. Different diagnostic tools have been useful in monitoring these patients, including the use of cardiac biomarkers and cardiac imaging studies.[35] However, there is no consensus regarding the best approach and optimal timing for testing. At MD Anderson Cancer Center (MDACC), we typically rely on serial imaging with two- and three-dimensional echocardiography with myocardial strain to monitor these patients as shown in Figure 62–6.

Multiple primary prevention measures have been suggested to lower the risks of anthracycline-induced cardiomyopathy. Continuous infusion instead of repetitive boluses has been shown to be associated with a lower incidence of myocyte damage.[36] The mechanism is believed to be related to the fact that the peak plasma level correlates with the degree of myocyte toxicity, and the area under the curve determines antitumor efficacy. The use of modified preparations of anthracyclines such as liposomal doxorubicin has been associated with lower risk. The use of dexrazoxane is thought to lower risk through iron chelation and through interference with the topoisomerase IIβ complex by preventing it from binding to anthracyclines. In addition, the use of β-blockers and ACE inhibitors or angiotensin receptor blockers has been associated with mixed results in several small prospective studies.[37,38] It is not clear if these medications exert potential cell protection effect or if they only have beneficial hemodynamic effect. At this stage, their role in primary prevention of chemotherapy-induced cardiotoxicity is uncertain.

Type II Myocardial Toxicity

This type of toxicity is associated with reversible disruption of myocyte contractile function; trastuzumab is the prototype drug. Other targeted chemotherapy agents, including several small-molecule oral TKIs, are also suspected to exert type II cardiotoxicity. The mechanism involves disruption of certain signaling pathways responsible for tumor growth and responsible for cardiac cell repair (ErbB2 in the case of trastuzumab), resulting in subsequent myocyte dysfunction but no cell death.[39] Up to one third of patients treated with trastuzumab develop evidence of LV systolic dysfunction or HF symptoms that are often reversible upon discontinuation of this agent.[40] Reinitiation or continuation of trastuzumab after LV systolic function recovers is usually well tolerated. The Food and Drug Administration (FDA) recommends monitoring LV function with imaging every 3 months during therapy. Observational studies, however, have shown that not all patients are at the same risk. Several predisposing factors increase susceptibility for trastuzumab

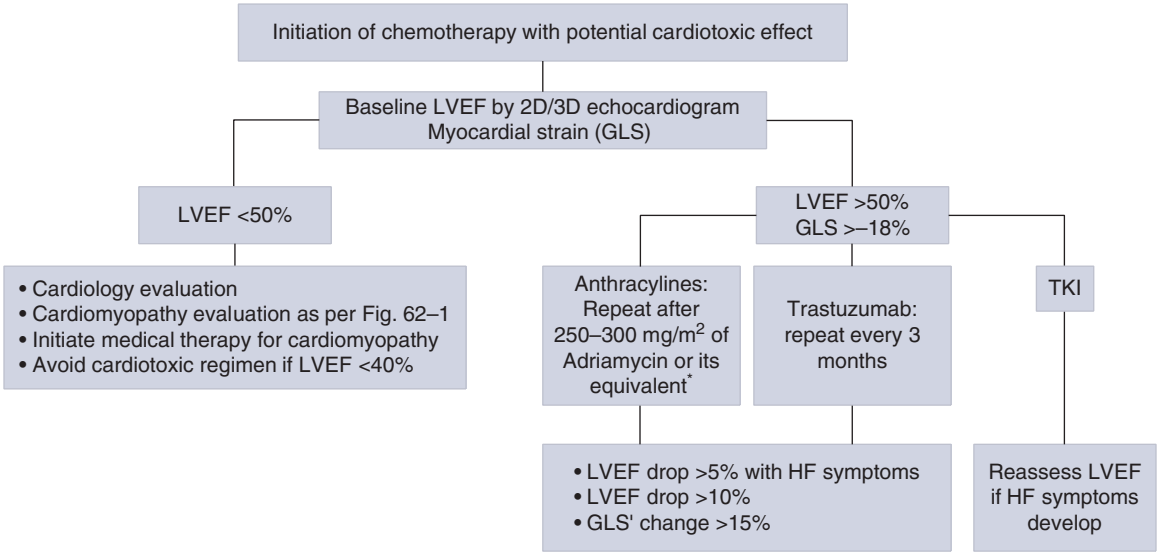

FIGURE 62–6 Algorithm for cardiac monitoring and management of patients receiving potentially cardiotoxic chemotherapy. *Asterisk* **indicates equivalent cardiotoxicity dose to 300 mg/m² of Adriamycin = 150 mg/m² of idarubicin = 900 mg/m² of epirubicin. cardiotoxicity. These factors include concomitant use of anthracyclines, advanced age, and hypertension or other underlying structural heart disease. There is an incremental increase in the incidence of LV systolic dysfunction or HF as the number of these risk factors increases. For example, the risk of myocardial dysfunction increases from less than 1% in a young woman with no risk factors to 27% in an older adult patient receiving concomitant anthracylines.[28] A clinical risk stratification model (National Surgical Adjuvant Breast Project (NASBP) cardiac risk score) has been proposed to help risk stratify these patients, but the model needs further studies to be validated.[41]

TKI-related LV dysfunction has been reported since early phase I and phase II clinical oncologic trails. Mechanisms of toxicity are not fully understood; several theories have been proposed, including apoptotic versus nonapoptotic cell death, dysregulation of cellular energy hemostasis through inhibition of 5-adenosine monophosphate-activated protein kinase (AMPK),[42] mitochondrial toxicity, and hypertension-mediated LV dysfunction.[43] The reported incidence of TKI-related cardiomyopathy and HF varies widely between each individual drug (mostly reported with sunitinib, sorafenib, and imatinib) and differs between studies by almost 10=-fold; this is partially related to the fact that cancer trials typically do not have CV events as outcomes, and this likely leads to underestimation of the incidence rate of such events. In addition, the usual clinical HF symptoms of fatigue, dyspnea, and edema of the legs are nonspecific to patients with cancer, leading to limitations in clinical diagnostic accuracy. The incidence of symptomatic HF necessitating medical therapy varies between 1.5% and 15%, and the rate of reported drop in LVEF is between 7% and 28%.[43–47] Time to onset of cardiomyopathy varies between a few weeks to several months after initiation of TKIs. Evidence of reversibility of significant LV dysfunction was seen in only half of the patients after TKIs were discontinued.

Management

When clinical HF or LV systolic dysfunction is confirmed, patients typically are taken off their TKI, and HF drugs are initiated (ACE inhibitors, β-blockers, and diuretics).[48–50] Depending on the patient risk factors and clinical presentation, workup for other possible causes of cardiomyopathy should be performed when appropriate (ie, ischemic heart disease, hypertension). In the absence of strong prospective data, there is not enough information at this stage to support the routine use of cardiac imaging to routinely monitor asymptomatic patients. It is common practice to obtain a baseline two-dimensional echocardiogram study before initiating these drugs with low clinical threshold to obtain repeated echocardiographic studies if dyspnea or fluid retention symptoms develop in patients treated with TKIs.[35,51,52]

Immune Checkpoints Inhibitor–Induced Myocarditis

The incidence of severe adverse events of myocarditis were reported in 0.09% to 2.4% of cancer patients receiving immune check point inhibitors (ICI).[53,54] The combination use of ICIs such as nivolumab and ipilimumab report more frequent and severe myocarditis than single-agent nivolumab (0.27% vs 0.06%; P <.001; five fatal events vs one event).[55] The median latency between receiving the combination of ipilimumab and nivolumab and developing myocarditis was 17 days after the first treatment (range, 13–64 days).[55] However, there have been cases of events developing beyond 32 weeks after starting treatment.[56]

The risk factors might include diabetes mellitus, obstructive sleep apnea, and body mass index greater than 26 in patients receiving combination therapy.[54] Patients with a previous history of cardiac diseases might develop myocarditis. In a small case series of 17 patients, no obvious cardiac- or cancer-specific clinical features predisposed patients to severe myocarditis. However, in a case series of eight patients, five had preexisting CV disease.[57]

Because immune-mediated myocarditis can have a fulminant progression, a close monitoring strategy is recommended, especially when patients with receiving combination therapy.[55] A baseline ECG and weekly testing of troponin levels during weeks 1 to 3 for patients receiving combination immunotherapy is a reported approach.[55] Nonetheless, upon the development of symptoms, a more extensive workup is necessary and should be directed by a consulting cardiologist.[58] Initial workup for those with symptoms includes ECG, troponin, BNP, echocardiography, and chest radiography. High clinical suspicion can require additional testing, including cardiac catheterization with endomyocardial biopsy, cardiac magnetic resonance imaging (MRI), or both.[54,58] The updated Lake Louise Criteria are used in diagnosing myocarditis by cardiac MRI. If one of the main criteria is present, either T2-based marker for myocardial edema (T2mapping or T2-weighted images) or T1-based marker for nonischemic myocardial injury, myocarditis is diagnosed by MRI. Supportive criteria include signs of pericarditis or systolic dysfunction with regional or global wall motion abnormalities (although most cases maintain a preserved LVEF).[57,59] The role of biomarkers is not completely clear, but a troponin T value of equal or greater than 1.5 ng/mL seems to indicate a signal in identifying patients with ICI-related myocarditis and a higher risk of major CV events.[60]

The Society for Immunotherapy of Cancer Toxicity Management Working Group and the American Society of Clinical Oncology have developed clinical practice guidelines that were published in 2017 and 2018, respectively.[58,60] Contrary to the general notion

with the majority of immune-related adverse events (irAEs) in which toxicity can be closely monitored if it is grade 1, the recommendation is to hold ICI for grade 1 cardiac irAEs and permanently discontinue ICI if the cardiac irAE is beyond grade 1. The management of grade 3 and 4 is according to 2019 National Comprehensive Cancer Network guidelines. Initial treatment recommendations include high-dose corticosteroids (1 mg/kg of methylprednisolone for 3–5 days) until cardiac function return to baseline that is then tapered over 4 to 6 weeks. If there is no improvement within 24 hours on steroids, patients with elevated troponin or conduction abnormalities may need immediate transfer to a coronary care unit for further investigation. Addition of antithymocyte globulin and infliximab might be considered.[61] Rechallenging with ICI after myocarditis is controversial given high risk for further cardiac complications.[60] Conduction abnormalities such as high-degree atrioventricular (AV) block maybe seen in fulminant cases.[55] Although the prognosis is poor, our institution reported a case of a patient who presented with third-degree AV block and survived. The patient worsened after treatment with high-dose steroids, but after adding mycophenolate mofetil, he showed clinical improvement. Another treatment to consider for severe, steroid-refractory ICI myocarditis is abatacept, a cytotoxic T-cell lymphocyte antigen-4 (CTLA-4) agonist. Abatacept inhibits CD28–B 7–mediated T-cell co-stimulation at the level of dendritic cells and thus may lead to rapid global T-cell anergy with limited off-target effects of ICI.[62]

Unfortunately, some cardiac toxicities are fulminant and progress to death. However, with prompt recognition and therapy, cardiac contractility and conduction abnormalities can improve.[63] Currently, the relative rarity of these adverse events limits the ability to predict progression or resolution with more certainty. Nevertheless, with more patients receiving immune therapies, the incidence of such events is anticipated to increase, which may provide clarity on treatment algorithms.

Preexisting Cardiac Dysfunction

Patients with underlying diastolic or systolic LV systolic dysfunction, including hypertensive heart disease, ischemic heart disease, or nonischemic cardiomyopathy, are at greater risk of HF in the setting of cancer and cancer therapy. Decompensated HF symptoms in these patients are often triggered by large amounts of intravenous (IV) fluids given during certain chemotherapy infusions (ie, cisplatin). These patients typically respond well to withholding fluids and using diuretics. Standard HF therapies, including β-blockers and ACE inhibitors, are indicated if LV systolic dysfunction is present.[64]

ISCHEMIC ARTERIAL DISEASE IN PATIENTS WITH CANCER

The association between malignancy and ischemic arterial diseases is well established in the literature. The clinical presentation and management of arterial ischemic events in general vary based on the arterial bed and the organ involved; the clinical spectrum includes stroke, myocardial infarction, and visceral and limb ischemia. Looking at two large separate cohorts of patients with cancer, Khorana et al[65,66] reported a 1.5% to 3.1% incidence of arterial ischemic events. The most common events were cardiac, and fewer than 0.5% of events involved limb ischemia. The rate of arterial ischemic events is much higher in specific cancer populations such as those with myeloproliferative disorders (MPDs) and those with hematologic malignancies with secondary amyloidosis. To assess the significance and outcome of these arterial events, Khorana et al[67] prospectively followed 4466 patients with cancer receiving active chemotherapy. Death from thromboembolism was a leading cause of death (9.2%) with a higher rate of death from arterial events compared with venous events.

Etiology and Mechanisms

In addition to the usual causes and the traditional risk factors typically associated with arterial ischemia in the general population, patients with underlying malignancy have added increased risks for arterial ischemic events related to the inherent thrombophilia associated with their cancer and its therapy (Table 62–3). From the clinical perspective, it is useful to divide these cancer-related causes into two broad categories; the first category includes mechanisms, and the second group includes cancer etiologies.

Specific Mechanisms of Arterial Ischemia in Patients with Cancer

Hypercoagulability

Multifactorial mechanisms have been implicated in the pathogenesis of hypercoagulability and thrombosis in the setting of underlying cancer. As shown in (Figure 62–7), circulating and in situ cancer cells can enhance the activity of tissue factor and other cancer procoagulant factors and can activate platelets. These mediators can then trigger coagulation in previously damaged vessels such as the coronary arteries or peripheral arteries or in even previously healthy vessels.[68] The result is cancer enhanced thrombosis, which manifests as (1) low-grade disseminated intravascular coagulation, (2) venous thrombophlebitis, (3) arterial thrombosis, (4) accelerated ischemic

cardiac and peripheral vascular disease, and (5) nonbacterial thrombotic endocarditis. Another subgroup of patients with cancer with a hypercoagulable condition present with digital ischemia with no evidence of large-vessel involvement (Fig. 62–8). The mechanism is thought to be capillary deposition with antigen-mediated antibody complexes from tumor cells. This paraneoplastic syndrome is usually very difficult to treat; symptoms do not respond to usual vascular therapy until the cancer is fully controlled.[69]

Other Mechanisms

Other reported causes include radiation therapy, tumor embolization, arterial wall invasion by tumor and paradoxical embolization. Often, a specific cause is never identified. In our cohort of 74 patients with acute arterial limb ischemia, 24 confirmed pathology samples were available. The majority of patients (67%) had thrombus, and 21% had associated underlying significant atherosclerotic disease.[70] Tumor invasion of the artery was observed in two patients, and only one patient with leukemia had leukemic cell aggregates (Fig. 62–9).

Thrombotic Events Associated with Specific Malignancies

Myeloproliferative Disorders

MPDs, such as polycythemia vera (PV) and essential thrombocythemia (ET), are associated with vascular events characterized by microcirculatory dysregulation and thrombosis in various central and peripheral terminal arterial beds, leading to ischemic strokes

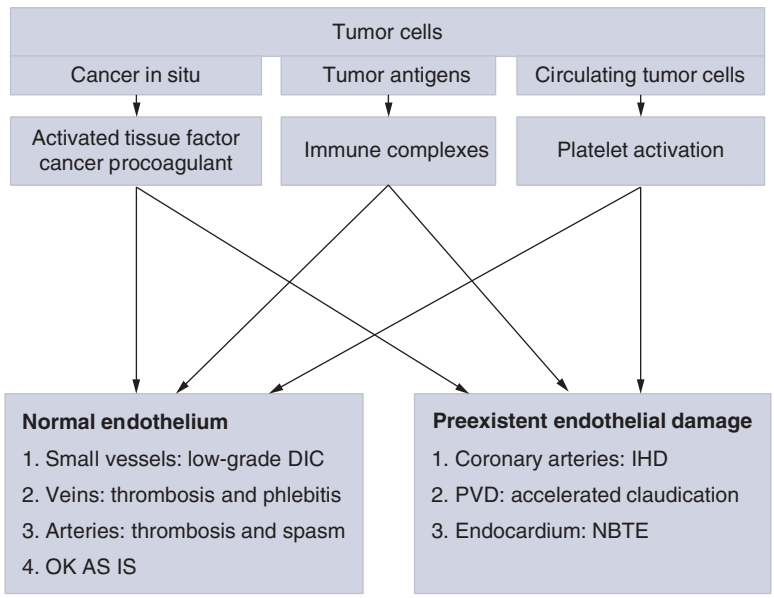

FIGURE 62–7 Suggested mechanisms for the enhanced thrombosis observed in patients with cancer.[47] DIC, disseminated intravascular coagulation; IHD, Ischemic heart disease; PAD, Peripheral Arterial Disease; NBTE, nonbacterial thrombotic endocarditis.

FIGURE 62–8 Digital ischemia in a 72-year-old man with small cell lung cancer.

and acute coronary syndrome.[71,72] The incidence of thrombosis upon diagnosis with PV and ET has been reported between 9.7% and 38.6% in various studies, with 64% to 96.7% of these being arterial events.[73] Primary prevention of thrombosis in MPD involves the use of aspirin.[74]

Acute Leukemia

Although hemorrhage is the typical complication in acute leukemia, arterial ischemic events caused by thrombosis can occur as well. De Stefano et al[75] reported a 1.4% incidence of thrombosis at presentation in acute lymphoblastic leukemia and a 9.6% incidence in acute promyelocytic leukemia. Thromboembolism was reported as the presenting manifestation in more than half of the patients in this study, with 80% venous thromboembolisms (VTEs) and 20% arterial ischemic events.[75] Options for management include leukapheresis, urgent chemotherapy, and sometimes revascularization for large-vessel occlusion.[75]

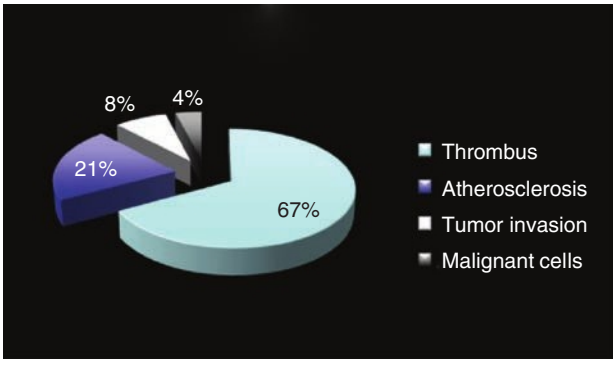

FIGURE 62–9 Cause of acute arterial ischemia at MD Anderson Cancer Center.[37]

Cardiac Amyloidosis

Primary amyloidosis, particularly AL type, has been associated with intracardiac thrombosis and thromboembolic events despite preserved LV ejection fraction and absence of cardiac arrhythmias, with an incidence ranging from 26% to 33%[76,77] and an arterial thromboembolism-related mortality rate of 26% in one study.[77] A variety of mechanisms have been proposed for this phenomenon, including endothelial dysfunction, endomyocardial damage,[78] direct myocardial toxic effect,[79] and hypercoagulability.[80] In managing these patients, the benefit of prophylactic anticoagulation needs to be balanced against the risk of hemorrhage from fragile blood vessels with amyloid deposition.[81]

Arterial Ischemic Events Related to Cancer Management and Therapy

Certain chemotherapeutic agents are known to have a stronger association with arterial ischemic events because of specific pathophysiological mechanisms. These drugs can be divided into two categories (Table 62–4). The first category includes several standard chemotherapeutic agents such as L-asparaginase, cisplatin, 5-FU, capecitabine, and gemcitabine. In a study by De Stefano et al,[75] the incidence of thrombosis in a population with acute lymphoblastic leukemia was shown to increase from 1.4% to 10.6% with L-asparaginase treatment. Cisplatin is known to induce thrombosis by causing endothelial damage and increasing monocyte tissue factor activity and platelet activation with a reported 12% to 17.6%[82] incidence of thrombosis, including strokes, recurrent peripheral arterial events, and aortic thrombosis.[83] 5-FU leads to a decrease in

TABLE 62–4 Chemotherapeutic Agents Associated with Arterial Ischemic Events

Fluorouracil
Gemcitabine
Capecitabine
Angiogenesis inhibitors: Thalidomide Bevacizumab Sunitinib Sorafenib Ponatinib

protein C and endothelial-independent vasoconstriction via protein kinase C.[84] Gemcitabine has been associated with vascular events ranging from systemic capillary leaks and thrombotic microangiopathy with digital ischemia to VTE.[85]

The second category of cancer drugs associated with arterial ischemia includes the group of angiogenesis inhibitors such as thalidomide and several targeted therapy drugs also known as the vascular signaling pathway inhibitors (VSPIs). These include bevacizumab and several TKIs such as sunitinib, sorafenib, axitinib, pazopanib, and ponatinib. Thalidomide is associated with a risk of vascular thrombosis because of its antiangiogenetic effect and its modulation of adhesion molecules.[86,87] This increased risk was evaluated by Libourel et al.[88] In their prospective cohort study of 195 patients with multiple myeloma, 11 patients developed an arterial ischemic event over a period of 522 patient-years (5.6%).[88] Interestingly, several of these patients developed arterial thrombosis while receiving anticoagulation therapy. Bevacizumab has been linked to serious arterial ischemic events[89,90] through mechanisms such as endothelial damage and overexpression of proinflammatory genes.[91–93] In their population of patients receiving concurrent bevacizumab and chemotherapy, Scappaticci et al[94] reported the absolute rate of arterial events as 5.5 events per 100-person years. Pereg and Lisher[89] reported efficacy of low-dose aspirin in preventing CV complications in patients 65 years of age or older who had a prior history of thromboembolic events and were currently receiving bevacizumab. The mechanism of vascular toxicities associated with TKIs is not well understood and is thought to be partially mediated by nitric oxide (NO) inhibition versus accelerated atherosclerosis and possible interference with platelet function. In a meta-analysis by Choueiri et al,[95] the incidence of arterial ischemia was reported at 4% with a threefold increase in risk in those patients being treated with sunitinib or sorafenib. Arterial ischemia with ponatinib has been reported to be more than 20%, leading to the implementation of major restrictions on indications and monitoring by the FDA.[96]

Management

The management strategy should be tailored to the patient's clinical condition and the cancer type. Primary preventive strategies include lifelong antiplatelet therapy and statins for radiation-induced and known underlying atherosclerotic disease; aspirin and/or hydroxyurea for those with MPDs[97]; and aspirin for patients with a history of prior CV events or who are older than 65 years of age and receiving bevacizumab.[89] Treatment of the acute event varies by type of organ involved (cardiac, central nervous system, limb, or bowel ischemia) and is aimed at reversing ischemia and minimizing organ damage followed by long-term therapy and secondary prevention. The decision to use medical therapy versus a surgical or percutaneous approach for revascularization should be determined by the general condition of the patient and availability of local expertise. Management of these patients is often a challenge based on their bleeding risks, especially in the setting of associated thrombocytopenia. Although acute coronary intervention has been shown to be reasonably safe in these patients,[98] there is a significant concern regarding the need for dual antiplatelet therapy for an extended period of time. Drug-eluting coronary stents pose a special problem in this setting and should be avoided. We typically recommend using bare-metal stents because many of these patients will end up receiving more chemotherapy or surgery for the management of their cancer. The type of long-term anticoagulation recommended for secondary prevention depends on the underlying mechanism and cause. Table 62–5 summarizes some of the therapeutic interventions for arterial ischemic events observed in the setting of malignancy and hematologic disorders.

TABLE 62–5 Therapeutic Interventions of Potential Benefit for Arterial Ischemic Events Observed in the Setting of Malignancy or Hematologic Disorders

Arterial Events Associated with	Treatment Options
Acute leukemia	Chemotherapy and leukapheresis Surgical thromboembolectomy
Radiation therapy	Antiplatelet therapy Statin therapy Percutaneous angioplasty with or without stenting Surgery
Paradoxical embolization	Systemic anticoagulation PFO closure for recurrent events
Myeloproliferative disorders	Aspirin (for primary and secondary prevention) Cell reduction therapy (ie, phlebotomy, hydroxyurea, anagrelide, interferon-α)
Cardiac amyloidosis	Systemic anticoagulation
Bevacizumab	Aspirin (for primary prevention in patients older than 65 years of age or with a history of cardiovascular events)
NBTE	Systemic anticoagulation

NBTE, nonbacterial thrombotic endocarditis; PFO, patient foramen ovale.

CARDIAC ARRHYTHMIA IN PATIENTS WITH CANCER

Patients with cancer have complex comorbidities that predispose them to certain arrhythmias and that limit the therapeutic options when using antiarrhythmia drugs. Patients with underlying malignancy can develop cardiac arrhythmia as a consequence of the malignancy itself or its therapy (Fig. 62–10). When patients with cancer present with cardiac rhythm disturbances, they typically have associated complex comorbidities, and the presence of a rapid heart rate or rhythm irregularity can be simply a sign of a much more complicated and severe acute illness (eg, atrial tachycardia or atrial fibrillation in the setting of acute pulmonary embolism, polymorphic ventricular tachycardia triggered by severe metabolic derangements and electrolyte imbalance while on a QT-prolonging agent). Adequate patient management necessitates accurate diagnosis and identification of the potential causes and mechanisms that trigger these arrhythmias.

Diagnosis and Management

In the absence of clinical data to support a different approach, the management of cardiac arrhythmia in patients with cancer should in general follow the well-established standard-of-care guidelines.[99] Treatment, however, can sometimes differ slightly from those without malignancy. The difference is mainly related to the choice of antiarrhythmic drugs and AV-blocking agents and the timing and safety of anticoagulation. The choice of these drugs should take into consideration the possibility of drug–drug interactions (ie, Cardizem and verapamil are potent CYP inhibitors that can alter the pharmacokinetics of many chemotherapeutic agents; several classes of antiarrhythmic drugs can potentiate QT prolongation observed with many cancer-targeted therapies). In addition, the decision for short- and long-term anticoagulation for atrial fibrillation or flutter should be tailored carefully in each case because many patients face higher risks of bleeding in the setting of thrombocytopenia secondary to the malignancy or its therapy.

Bradyarrhythmias

Bradyarrhythmias can generally be categorized as sick sinus syndrome or heart block. The most common presenting symptoms of bradyarrhythmias include fatigue, lightheadedness, dizziness, or syncope. Many different causes have been linked to bradyarrhythmias in patients with cancer. These include myocardial infiltration, AV nodal blocking drugs such as antiemetics, and certain chemotherapies and immunotherapies. Chemotherapies know to cause bradycardia include paclitaxel and thalidomide. Possible suggested mechanisms include direct effect on the Purkinje system and extracardiac autonomic controls. The incidence of bradycardia with paclitaxel has been reported as high as 31%. A less common but equally important cause of bradycardia is baroreflex failure. This is typically characterized by volatility of heart rate and BP, including profound and severe bradycardia necessitating use of a permanent pacemaker. This is most often seen in patients with cancer who undergo extensive head and neck surgery or receive neck radiation therapy, causing

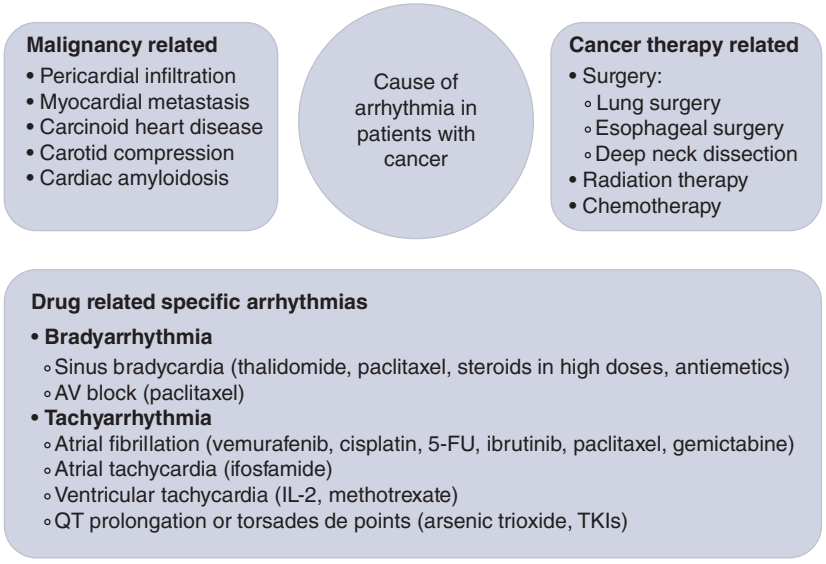

FIGURE 62–10 Causes and mechanisms of cardiac arrhythmia related to cancer and its management. 5-FU, 5-fluorouracil; IL-2, interleukin-2; TKI, tyrosine kinase inhibitor.

dysregulation of the autonomic system at the level of the vascular baroreceptors, the glossopharyngeal or vagal nerves, or the brain stem.[100]

Treatment

Treatment of bradyarrhythmias begins with identifying and removing any potentially offending agents that can exacerbate bradycardia. For severely symptomatic patients, urgent medical therapy with atropine or an IV inotrope, such as dopamine or epinephrine, may be used. In emergency situations, transcutaneous or transvenous pacemaker therapy may be required to maintain hemodynamic support. Long-term support with permanent pacing will depend on the severity of the symptoms related to the bradyarrhythmia and whether or not it is reversible.

Tachyarrhythmias

These are typically classified into four different categories:

1. Irregular tachycardia: atrial fibrillation, atrial flutter, multifocal atrial tachycardia (MAT)
2. Regular narrow QRS-complex tachycardia: sinus tachycardia, atrial tachycardia, supraventricular tachycardia (SVT)
3. Wide QRS-complex tachycardia: ventricular tachycardia, SVT with aberrancy, preexcited tachycardia
4. Polymorphic ventricular tachycardia

Sinus tachycardia is by far the most common cause of rapid heart rate in patients with cancer. It is usually secondary to other concomitant acute illnesses (eg, infection, pneumonia, pulmonary embolism, surgery). Evaluation and treatment of the primary and the precipitating causes are effective.

Atrial fibrillation has been shown in several epidemiologic studies to be more prevalent in patients with cancer compared with the general population.[101] Guzzetti et al[102] reported a threefold increase in the prevalence of atrial fibrillation in patients hospitalized with colon cancer compared with those admitted for non-neoplastic diseases. The highest incidence of malignancy-related atrial fibrillation has been reported in patients undergoing thoracic (6%–32%)[103] and esophageal (9.2%)[104] cancer surgery. Pos-operative atrial fibrillation appears to be associated with higher in-hospital length of stay, intensive care unit admissions, and most important, higher short- and long-term mortality rates.[102]

Acute management of patients with atrial fibrillation follows the general recommendations of urgent cardioversion for hemodynamically unstable patients and initial rate control for stable patients. Ventricular rate control can be achieved using AV-blocking agents such as digoxin, β-blockers, or the nondihydropyridine calcium-channel antagonists (Cardizem or verapamil). Amiodarone can also be considered for rate control in patients with marginal BP or LV dysfunction. For the subgroup of patients with previously known and documented permanent atrial fibrillation, controlling the heart rate and reversing the cause of acute decompensation should suffice.

The clinical decision for short- and long-term anticoagulation for atrial fibrillation is challenging and should be tailored carefully to each patient individually because patients can be at high thromboembolic risk based on the standard risks scores used in cardiology and concomitantly face higher risks of bleeding in the setting of thrombocytopenia secondary to the malignancy or its therapy. On the other hand, a patient with low thromboembolic risks based on these same scores can still be at high risk secondary to an acquired hypercoagulable state related to cancer or its therapy. Figure 62–11 shows a suggested algorithm to help risk stratify patients for anticoagulation in the setting of atrial fibrillation based on their thromboembolic and bleeding risk scores. (This algorithm has not been validated).

Polymorphic Ventricular Tachycardia and QT Prolongation

Patients with cancer require special consideration because of the risk of QT prolongation and torsades de pointes from both chemotherapeutic agents and adjunctive medications. QT intervals as measured by ECG reflect the total duration of the action potential at the cellular level. QT prolongation is associated with increased risk for polymorphic ventricular tachycardia, also known as torsades de pointes, and subsequent sudden cardiac death. The corrected QT interval is considered prolonged when it is greater than 460 ms in women and 440 ms in men. The QT interval varies with the cardiac rate and is typically reported as corrected QT interval (QTc) after correction for the patient's heart rate. Current ECG technology and digital diagnostic algorithms can generate immediate measurement of the QTc interval. It is important to recognize that accurate measurement and interpretation of QTc are essential in minimizing the chances of inappropriate drug discontinuation or overestimation of the true incidence of QT prolongation with these drugs.

In the cancer population, there are several risk factors predisposing patients to QT prolongation and subsequent torsades de pointes. These risks factors include electrolyte imbalance (hypomagnesemia, hypokalemia, hypocalcemia), metabolic derangements (hypothyroidism), and certain cancer therapies including chemotherapeutic agents (Table 62–6). It is of clinical importance to correct any concomitant contributing factors that may predispose to or worsen

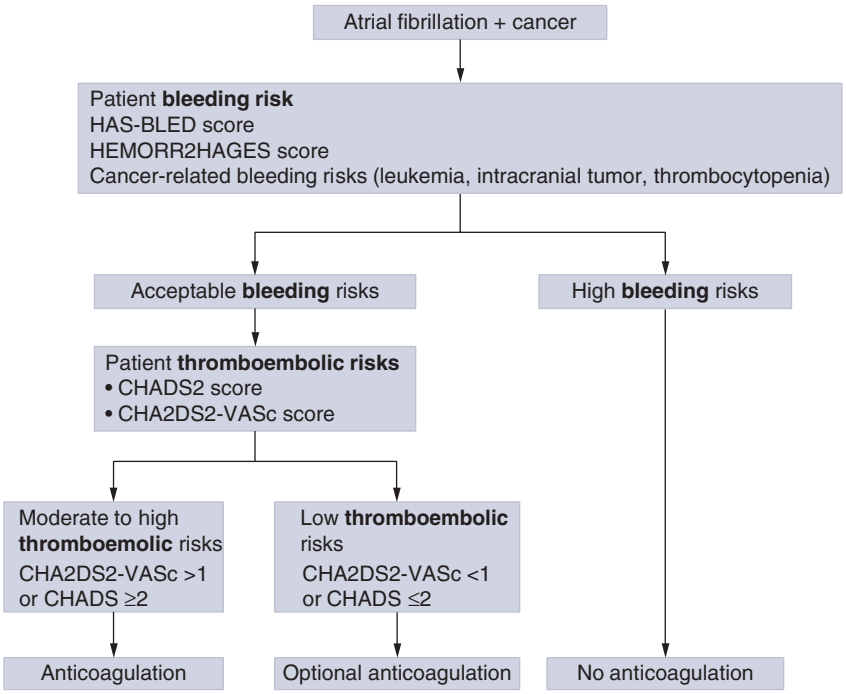

FIGURE 62–11 **Algorithm for decision making regarding antithrombotic therapy in patients with cancer and atrial fibrillation. QT interval prolongation. Cancer treatment interruption is typically advised when a QT interval is above 500 ms, and permanent treatment discontinuation is recommended if QT prolongation recurs or is associated with ventricular tachycardia or reported syncope. Figure 62–12 shows a useful algorithm to screen and monitor patients being considered for therapy with agents associated with potential QT prolongation and torsades de pointe.

Among the TKIs, a high incidence of QT prolongation has been reported with several of these drugs, leading to an FDA black box warning mandating close ECG monitoring and management recommendations as listed in (Table 62–7).

HDAC, histone deacetylase.

PERICARDIAL DISEASES IN PATIENTS WITH CANCER

Pericardial diseases are common in patients with cancer and can manifest as acute pericarditis, pericardial effusion, cardiac tamponade, or constrictive pericarditis. Triggers of pericardial diseases include infectious causes, tumor invasion of the pericardium, or the side effect of cancer therapy, specifically chest radiation or chemotherapy (Table 62–8). The lack of randomized clinical trials makes the management of these syndromes in patients with cancer mainly empirical based on expert opinion and limited data extrapolated from the few trials done in noncancer population.[105,106]

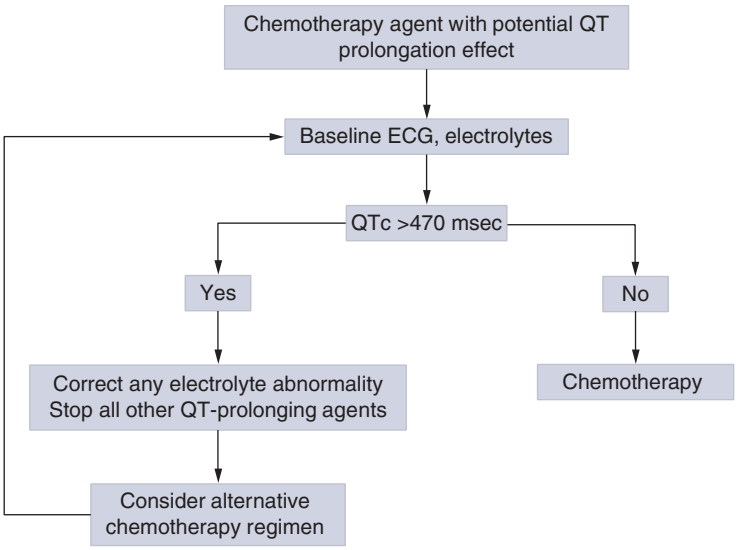

FIGURE 62–12 **Suggested algorithm for the initial assessment and management of patients being considered for potential QT-prolonging chemotherapeutic agents. ECG, electrocardiogram.**

Acute Pericarditis

The diagnosis of pericarditis is based on the findings of pleuritic chest pain, fever, and ST elevation detected by ECG. Patients are typically hospitalized after they present with acute pericarditis if they show evidence of high fever, suspected myopericarditis, or the presence of a large (>20 mm in diameter) pericardial effusion or tamponade physiology detected by echocardiography. Nonsteroidal antiinflammatory drugs (NSAIDs) and aspirin are the mainstays of therapy for acute pericarditis. Intermediate to high doses of NSAIDs are typically used for 10 to 15 days followed by a slow taper over an additional 1 to 2 weeks. Colchicine is often added to the regimen at a dose of 0.6 mg/day for 3 months to help minimize recurrence.[107,108] It is a well-tolerated drug with few side effects reported. Unfortunately, however, the few contraindications to the use of colchicine are common in patients with cancer, particularly in recent stem cell transplant recipients. These contraindications include significant interactions with several drugs, including antifungals, antibiotics, and immunosuppressants such as tacrolimus. These drugs can alter colchicine metabolism such that the level is significantly increased.

The use of corticosteroids is typically discouraged in patients without cancer because of significant side effects and the association with increased incidence of recurrent pericarditis. The situation, however, is often reversed in patients with cancer because of the numerous contraindications to the use of aspirin and NSAIDs in this population. Steroids are typically used in patients with low platelet counts or patients with blood dyscrasias when NSAIDs cannot be used. The evidence comparing the effectiveness of low- versus high-dose steroids is weak. High-dose prednisone of 1.0 to 1.5 mg per kilogram (or its equivalent) over many weeks with a very slow taper is associated with the lowest rate of recurrence but with a high rate of steroid-related side effects. On the other hand, a lower dose of prednisone of 0.2 to 0.5 mg per kilogram is associated with fewer side effects but a higher relapse rate. Because there are no strong data to support one option over the other, we typically use the protocol summarized in (Fig. 62–13).

Pericardial Effusion

Pericardial effusion is a common finding and has been reported in up to 34% of autopsies performed on patients with cancer. Its management is guided by three main factors:

1. Clinical significance of the effusion (presence or absence of associated symptoms)
2. Effusion size
3. Cause of the effusion

ETIOLOGY

In patients with cancer, up to two thirds of pericardial effusions are nonmalignant. The mechanism of effusion in this setting is likely related to a loss of adequate lymphatic drainage of the pericardial sac secondary to lymphangitic spread of the malignancy or mediastinal irradiation. Other causes include infection, radiation, and certain drugs (see Table 62–8). Clarifying the specific cause

TABLE 62–7 Monitoring Recommendations for Small-Molecule Tyrosine Kinase Inhibitors Associated with Prolonged QT Interval

Drug	Monitoring
Pazopanib (Votrient) Bosutinib (Bosulif) Crizotinib (Xalkori) Dasatinib (Sprycel) Lapatinib (Tykerb)	Use caution in patients at risk for QT prolongation, including patients with long QT syndrome, patients taking antiarrhythmic medications or other medications that lead to QT prolongation or potassium-wasting diuretics, and patients with cumulative high-dose anthracycline therapy and conditions that cause hypokalemia or hypomagnesemia Correct hypokalemia and hypomagnesemia before initiation of therapy.
In addition to the general recommendations listed above, the ECG monitoring guidelines listed below must be followed when patients take certain TKIs.	
Vandetanib (Caprelsa)	1. Do not initiate treatment unless the QTcF is <450 msec. 2. Order an ECG at baseline, at 2–4 weeks, at 8–12 weeks, and every 3 months thereafter. 3. During treatment, if QTcF >500 msec, withhold vandetanib and resume at a reduced dose when QTcF is <450 msec.
Nilotinib (Tasigna)	Monitor ECG and QT_c at baseline, at 7 days, with dose change, and periodically. 1. QT_c >480 msec: Withhold treatment, monitor and correct potassium and magnesium levels, and review concurrent medications. 2. If QT_cF returns to <450 msec and to within 20 msec of baseline within 2 weeks, resume at prior dose. 3. If QT_cF returns to 450–480 msec after 2 weeks, reduce dose to 400 mg once daily. 4. If QT_cF >480 msec after dosage reduction to 400 mg once daily, discontinue treatment.
Vemurafenib (Zelboraf)	1. Do not initiate treatment if baseline QT_c >500 msec. 2. Monitor ECG at baseline, at 15 days, then monthly for 3 months, and then every 3 months and with dosage adjustments. 3. During treatment, if QT_c >500 msec, temporarily interrupt treatment; may reinitiate with a dose reduction once QT_c falls to <500 msec. 4. Discontinue (permanently) if, after correction of risk factors, the QT_c continues to increase >500 msec.

[a]ECG, electrocardiogram; TKI, tyrosine kinase inhibitor; QTcF, Fridericia-corrected QT interval.

of an effusion not only helps to define treatment modality but also helps to determine prognosis because malignant effusions are associated with a dismal prognosis of 16% 1-year survival rate compared with a 55% 1-year survival rate in patients with nonmalignant effusions.[109]

Diagnosis

Patients with pericardial effusion may be asymptomatic but may also present with mild symptoms of chest pain, cough, or dyspnea. Extreme cases can present with frank tamponade and shock. Clinicians should be very careful when relying on vital signs to guide management in patients with a pericardial effusion; stroke volume and cardiac output start to drop at an early stage (as the effusion builds up). BP, on the other hand, is maintained by progressive increase in heart rate until it reaches a plateau, after which a threshold is reached and a severe drop in BP follows. Waiting for these clinical findings to manifest (ie, rapid heart rate and a drop in BP) may be too late, and the patient can rapidly progress to shock. Echocardiography is the main diagnostic tool for confirming the diagnosis of a pericardial effusion and detecting tamponade physiology. Pericardial effusion size is classified as small, moderate, or large; large effusions are larger than 2 cm in diameter. Helpful echocardiographic findings to detect early tamponade physiology include the presence of chamber collapse or significant respiratory variation in the mitral or tricuspid valve inflow; these features manifest much earlier than BP drop and heart rate increase.

TABLE 62–8 Causes of Pericardial Diseases in Patients with Cancer

Infection
Tumor invasion
Radiation
Chemotherapy Purine analogues (eg, fludarabine) Antimetabolites (eg, capecitabine) Anthracyclines (eg, doxorubicin) Alkylating agents (eg, cyclophosphamide) Immunotherapy (eg, Immune Checkpoint Inhibitors (ICIS))

Management

There is no evidence that medical therapy plays any role in the management of an effusion, except in the

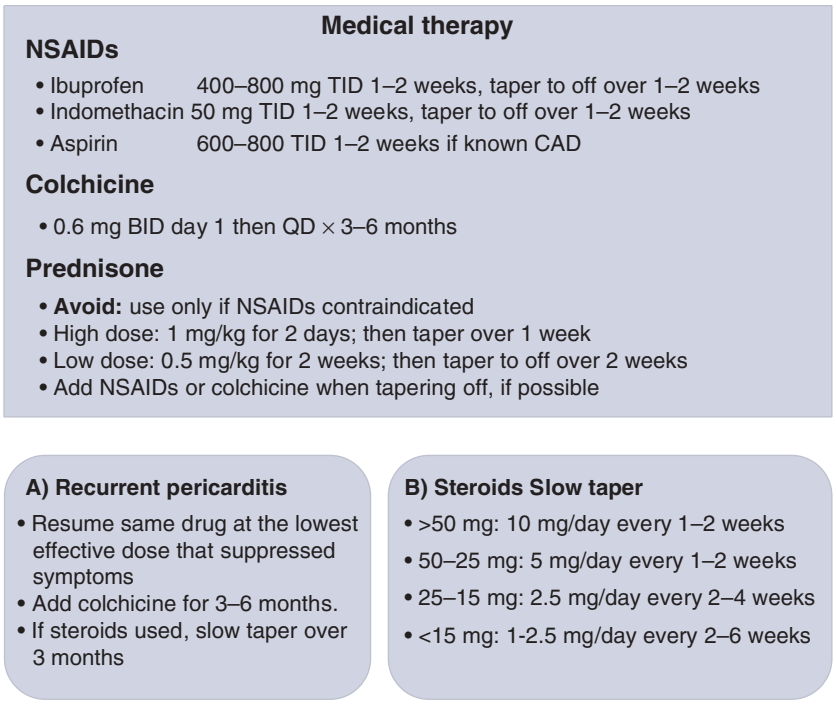

FIGURE 62–13 **Medical management of patients with acute pericarditis. BID, twice a day; CAD, coronary artery disease; NSAID, nonsteroidal antiinflammatory drug; QD, every day; TID, three times a day.**

case of concomitant inflammation (ie, pericarditis). At MDACC, the three main indications for pericardial fluid drainage are: large effusion (>2 cm in diameter), diagnostic purposes, and the presence of clinical or echocardiographic evidence of tamponade physiology. As shown in Figure 62–14, the first step after the detection of a moderate to large pericardial effusion is to assess for clinical or echocardiographic evidence of tamponade. If there is no sign of tamponade, then the effusion size dictates the next step in management: small to moderate effusions (<2 cm in diameter) are monitored clinically and with serial echocardiograms. Larger effusions (those >2 cm in diameter) require drainage because about one third of these patients eventually progress to tamponade.[110]

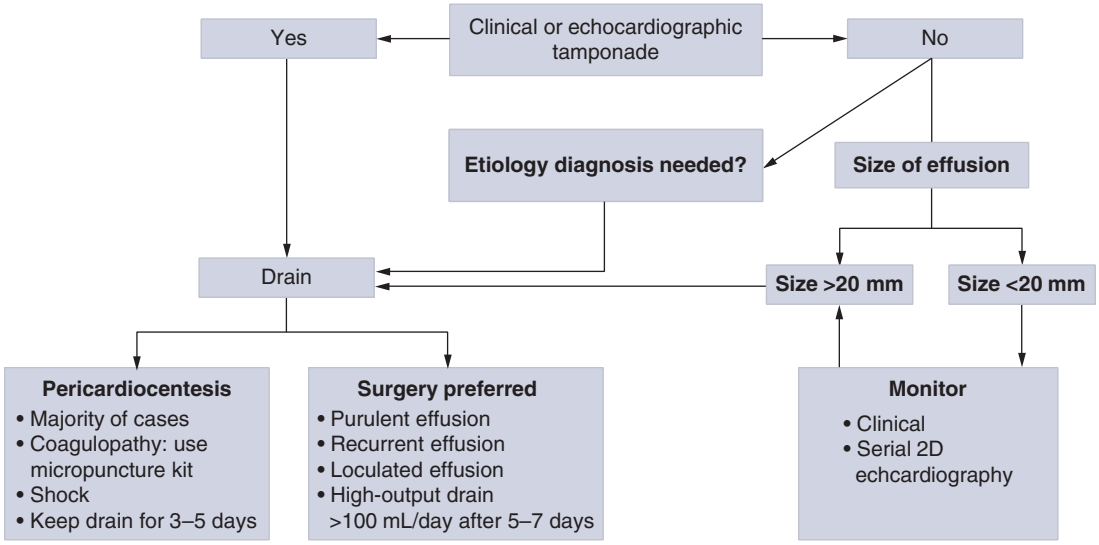

FIGURE 62–14 **Management algorithm for patients with pericardial effusion. 2D, two-dimensional.**

Draining a pericardial effusion can be achieved percutaneously or surgically by creating a pericardial window, and in some clinical centers, by thoracoscopy. Surgery is preferred in the setting of recurrent effusions, purulent effusions, or high-output drainage (>100 mL per day for 5–7 days after percutaneous pericardiocentesis). The percutaneous approach is preferred in the majority of patients at MDACC, especially if the patient has hypotension or a coagulopathy. After pericardiocentesis, pericardial fluid is sent to the laboratory for chemistry, microbiology, cytology, and flow cytometry and sometimes to check for tumor markers.[111] A pericardial draining catheter is typically left in place for 5 days because this approach has shown to lower the effusion recurrence rate by two thirds. Sometimes the catheter is removed early if drainage output is less than 25 mL over 24 hours and if there is no significant residual effusion on an echocardiogram. When performed by experienced teams, pericardiocentesis is a safe procedure with a low complication rate (<5%) and a high success rate (98%).[112] Recently, we were able to demonstrate the feasibility and safety of this approach in a cohort of patients with severe thrombocytopenia related to leukemia or chemotherapy.[113] After initial pericardiocentesis, almost one in four patients will develop recurrent effusions. Chemical pericardiodesis can be considered. However, this approach can be complicated by severe pain, risk of infection, and long-term constrictive physiology in addition to a 10% recurrence rate despite chemical pericardiodesis.[109]

HYPERTENSION AND CANCER MANAGEMENT

Hypertension is known to be the most commonly diagnosed comorbidity in patients with cancer (37%); its prevalence before chemotherapy exposure is similar to that reported in the general population (29%). A much higher rate has been reported in association with certain cancer therapies, including alkylating agents, angiogenesis inhibitors, immunosuppressants, and hormones such as steroids and erythropoietin (EPO) (Table 62–9).[114–116]

Etiology and Pathophysiology

The most common chemotherapeutic agents known to cause hypertension include several of the angiogenesis inhibitors, also referred to as VSPIs. These drugs include anti-VEGF antibody (bevacizumab) and several TKIs (sunitinib, sorafenib, pazopanib, and vandetanib). Hypertension is one of the most common side effects of these drugs. VEGF normally plays an important role in maintaining a balanced vascular tone by regulating NO production in endothelial cells. Hypertension develops when NO bioavailability is reduced, leading to vasoconstriction, increased endothelin production, capillary rarefaction, and increased peripheral resistance.[117,118] New-onset or worsening hypertension with these agents can develop very early (within 24 hours) after initiation but is typically observed within the first few weeks. BP usually returns to baseline shortly after therapy has been discontinued. Several previous limited observations raised the interesting concept of using hypertension as a biomarker of cancer response to VSPIs.[118] More data are needed to further clarify the clinical significance of such observation.

Other classes of chemotherapeutic agents are known to cause hypertension. Incidence and time to hypertensive effect for the VSPIs as well as the other agents used in cancer therapy are provided in Table 62–9. Alkylating agents are commonly used in a large number of oncology protocols to treat patients with various solid tumors and blood cancers. Hypertension is frequent with these agents and is most commonly seen with cisplatin and busulfan and much

TABLE 62–9 Cancer Therapies Associated with New-Onset or Worsening Hypertension

Medications	Overall Incidence of Hypertension (%)
Anti-VEGF antibody	
Bevacizumab	4–35
Tyrosine kinase inhibitors	
Pazopanib	40–47
Sorafenib	17–43
Sunitinib	15–34
Vandetanib	33
Alkylating agents	
Busulfan	36
Cisplatin	39
Calcineurin inhibitors	
Cyclosporine	60–80
Tacrolimus	30
Immunosuppressants	
Mycophenolate mofetil	28–78
mTOR inhibitor: sirolimus	45–49
Other	
Steroids	20
Erythropoietin	13.7–27.7

mTOR, mammalian target of rapamycin; VEGF, vascular endothelial growth factor.

less often with cyclophosphamide. Their effect has been observed both acutely as well as years after therapy has been discontinued; the mechanism is thought to be the result of endothelial dysfunction and arterial vasoconstriction.[114] Calcineurin inhibitors, used for the treatment of graft-versus-host disease, are also associated with a high incidence of hypertension. Cyclosporine and tacrolimus are the major drugs in this class. Their effects are generally seen within the first 6 weeks of therapy and are thought to be the result of the sympathetic system activation and an increase in endothelin-1 synthesis, leading to vasoconstriction.[116] After transplant, many patients also receive immunosuppression with mycophenolate mofetil and the mTOR (mammalian target of rapamycin) inhibitor sirolimus. The mechanism by which these agents cause hypertension is not well understood. Corticosteroids are frequently used in the management of patients with cancer, and they have been associated with variable rates of dose-dependent hypertension. The mechanism by which they cause hypertension is complex but likely involves increased production of angiotensinogen, which induces salt and fluid retention, activation of the sympathetic nervous system, and an increase in patient sensitivity to vasoactive substances. Patients receiving EPO for anemia are also at risk for experiencing severe hypertension. The driving mechanism behind the hypertension is complex and goes beyond just volume expansion. It is also the result of an activation of the renin–angiotensin system and an increase in endothelin-1 with a decrease in NO production caused by changes in the EPO receptor.[116]

Diagnosis and Management

Because hypertension is a risk factor for chemotherapy-induced cardiotoxicity, and poorly controlled hypertension can lead to discontinuation of certain cancer therapies, a prompt and adequate intervention is essential to prevent potential irreversible damage. The Investigational Drug Steering Committee of the National Cancer Institute established a panel of experts to address the concern regarding VSPI-induced hypertension. The recommendations of this panel were published in 2010, and they focused on the evaluation, surveillance, and management of BP problems in patients receiving VSPIs.[119] Treatment of hypertension should begin at the time of diagnosis, without a concern of negatively impacting cancer treatment outcomes.

The choice of a pharmacologic regimen to manage hypertension in patients with cancer should take into consideration several factors. For example, the underlying pathophysiology leading to BP elevation in calcineurin-induced hypertension is caused by excessive vasoconstriction that responds well to dihydropyridine calcium-channel blockers, diuretic agents can help relieve fluid retention associated with steroid-related hypertension, and clonidine has been recommended for the management of severe BP swings in patients with baroreflex failure. Other important factors that need to be considered include the risk of drug–drug interactions. It is also important to consider agents that may have compelling indications in specific types of cancer. Several recent epidemiologic studies reported potential oncologic benefit of β-blockers in melanoma, breast, lung, and colon cancers with mechanism suspected to be mediated by altering β-adrenergic signaling in cancer.[120] It is also important to consider the risks and benefits of medications that target NO or angiotensin II production when determining management strategies for patients taking specific agents such as the VSPIs. Because these anticancer agents cause vasoconstriction in part through a decrease in NO production, medications such as nitrates, phosphodiesterase-5 inhibitors, and nebivolol, a NO-producing β-blocker would in theory seem beneficial. However, there is a theoretical concern that by targeting this pathway, these antihypertension medications might in fact compromise the efficacy of the antitumor therapy.

RADIATION THERAPY–RELATED CARDIOVASCULAR TOXICITY

Radiation therapy to the mediastinum, left breast area, and neck region is a risk factor for premature coronary and carotid atherosclerotic disease (Fig. 62–15). The risk of arterial ischemic events depends on the radiation dose, technique, extent of vasculature exposed, and type of cancer.[121] Radiation therapy is known to accelerate atherosclerosis by triggering oxidative stress, leading to endothelial damage.[122] The acute injury during therapy is sustained for a long period of time via activation of nuclear factor B.[123] Symptoms typically manifest after a long latent period of 5 to 10 years after exposure. Mediastinal exposure is also responsible for a spectrum of CV syndromes, including acute pericarditis, chronic constrictive pericardial disease, valvular heart disease, and myocardial dysfunction with restrictive cardiomyopathy. There does not appear to be a defined threshold level below which radiation therapy is safe to the CV system. Modification of radiation protocols including field planning and breath-holding techniques are currently being used to reduce radiation dose to the CV system. The challenge in managing these patients is the long latency period between exposure and clinical manifestation with many affected patients

being no longer under the care of a treating oncologist. The 2013 expert consensus by the American Society of Echocardiography and the European Association of Cardiovascular Imaging recommend yearly clinical evaluation with a history and physical examination and as needed echocardiogram studies in symptomatic patients. They also recommend a screening echocardiogram at 10 years after chest radiation and every 5 years thereafter. Primary prevention in patients with documented atherosclerosis after radiation therapy includes management of traditional atherosclerotic risk factors.[121] Lifelong antiplatelet therapy and statin therapy are recommended for their antiinflammatory and antithrombotic effects on the irradiated endothelium.[124] Radiation-induced scarring makes surgical intervention difficult; hence, percutaneous angioplasty with or without stenting is becoming the preferred revascularization method with encouraging results for radiation-induced renal, iliac, and femoral arterial disease.[125] Figure 62–16 shows the Department of Cardiology at MDACC recommended algorithm for management and monitoring of these patients.

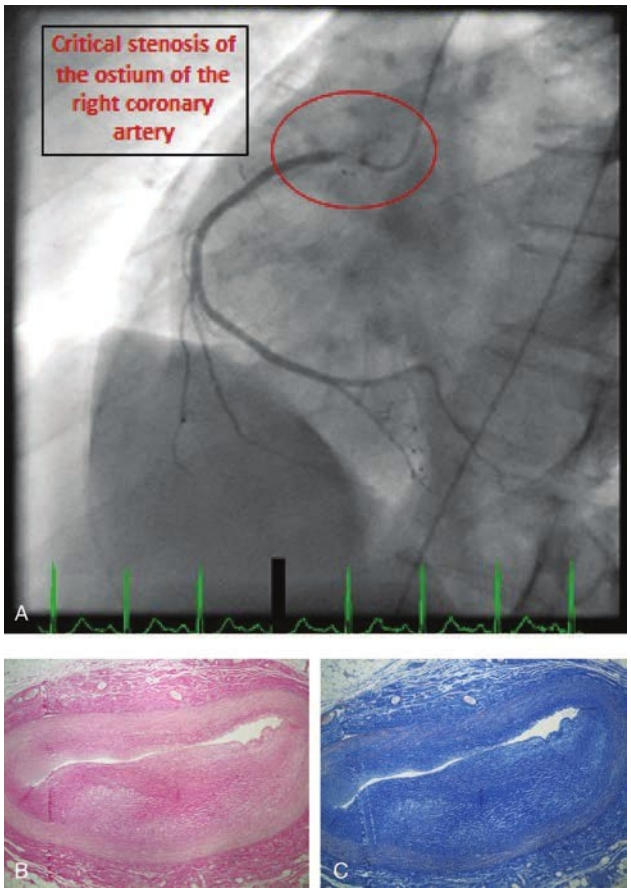

FIGURE 62–15 **A.** Coronary angiogram showing critical, near occlusion of the ostium of the right coronary artery in a 36-year-old patient with prior chest radiation for lymphoma at the age of 5 years. **B.** and **C.** Pathology findings consistent with radiation arteritis.

MD ANDERSON PRACTICE TIPS

- Patients with cancer are at higher risk for CV events compared with control, including a 2-fold increase in risk of arterial ischemia and up to a 15-fold increased risk for cardiomyopathy and HF. Cancer survivors are reported to have a 3.6-fold increased risk of CV-specific mortality at 5 years. These increased CV risks are likely the results of normal age-related pathologies in association with secondary effects of cancer therapies and may explain the increased incidence of certain CV syndromes in this population.
- Despite a lack of consensus, *cardiotoxicity* generally is defined as a drop in LVEF by 5% or more, to less than 55% in the presence of HF symptoms, or an asymptomatic drop in LVEF by 10% or more to less than 55%.
- The majority of patients with cancer with HF have symptoms triggered by one of two broad mechanisms: The first include the acute new-onset cardiomyopathies related to sepsis, stress cardiomyopathy, and myocarditis (toxic or infectious). The second include patients presenting with subacute on chronic HF symptoms related to underlying structural heart disease (chronic ischemic or valvular heart disease), chemotherapy-induced cardiomyopathy, or infiltrative myocardial conditions related to their underlying malignancies (ie, amyloidosis) or to cancer therapy (ie, iron overload).
- Patients with underlying malignancy have added increased risks for arterial ischemic events related to the inherent thrombophilia associated with their cancer and its therapy. Chemotherapeutic agents known to have a stronger association with arterial ischemic events include the group of standard chemotherapeutic agents such as L-asparaginase, cisplatin, 5-FU, capecitabine, and gemcitabine. The second category includes the group of angiogenesis inhibitors such as thalidomide and the VSPIs such as bevacizumab, sunitinib, sorafenib, pazopanib, and ponatinib.
- Radiation therapy can accelerate atherosclerosis by triggering oxidative stress, leading to endothelial damage. Mediastinal exposure is also responsible for a spectrum of CV syndromes, including acute pericarditis, chronic constrictive pericardial disease, valvular heart disease, and myocardial dysfunction with restrictive cardiomyopathy. Protocols including field planning and breath-holding techniques are currently being used to reduce radiation dose to the CV system. Primary prevention in patients with documented atherosclerosis after radiation therapy includes management of traditional atherosclerotic risk factors. Radiation-induced scarring makes surgical intervention difficult; hence, percutaneous angioplasty with or without stenting is becoming the preferred revascularization method for coronary and carotid artery revascularization in these patients.
- The three main indications to drain a suspected neoplastic pericardial effusion are large size effusion (>2 cm in diameter), the need for pathology samples for diagnostic or staging purposes, and the presence of clinical or echocardiographic evidence of tamponade physiology. Percutaneous pericardiocentesis is preferred over surgery. It is a safe procedure with a low complication rate (<5%) and a high success rate (98%). After pericardiocentesis, a pericardial draining catheter is typically left in place for 3 to 5 days because this approach has been shown to be associated with a lower rate of effusion recurrence (12%)

63 Pulmonary Complications of Cancer Therapy

KEY CONCEPTS

- Lung injury caused by cancer therapy results in stereotypical histopathologic disease patterns and syndromes. These lung injury patterns may be triggered by conventional chemotherapy, molecularly targeted agents, and immune modulators. The diagnosis is suggested by a temporal association with the drug and the development of compatible findings, coupled with exclusion of competing diagnoses. Recommendations to guide management of drug-induced lung injury are available, but evidence-based guidelines are limited.
- Albeit rare when compared to other forms of immune-related adverse events (IrAEs), lung involvement, specifically pneumonitis, is recognized as potentially one of the most lethal forms of IrAEs. The Common Terminology Criteria for Adverse Events stratifies pneumonitis based on the presence and severity of clinical symptoms, and treatment recommendations are based on these categories.
- Various cancer-related conditions may cause pulmonary hypertension (PH), and each condition is represented in the five categories of the revised 2019 World Health Organization classification scheme for PH. Each PH category is managed in a specific manner, and treatment of the underlying malignancy may lead to resolution or improvement of PH in some instances.
- Symptoms of malignant central airway obstruction (CAO) may mimic other more common diseases and may not develop until greater than 50% narrowing of the main airways has occurred. A high degree of suspicion must be maintained in patients at increased risk for CAO presenting with symptoms of cough, hemoptysis, stridor, focal wheezing, dyspnea, atelectasis, or recurrent or persistent postobstructive pneumonia.
- Pleural effusion is common in patients with cancer and can arise from malignant involvement of the pleura or secondary to a variety other causes such as bronchial obstruction, infiltration of mediastinal lymph nodes, superior vena cava syndrome, trapped lung, pulmonary embolism, or atelectasis. Chest radiography, chest computed tomography (CT), and thoracic ultrasonography are the imaging modalities most commonly used in evaluating potential causes and contributors to pleural effusion.
- Sleep disturbances are quite common in patients with cancer and can include insomnia, poor sleep efficiency, early awakening, excessive daytime sleepiness, and restless legs. These sleep disorders may occur during all phases of cancer care and can persist for months to years after completion of cancer therapy. Cognitive behavioral therapy is the treatment of choice for patients with many of these sleep disturbances.

Chest medicine is inextricably intertwined with cancer medicine as a result of the propensity for cancer therapy or the disease itself to affect the lungs. Pulmonary complications in patients with cancer may manifest as injury to the pulmonary interstitium, alveolar–capillary membrane, pleura, pulmonary circulation, or airways or may involve multiple intrathoracic structures. This chapter reviews cancer-related pulmonary complications, including lung toxicities associated with aggressive chemotherapy and radiotherapy regimens; noninfectious lung disorders arising in the post–stem cell transplant setting; and cancer-related pleural diseases, sleep disorders, and vascular disease. A focus of this review is to identify, discuss, and provide practical algorithms for the diagnosis and treatment of these complications with emphasis on issues in which early diagnosis may have a significant impact on patient management and outcome.

CHEMOTHERAPY-INDUCED LUNG INJURY

Injury to the lung caused by cancer therapy results in stereotyped histopathologic disease patterns and syndromes (Tables 63–1 and 63–2). Lung toxicity has been described after exposure to conventional chemotherapy as well as molecularly targeted agents and immune modulators. Interstitial lung disease and alveolar lung injury patterns are the most frequent. Pleural effusions, pulmonary vascular disease, and, less frequently, drug-induced granulomatous disease, and lymphadenopathy have also been described. In addition to direct lung injury, chemotherapy-induced immune suppression may predispose patients to life-threatening pneumonias.

The diagnosis of drug-induced lung injury (DILI) is hampered by the frequent use of multi-agent and multimodality therapies. In addition, overlapping clinical, radiographic, and pathologic manifestations of lung injury caused by infections, aspiration, cancer relapse, radiation and cancer-induced cardiac disease confound clinical distinctions between these entities and render precise estimates of DILI difficult. Other conditions that may mimic DILI include aspiration pneumonitis, diffuse alveolar hemorrhage (DAH), and cardiogenic pulmonary edema.[1,2] Predisposing factors, such as older age, cumulative dose, concomitant or sequential radiotherapy, oxygen administration, prior lung injury, and the use of multidrug regimens not only increase the risk of DILI but may also shorten the latency period between drug exposure and the development of clinical symptoms.

The diagnosis of DILI is suggested by a temporal association between drug exposure and the development of compatible clinical, radiographic, and laboratory evidence of lung injury, coupled with the exclusion of competing diagnoses. Interstitial and mixed alveolar–interstitial opacities, manifested as ground-glass opacities, reticular lines, septal thickening, and mosaic attenuation, typically localize to the peripheral and lower lung zones on chest imaging studies. Upper lobe–predominant disease may be seen with hypersensitivity reactions and accompanied by skin rash and wheezing. Bronchoscopy with performance of bronchoalveolar lavage (BAL), transbronchial biopsies, or both may be helpful in excluding infection or background disease. For example, findings of BAL eosinophilia of greater than 25% are supportive of drug-induced eosinophilic pneumonia (EP). Increased numbers of hemosiderin-laden macrophages on BAL fluid or progressively bloody saline aliquots on sequential BAL samples is supportive of DAH. A BAL lymphocytosis of greater than 50% with decreased CD4/CD8 ratios on BAL fluid are suggestive of interstitial lung disease; however, these findings are not sufficient to distinguish interstitial lung disease caused by drug toxicity from other causes. None of these histopathologic findings are pathognomonic of DILI.

Clinical manifestations of drug-induced interstitial lung disease include low-grade fever, dry cough, and dyspnea, which typically develop insidiously, usually within weeks to a few months after initiation of the first or subsequent cycles of therapy.[3,4] Pulmonary fibrosis may immediately ensue or occur as a late manifestation of DILI months to years after exposure to some agents, such as bleomycin, busulfan, cyclophosphamide, gemcitabine, and BCNU (carmustine). Bronchospasm and allergic reactions are common manifestations of infusion reactions that typically occur within minutes to hours of therapy.

Evidence-based guidelines in the management of patients with DILI are limited. In most cases, drug withdrawal is recommended after sufficient evidence to implicate the culprit agent with pneumotoxicity is established. Systemic corticosteroids have proven efficacy in the treatment of patients with DILI patterns such as hypersensitivity pneumonitis (HP), EP, and bronchiolitis obliterans organizing pneumonia (BOOP) . In other entities, (pulmonary fibrosis, bronchiolitis obliterans), no beneficial role has been established. Corticosteroid therapy should be considered in patients with progressive, steroid-responsive, or advanced-stage lung injury patterns. No guidelines for corticosteroid management in patients with DILI are currently available. General recommendations include starting doses of prednisone at 40 to 60 mg or weight-based dosing at 0.75 to 1 mg/kg daily with tapers over a 1- to 3-month time period, pending response to therapy. With few exceptions (see later), drug rechallenge is not recommended.

SPECIFIC HISTOPATHOLOGIC CORRELATES OF DRUG-INDUCED LUNG INJURY

Organizing Pneumonia

Organizing pneumonia (OP) represents an inflammatory process resulting from lung injury in which intraluminal polyploid plugs of proliferating fibroblasts and myofibroblasts form buds within alveolar ducts within the distal alveolar spaces. OP is a well-known histopathologic response to DILI. This pathological pattern is not specific for DILI and may develop as a result of injury caused by other lung insults, including infection or trauma. Low-grade fever, cough, dyspnea, and pulmonary infiltrates on chest imaging are prominent clinical findings. Migratory patchy, alveolar opacities predominating in the lung periphery are the most common findings on computed

TABLE 63–1 Lung toxicity Caused by Conventional Chemotherapeutic Agents: Histologic Patterns of Lung Injury

Disorder	Alkylating Agents	Antimetabolites and Purine Analogs	Cytotoxic Antibiotics	Nitrosoureas	Podophyllotoxins	Taxanes	TKIs and Immunomodulators	Other
NCPE, ARDS, PF	Busulfan Cyclophosphamide	Methotrexate Azathioprine Ara-C Fludarabine Gemcitabine Pentostatin	Bleomycin Mitomycin C	BCNU CCNU	Irinotecan Topotecan	Paclitaxel Docetaxel	G-CSF GM-CSF IL-2 TNF IFN-γ	
Bland pulmonary hemorrhage		Azathioprine						ATRA
NSIP	Busulfan Cyclophosphamide Temozolomide Melphalan Chlorambucil	Methotrexate Azathioprine Fludarabine Gemcitabine	Bleomycin	BCNU CCNU	Irinotecan Etoposide	Paclitaxel Docetaxel	G-CSF GM-CSF IFN-γ Thalidomide	Procarbazine
Airway disease	Cyclophosphamide Oxaliplatin Iphosphamide	Gemcitabine Nelarabine	Bleomycin Mitomycin C		Irinotecan Etoposide	Paclitaxel Docetaxel	IFN-α	Anthracyclines L-asparaginase
Hypersensitivity pneumonitis	Cyclophosphamide Oxaliplatin Busulfan	Methotrexate Ara-C Gemcitabine 6-Mercaptopurine	Bleomycin	BCNU	Etoposide Teniposide	Docetaxel		Procarbazine BCG
Organizing pneumonia	Busulfan Cyclophosphamide Oxaliplatin	Methotrexate	Bleomycin	BCNU CCNU	Topotecan		IFN-γ Thalidomide GM-CSF	
Eosinophilic pneumonia	Oxaliplatin	Methotrexate Fludarabine Cladribine	Bleomycin				IL-2 IFN-γ	
Granulomas		Fludarabine					IFN-α	Procarbazine
Pleural disease	Cyclophosphamide	Methotrexate Azathioprine Gemcitabine	Mitomycin C	BCNU	Docetaxel	Docetaxel	IL-2 IFN-α G-CSF/GM-CSF	ATRA Procarbazine
Mediastinal or hilar lymphadenopathy		Methotrexate	Bleomycin				IFN-γ	
PH: PAH, PVOD, PE		Gemcitabine (PVOD) Zinostatin (PAH)	Bleomycin (PVOD) Mitomycin C (PAH, PVOD)	BCNU (PVOD) CCNU (PVOD)	Etoposide (PVOD)		IL-2 (PAH) IFN-α, -γ, -β Thalidomide (PE) Lenalidomide (PE) Pomalidomide (PE)	Tamoxifen L-asparaginase Thalidomide Revlimid

Ara-C, cytarabine; ARDS, acute respiratory distress syndrome; ATRA, all-*trans*-retinoic-acid; BCNU, carmustine; CCNU, lomustine; G-CSF, granulocyte-colony stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL-2, interleukin-2; mAbs, monoclonal antibodies; NCPE, noncardiogenic pulmonary edema; NSIP, nonspecific interstitial pneumonitis; PAH, pulmonary arterial hypertension; PE, pulmonary embolism; PF, pulmonary fibrosis; PH, pulmonary hypertension; PVOD, pulmonary veno-occlusive disease; TNF, tumor necrosis factor; TKI, tyrosine kinase inhibitor.

TABLE 63–2 Lung Toxicity Caused by Targeted Therapies and Immune Checkpoint Inhibitors: Histologic Patterns of Lung Injury

Disorder	Monoclonal Antibodies	Tyrosine Kinase Inhibitors	Rapamycin Inhibitors	Proteosome Inhibitors	Immune Checkpoint Inhibitors
Pneumonitis or ILD dyspnea not otherwise specified		EGFR: imatinib, gefitinib, erlotinib, afatinib, osimertinib ALK: crizotinib, ceritinib, alectinib, brigatinib MEK: trametinib, cobimetinib, binimetinib Bcr-Abl: imatinib, nilotinib, dasatinib PIK3: idelalisib, copanlisib, duvelisib MET: capmatinib Bcr-Abl: imatinib, nilotinib, dasatinib PIK3: idelalisib, copanlisib, duvelisib, apelisib FLT3: midostaurin, gilteritinib BRAF: encorafenib, binimetinib, vemurafenib			
NCPE, ARDS, and PF	EGFR: panitumumab CD20: rituximab CD22: Moxetumomab Her2: trastuzumab, Ado-trastuzumab-emestane, fam-trastuzumab deruxtecan	EGFR: imatinib, gefitinib, erlotinib ALK: crizotinib, ceritinib, alectinib, brigatinib MEK: trametinib, cobimetinib, binimetinib	Everolimus Temsirolimus	Bortezomib Carfilzomib Ixazomib	CTLA-4–ipilimumab PD-1: nivolumab, pembrolizumab, cemiplimab PD-L1: atezolizumab, avelumab, durvalumab
Pulmonary hemorrhage	VEGF: bevacizumab CD20: rituximab CD33: gemtuzumab				PD-1: nivolumab, pembrolizumab
NSIP	Rituximab Trastuzumab	Gefitinib Dasatinib	Temsirolimus Everolimus	Bortezomib Carfilzomib	CTLA-4–ipilimumab PD-1: nivolumab, pembrolizumab, cemiplimab PD-L1: atezolizumab, avelumab, durvalumab
Bronchospasm	All mAbs: drugs formulated using fully mouse and chimeric (mouse, human) proteins confer highest rates			Bortezomib	
Granulomatous inflammation (sarcoid-like reactions)		BRAF: dabrafenib, vemurafenib			All immune checkpoint inhibitors

(*Continued*)

TABLE 63–2 Lung Toxicity Caused by Targeted Therapies and Immune Checkpoint Inhibitors: Histologic Patterns of Lung Injury (*Cont.*)

Disorder	Monoclonal Antibodies	Tyrosine Kinase Inhibitors	Rapamycin Inhibitors	Proteosome Inhibitors	Immune Checkpoint Inhibitors
Organizing pneumonia	CD20: rituximab Her2: trastuzumab				
Cytokine release syndrome		Jakafi: ruxolitinib FLT3: gilteritinib			CAR T TILs
Pleural disease		EGFR: gefitinib Bcr-Abl: dasatinib > imatinib, bosutinib, nilotinib			
Infections	CD52: alemtuzumab				
Pulmonary vascular disease: PAH, PVOD, DVT	VEGF: bevacizumab	Dasatinib		Bortezomib	

ALK, anaplastic lymphoma kinase; ARDS, acute respiratory distress syndrome; Bcr-Abl, breakpoint cluster region-Abelson; CAR T, chimeric antigen receptor T-cells; CD, cluster of differentiation; CTLA-4, cytotoxic T-cell lymphocyte antigen-4 ; DVT, deep vein thrombosis; EGFR, epidermal growth factor receptor; FLT3, fms-like tyrosine kinase 3; HER2, human epidermal growth factor receptor 2; ILD, interstitial lung disease; MEK, mitogen-activated extracellular signal-regulated kinase; NCPE, noncardiogenic pulmonary edema; NSIP, nonspecific interstitial pneumonitis; PAH, pulmonary arterial hypertension; PD-1, programmed cell death protein 1; PD-L1, programmed death-ligand 1; PF, pulmonary fibrosis, PIK3, phosphoinositide 3 kinase; PVOD, pulmonary veno-occlusive disease; TIL, tumor infiltrating lymphocyte; VEGF, vascular endothelial growth factor.

tomography (CT) imaging of the chest (Fig. 63–1). Other imaging patterns, including solitary inflammatory infiltrates and diffuse bilateral infiltrates in association with interstitial opacities and small superimposed alveolar opacities, are less common. OP is established by excluding alternative diagnoses such as infection or malignancy. Lung biopsy is often necessary for definitive diagnosis. OP has been associated with an extensive list of cytotoxic agents, including anthracyclines, cladribine, oxaliplatin, interferon-α (INF-α), rituximab, and thalidomide. Molecular targeted agents, including (epidermal growth factor receptor [EGFR]) inhibitors,[5–13] Bcr-Abl (breakpoint cluster region-Abelson) tyrosine kinase inhibitors (TKIs),[14–17] anaplastic lymphoma kinase (ALK) inhibitors,[13,18] mitogen-activated protein kinase enzymes MEK1 and MEK2,[19] phosphoinositol kinase 3,[20,21] CD20 inhibitors,[22] Her2 receptor antagonists,[23–25] rapamycin analogs,[26,27] and immune checkpoint inhibitors (ICIs),[28–32] have also been implicated in the development of OP. Cessation of the culprit agent and initiation of systemic corticosteroids results in rapid resolution of respiratory signs and symptoms in most cases.

Nonspecific Interstitial Lung Disease

Nonspecific interstitial pneumonitis (NSIP) is one of the most common morphologic patterns of interstitial lung disease. Dry cough and progressive dyspnea develop insidiously, over weeks to months, after drug exposure. Radiographic findings may include pleural-based, lower lobe ground-glass attenuations, reticular lines, mosaic patterns, and nodules. Injury to epithelial and endothelial cells leads to alveolar edema and diffuse alveolar damage early on, which may progress

FIGURE 63–1 A 66-year-old man with advanced-stage adenocarcinoma of the lung presented 2 days after cycle 2 of nivolumab, carboplatin, and pemetrexed with a dry cough and dyspnea. Bilateral patchy areas of ground-glass opacities and consolidation seen on chest computed tomography (CT) imaging (B) were new when compared with baseline studies (A). Notice the prominent air bronchogram (*arrow* in B). Bronchoscopy with bronchoalveolar lavage and biopsies were positive for organizing pneumonia. Microbiologic studies were negative for infection. Symptoms resolved and CT abnormalities were markedly improved after 4 weeks of high-dose steroid treatment (C).

to end stage fibrotic lung disease despite drug withdrawal and corticosteroid therapy. Cytotoxic agents that have been most frequently associated with NSIP include bleomycin, mitomycin, the nitrosoureas, busulfan, gemcitabine, paclitaxel, cyclophosphamide, ifosfamide, methotrexate, irinotecan, and oxaliplatin. Among the molecular targeted therapies, the mammalian target of rapamycin (mTOR) inhibitors (everolimus, temsirolimus), EGFR inhibitors (gefitinib, erlotinib, cetuximab, panitumumab), and proteasome inhibitors (bortezomib, carfilzomib) are frequently cited (Fig. 63–2).[26,33–35]

Noncardiogenic Pulmonary Edema, Diffuse Alveolar Damage, and Acute Respiratory Distress Syndrome

Drug-induced injury to the alveolar–capillary membranes may result in capillary leak and a permeability (noncardiogenic) pulmonary edema. Acute respiratory distress syndrome (ARDS) and its histologic hallmark, diffuse alveolar damage (DAD), may ensue as the disease progresses. These reactions may be unrelated to drug dosage or duration of therapy. Busulfan, bleomycin, cyclophosphamide, gemcitabine, oxaliplatin, etoposide, cytarabine, and vinblastine; the molecularly targeted agents (gefitinib, erlotinib, cetuximab, moxetumomab); the antilymphocyte monoclonal antibodies (mAbs; rituximab, alemtuzumab, ofatumumab); and the rapamycin inhibitors (everolimus, temsirolimus) are most often implicated in the development of drug-induced noncardiogenic pulmonary edema (NCPE). NCPE leading to ARDS has been described after use of ruxolitinib, a novel JAC1/2 inhibitor, as a result of a cytokine rebound reaction. This reaction is mitigated with the preemptive use of corticosteroids and supportive therapy.[36,37] Cytokine storm has also been described after all-*trans*-retinoic acid (ATRA) and arsenic trioxide therapies in the treatment of patients with acute promyelocytic leukemia (APL). The so-called differentiation syndrome occurs in up to 25% of patients with APL undergoing induction therapy, which is characterized by potentially fatal NCPE and ARDS. Unlike many of the lung injury processes, in patients with ATRA and arsenic-related differentiation syndrome, de-escalation of drug dose, rather than drug withdrawal, along with systemic steroid therapy has been associated with successful resolution of toxicity in patients with mild to moderate forms of this syndrome.[38,39] DAH is typically seen as sequelae of alveolar–capillary membrane injury and thus in the setting of ARDS and DAD. Occasionally, bland alveolar hemorrhage have been described in the absence of DAD after rituximab and alemtuzumab therapy.[36,40] Massive, and sometimes fatal, bleeding has been reported during bevacizumab therapy for treatment of central airway tumors.[41] ARDS with and NCPE has been implicated in granulocyte and granulocyte-macrophage colony-stimulating factors administration, particularly in association with non-Hodgkin's lymphoma.

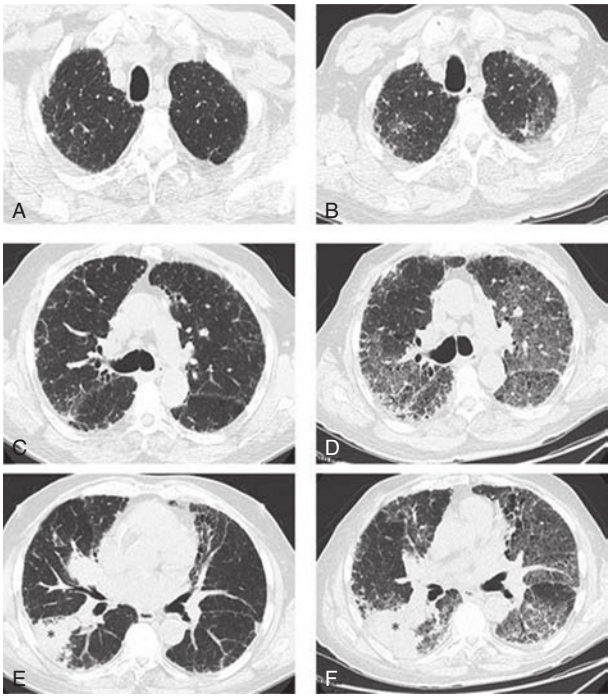

FIGURE 63–2 **A 68-year-old man presented with progressive dyspnea and dry cough 4 months after initiation of panitumumab for colorectal cancer. At baseline, emphysematous changes and subpleural reticulations are seen (A, C, and E), consistent with the patient's known history of idiopathic pulmonary fibrosis. Repeat chest computed tomography (CT) imaging demonstrated a significant interval increase in mid- and lower lobe–predominant bilateral patchy ground-glass attenuation with increased underlying septal thickening and focal sparing along the pleural surfaces (B, D, and F). CT findings were consistent with nonspecific interstitial pneumonitis, which was confirmed on lung biopsy. Metastatic lesions are noted in both lungs, the largest of which overlies the right lower lobe (E and F, *asterisks*)**

Diffuse Alveolar Hemorrhage

AH is characterized by diffuse pulmonary infiltrates, increased hemosiderin-laden macrophages in the BAL fluid and progressively hemorrhagic BAL return. Drug-induced DAH is rare but has been reported in association with azathioprine, ATRA, gemtuzumab, and rituximab. Fatal DAH has been reported.[42–44] Acute dyspnea, hypoxia, and occasionally fever and hemoptysis are presenting symptoms. Treatment strategies include drug withdrawal and high-dose steroids, although evidence-based support for the later has not been validated in any large, randomized trials.

Eosinophilic Pneumonia

EP is characterized by marked eosinophil accumulation within the lung interstitium and alveolar spaces and may be caused by variety of infectious agents, inhaled toxins, and pharmacologic agents. Methotrexate, bleomycin, cladribine, fludarabine, and INF-α are the most frequently implicated agents in the development of EP. Patients typically present with an acute febrile illness, dry cough, and dyspnea accompanied by bilateral parenchymal infiltrates on CT imaging. A compatible history coupled with imaging findings, exclusion of competing diagnoses, and greater than 25% eosinophils on BAL fluid establishes the diagnosis. Peripheral eosinophilia may be absent initially but increases with progressive disease. Late disease is marked by hypoxemic respiratory failure. Drug-induced EP is typically steroid responsive with a favorable prognosis when diagnosed early. Withdrawal of the culprit agent may be sufficient in early stages of disease. Steroids are indicated for advanced cases associated with respiratory failure.[45–47]

Granulomatous Pneumonitis

Several drugs, including fludarabine, rituximab, procarbazine, INF-α, and the class of drugs known as ICIs, are capable of inducing granulomatous reactions in the lungs, similar to HP and sarcoidosis. Granulomatous inflammation caused by drugs is typically non-necrotizing, as opposed to necrotizing granulomas seen with infections. However, infectious causes, such as mycobacteria and fungal pathogens, must be excluded.

Hypersensitivity Pneumonitis

HP-like reactions typically occur after repeated drug exposure to an offending agent and are characterized clinically by fever, dyspnea, dry cough, and rash. Symptoms typically occur over the first 3 to 4 weeks after drug exposure and may wax and wane without adjustments in therapy. Poorly formed noncaseating granulomas and BAL lymphocytosis are common histopathologic findings. Upper lobe–predominant disease is characteristic, particularly in chronic forms of the disease. Methotrexate is the prototype agent associated with HP, which may develop after oral, intravenous, intrathecal, and intramuscular routes of methotrexate administration. HP has also been reported after bleomycin, gemcitabine, oxaliplatin, procarbazine, the nitrosoureas, 6-mercaptopurine, busulfan, and Bacillus Calmette-Guerin (BCG) therapy. Drug withdrawal and steroid therapy typically produce favorable outcomes, with complete resolution of clinical signs and symptoms in most cases.

Sarcoid-Like Reactions

Sarcoid-like reactions are uncommon sequelae of anti–tumor necrosis factor (TNF) agents (etanercept, adalimumab), INF therapy, methotrexate, the *BRAF* inhibitors (vemurafenib and dabrafenib), and the ICIs.[48–55] These agents may elicit a systemic granulomatous reaction that is indistinguishable from sarcoidosis. Asymptomatic infiltrates and micronodules distributed along bronchovascular bundles and hilar and mediastinal lymphadenopathy signal the onset of disease, which typically develops early, after the first few cycles of therapy (Fig. 63–3). Mild dyspnea and dry cough are infrequent complaints. Extrathoracic sarcoid-like reactions involving the skin, liver, and brain occurring concomitantly or sequentially have also been described (Fig. 63–4). Whether drug-related sarcoid-like reactions exacerbate subclinical sarcoidosis, render the immune system more susceptible to sarcoidosis, or is a distinct entity from true sarcoid is unclear. Sarcoid-like reactions are characterized by lymphangitic distribution of non-necrotizing granulomas, mediastinal lymphadenopathy, and pulmonary infiltrates. BAL fluid analysis frequently demonstrates a CD4-predominant lymphocytosis, giving rise to an increased CD4/CD8 ratio (CD4/CD8 ratio >1). Spontaneous resolution often occurs with discontinuation of the offending agent. Systemic corticosteroid therapy is typically not required but has been used in patients in which the culprit drug is continued because of its therapeutic efficacy in treating the underlying disease and lack of other treatment options.[56]

Pleural Effusions

Drug-induced pleural effusions may occur as an isolated toxicity to the pleura or as a manifestation of a generalized pleuroparenchymal abnormality. Drugs that have been associated with the development of pleural effusions include docetaxel, ATRA, methotrexate, INF-α, and the TKIs (dasatinib, imatinib, and bosutinib).[57–61] These small- to moderate-sized effusions are typically exudative and lymphocyte predominant and may be unilateral or bilateral. Withdrawal of the offending agent may result in spontaneous resolution in some cases.

Pulmonary Vascular Disorders

The development of thromboembolic disease, pulmonary hypertension (PH), and pulmonary veno-occlusive disease have all been described after use of conventional chemotherapeutic, molecularly targeted, and immune modulating agents. Increased rates of venous thromboembolism (VTE; pulmonary embolism [PE] and deep vein thrombosis [DVT]) have been reported

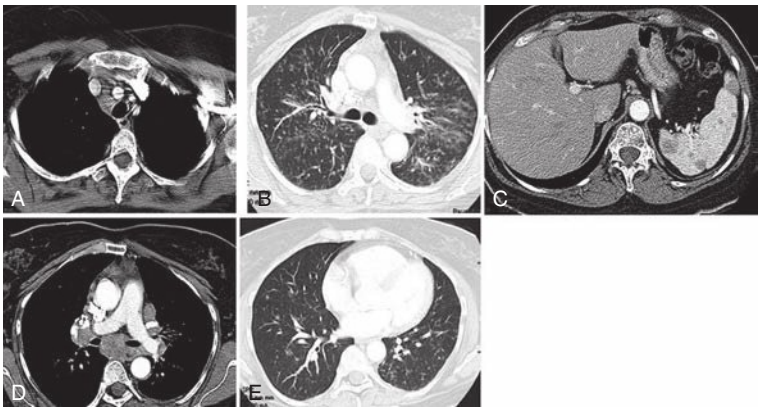

FIGURE 63–3 **A to E. Ipilimumab-related sarcoidosis. A 66-year-old man developed dry cough and dyspnea after the third cycle of ipilimumab therapy for refractory malignant melanoma. Bronchoscopy with bronchoalveolar lavage and transbronchial biopsies revealed T-lymphocyte alveolitis with increased CD4 and noncaseating granulomas without associated evidence of infection or malignancy.**

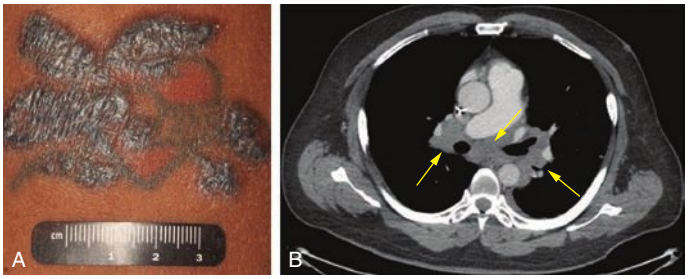

FIGURE 63–4 **A 52-year-old man presented with nodular skin lesions, including lesions growing over the area of an old tattoo (A), and bilateral hilar lymphadenopathy (B, *arrows*) after cycle 3 of ipilimumab and nivolumab for urothelial carcinoma. Biopsy of the skin lesions and endobronchial ultrasound biopsies of the hilar lymph nodes showed noncaseating granulomas, consistent with sarcoidosis. Skin lesions and lymphadenopathy resolved after 3 months of systemic steroid therapy.**

with ALK-inhibitor (crizotinib), Bcr-Abl inhibitor (ponatinib), and the vascular endothelial growth factor (VEGF) inhibitors (bevacizumab, sunitinib, sorafenib, pazopanib).[41,62–64] In addition, the immunomodulating, angiogenesis inhibitors (thalidomide, Revlimid) in combination with steroids, doxorubicin, or BCNU are associated with 14% to 43% increased risk of thromboembolic events (Fig. 63–5). The risk of thrombosis is reduced to 3% with DVT prophylaxis, which is now the standard of care for patients undergoing thalidomide- or lenalidomide-based therapies. Other agents, including hormonal therapies, growth factors, and erythropoietic agents, contribute to cancer-associated VTE.

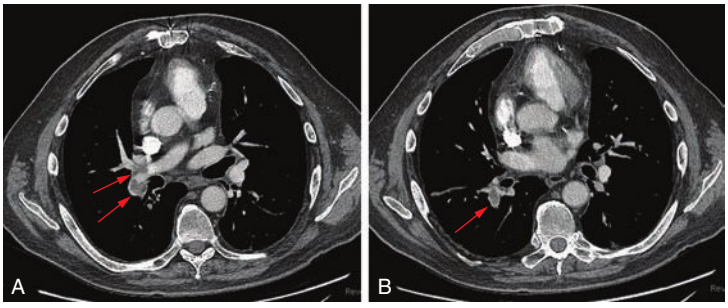

FIGURE 63–5 **Computed tomography angiogram showing multiple filling defects within the right-sided pulmonary artery (A, *arrows*) extending to the segmental and subsegmental branches (B, *arrows*), consistent with large pulmonary emboli. The patient was being treated with thalidomide-based therapy for melanoma.**

Pulmonary Hypertension

PH has been associated with several drugs, including bleomycin, busulfan, BCNU, and INF. Pulmonary arterial hypertension (PAH) has been definitively associated with dasatinib (a multi-kinase Bcr-Abl TKI) and possibly with bosutinib, and INF-α and INF-β. After dasatinib-associated PAH develops, drug withdrawal without rechallenge is recommended. Pulmonary vasodilator therapy may be needed until pulmonary arterial pressures improve. No reports of PAH after exposure to imatinib or the more selective Bcr-Abl–targeted TKIs (nilotinib, ponatinib) have been reported, but bosutinib has been implicated as well.[65–68] Bleomycin and BCNU have also been implicated in the development of pulmonary veno-occlusive disease (PVOD), an irreversible and often fatal form of PH that is characterized by fibrous obliteration of pulmonary venules.

Drug-Induced Airway Disease

Intravenous (IV) administration of virtually all chemotherapeutic and targeted agents may trigger an infusion reaction. Symptoms of dry cough, dyspnea, wheezing, chest pain, and hypoxia typically develop within minutes to several hours after drug infusion and may be life threatening. Infusion reactions may manifest as IgE-mediated, type 1 hypersensitivity reactions (carboplatin, oxaliplatin, and L-asparaginase) or as anaphylactoid reactions, mediated by cytokine release. Although vinca alkaloids are rarely associated with lung toxicity, severe bronchospasm has been described when these agents are given with concurrent or sequential administration of mitomycin therapy.[69,70] Other agents that commonly cause bronchospasm during or shortly after infusion include alemtuzumab, L-asparaginase, and the anthracyclines.[60,71–76] mAb infusion is a notorious source of infusion reactions, with the highest rates are seen among agents that contain the higher amounts of mouse protein. Infusion reactions may be triggered by the drug itself or in response to the vehicle in which the drug is formulated. The latter reaction is often seen following the administration of many of the mAbs. This is particularly true of the taxane class of drugs. For example, paclitaxel is formulated in Cremophor EL, a highly allergenic polyoxyethylated castor oil solvent. Docetaxel is formulated in polysorbate 80. Both vehicles may induce mast cell or basophil activation and subsequent hypersensitivity reaction. Other drugs that are formulated in Cremophor EL (cyclosporine, teniposide, ixabepilone) or polysorbate 80 (etoposide) may trigger similar reactions and should be avoided in patients with a history of infusion reactions after taxane administration.[77,78] Histamine receptor antagonists and steroids are recommended as standard prophylaxis before taxane administration, which has reduced the incidence of taxane-induced bronchospasm from 30% to 2%.[78] Close monitoring during and immediately after drug infusion is critical because breakthrough infusion reactions may occur despite prophylaxis.

Pneumonitis Associated with Immunotherapy: Immune Checkpoint Inhibitors

ICIs with their primary targets, programmed cell death receptor 1 (PD-1), programmed cell death-ligand 1 (PD-L1), and cytotoxic T-cell lymphocyte antigen-4 (CTLA-4), represent a significant addition in the therapeutic landscape for patients with advanced cancers. Initially approved for the treatment of patients with malignant melanoma, these agents are now approved for a broad array of hematologic malignances and solid tumors, including Hodgkin lymphoma and advanced-stage carcinomas involving the kidneys, lung, head and neck, bladder, and skin. ICIs act by releasing the negative regulatory controls involved in T-cell activation, thereby increasing T-cell–mediated immune response. This mechanism of action is thought to be responsible for both the therapeutic efficacy of ICI therapy and the driver behind a peculiar spectrum of toxicities, known as immune-related adverse events (IrAEs). IrAEs are common sequelae of ICI therapy, with a variable incidence of 20% to 90% across ICI regimens and cancer types.[79,80] These off-target, T-cell–driven inflammatory responses may affect virtually every organ system. Lung involvement is less common than other forms of IrAEs, occurring in 3% to 10% of patients.[31,81–83] However, pneumonitis, the most common form of lung IrAE, is recognized as one of the most potentially lethal forms of ICI-related toxicity and is therefore clinically relevant.

The incidence and clinical presentation of ICI-related lung injury are conditioned by the tumor type being treated, preexisting comorbidities, and the specific drug category and ICI treatment combinations. For instance, pneumonitis rates are highest among patients with non–small cell lung cancer (NSCLC; 7.2%–19%, all grades) compared with patients with other tumor types, including melanoma, head and neck squamous cell carcinoma, and urothelial carcinoma.

Patients with preexisting fibrotic lung disease and prior radiotherapy also appear to have an augmented risk of ICI-related pneumonitis, although these associations have not been fully elucidated.[84–89] The relationship between ICI drug class and pneumonitis risk is well established, with excess rates of pneumonitis among patients given PD-1–PD-L1 axis blockade as monotherapy compared with those given CTLA-4 blocking agents (Fig. 63–6). Anti–PD-1–CTLA-4 dual therapies and ICIs plus chemotherapy or chemoradiation combinations that confer their own toxicity risk

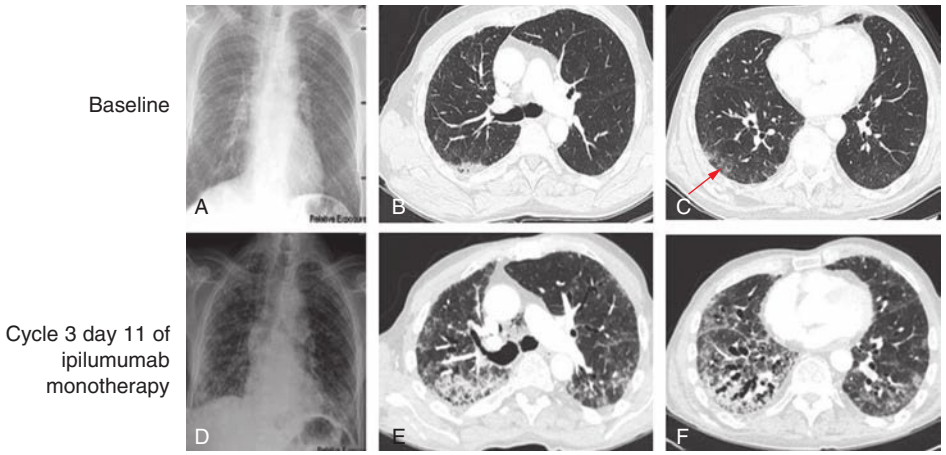

FIGURE 63–6 **Posteroanterior chest radiograph at baseline (A) and after three cycles of ipilimumab monotherapy (D) for prostate cancer. At baseline, subpleural reticular changes are noted and appear most prominent at the lung bases, consistent with a known history of idiopathic pulmonary fibrosis (B and C, *arrow*). After cycle 3 of ipilimumab, increased septal thickening with marked worsening of subpleural fibrotic changes and ground-glass opacities are seen (E and F). The acute worsening in pulmonary fibrosis may have been potentiated by ipilimumab therapy.**

are associated with a two- to threefold increase in pneumonitis incidence compared with ICI monotherapy.[86,90,91] In addition, ICI-related pneumonitis after dual and multimodality therapies is often more severe with slower recovery times.[91]

The Common Terminology Criteria for Adverse Events (CTCAE) stratifies pneumonitis based on the presence and severity of clinical symptoms (Table 63–3). In this scoring system, asymptomatic radiographic abnormalities (grade 1) and radiographic changes accompanied by mild dyspnea or cough (grade 2) are specified as low-grade pneumonitis, severe or medically significant symptoms that are not immediately life threatening (grade 3) or life-threatening symptoms that require urgent medical attention (grade 4) designate high grade pneumonitis, and all respiratory-related deaths are assigned to grade 5 pneumonitis. The spectrum of ICI-related pneumonitis patterns is similar to histopathologic correlates caused by other drugs. OP and NSIP are the most frequently observed patterns HP, DAD with ARDS, PF, DAH, bronchiolitis, and sarcoid-like reactions have also been reported.[29,31,86,87,92] Lung injury may manifest as a single histopathologic pattern, as more than one pattern simultaneously, or as different patterns with relapsed disease.

The concomitant or sequential appearance of other IrAEs involving the gut, liver, endocrine glands, and skin occurs in 60% of patients and should heighten the suspicion for lung-related IrAE. At presentation, nearly two thirds of patients have low-grade pneumonitis associated with asymptomatic pulmonary infiltrates (CTCAE grade 1) or nonspecific symptoms of dyspnea, cough, and rarely chest pain (CTCAE grade ≤2). Patients with higher grade disease commonly present with life-threatening signs and symptoms of hypoxemia and acute respiratory distress.[89] No pathognomonic signs are noted on physical examination. Auscultation of rales at the lung bases is a nonspecific finding and more often observed in patients with higher grade disease. Unlike toxicity associated with other systemic antineoplastic therapies, signs and symptoms of pneumonitis commonly occur months to years after the last dose of ICI therapy, with a median time to onset between 5.2 and 12 weeks. Shorter intervals have been reported among patients with primary lung cancer (2.9–7.7 weeks) and patients treated with combination therapy regimens (median onset, 2.7 months; range, 9 days–6.9 months).[31,86]

TABLE 63–3 National Cancer Institute Common Terminology of Criteria for Adverse Events

Pneumonitis Grade	Characteristics
1 (mild)	Asymptomatic; radiographic findings
2 (moderate)	Symptomatic; not interfering with ADLs
3 (severe)	Symptomatic; interfering with ADLs or oxygen indicated
4 (life threatening, disabling)	Life threatening or ventilator support required
5 (Death)	

ADLs, activities of daily living.

The diagnosis of ICI pneumonitis is based on a compatible history and CT findings coupled with the exclusion of competing diagnoses, including infection, tumor progression, pulmonary edema, and alveolar hemorrhage. Bronchoscopic examination is an important early tool in the diagnostic evaluation and should be used to interrogate alternative diagnoses. BAL fluid cultures are helpful when results are positive, although negative culture results may not definitively exclude infection. BAL fluid analysis typically reveals a predominant CD8-positive lymphocytosis. Elevated eosinophils on BAL fluid have also been reported. Examination of tissue obtained from transbronchial or surgically obtained lung biopsies may be helpful in identifying a specific histologic subtype of pneumonitis, which may have prognostic significance. Impairment of forced expiratory volume in 1 second (FEV_1) and diffusing capacity of the lung for carbon monoxide on pulmonary function tests (PFTs) may precede clinical and radiographic findings and represent two of the earliest signals of lung injury.[86] However, the role of pulmonary testing as a reliable predictor of pneumonitis and the threshold change that signals clinically significant disease have not been clarified.

TREATMENT AND OUTCOME

Several investigations suggest that early development of IrAEs within 4 to 6 weeks of ICI initiation predicts improved overall survival and progression-free survival.[93] However, the incidence of pneumonitis was low in these studies. In studies in which the incidence of ICI-related pneumonitis is higher, pneumonitis is a clear poor prognosticator, particularly among patients with NSCLC and in patients with higher grade disease.[93–95]

Treatment strategies for ICI pneumonitis have not been validated in any prospective trials and are guided by CTCAE pneumonitis grades (Table 63–4). Asymptomatic patients (grade 1) may be monitored as outpatients for the development of symptoms. If the patient remains asymptomatic and there is no evidence of disease progression on a CT chest or deterioration in lung function before the subsequent scheduled dose of ICI (within 3–4 weeks), ICI therapy may be cautiously continued. If any symptoms develop, ICI therapy should be interrupted and treatment strategies escalated to grade 2 or higher, depending on the severity of symptoms. Systemic corticosteroid therapy is recommended for patients with pneumonitis that is grade 2 or higher after infection and other competing diagnoses have been excluded. No randomized controlled trials are available to guide optimal steroid dose or duration in this setting; therefore, treatment duration is largely dictated by response to steroid therapy. Steroids are usually dosed at 1 to 2 mg/kg/day and continued over 4 to 6 weeks. Patients with grade 2 pneumonitis are typically managed as outpatients and may be considered for drug rechallenge with close follow-up after resolution of signs and symptoms.

Permanent withdrawal of ICI therapy and inpatient initiation of corticosteroids at 1 to 2 mg/kg/day is recommended for patients with pneumonitis grades 3 and 4. We typically continue the higher dose steroids until symptoms have returned to grade 1 (usually 7 days), at which time steroids may be slowly tapered. Pneumonitis flares have been reported after rapid steroid tapers in 25% of patients.[86] The steroid taper should be tailored to the severity of the pneumonitis event and response to initial therapy, typically 6 weeks. If no clinical improvement is demonstrated after 48 to 72 hours of corticosteroid therapy, intensification of immunosuppressive therapy with the addition of other immunosuppressive agents is generally recommended. Infliximab, azathioprine, mycophenolate mofetil, cyclophosphamide, and tocilizumab have been used but not rigorously studied in this setting. Thus, the optimal timing, dose, duration, and favored secondary immunosuppressive agent in this setting has not been determined. Andecdotal support for the TNF-α inhibitor, infliximab, in recalcitrant ICI pneumonitis is largely based on extrapolated reports of successful treatment of ICI-related colitis.[96,97] Support for other agents, such as intravenous immunoglobulin) and the interleukin-6 inhibitor tocilizumab is derived from small case reports and case series.[98] Infectious prophylaxis against *Pneumocystis jirovecii pneumonia* (PJP) for patients requiring prolonged, high-dose steroid therapy is generally advocated, although the dose of steroids defines "high dose" and the duration of steroids that defines "prolonged" have not been clearly established. In general, PJP prophylaxis is recommended for steroid doses of 20 mg or higher for a duration of 30 days or longer.[99,100] Pharmacologic prophylaxis against steroid-induced gastrointestinal (GI) stress ulcers should also be considered. Baseline screening for tuberculosis is suggested for all patients before initiating anti–TNF-α agents, given the known propensity for these agents to increase the susceptibility to serious infections, including reactivation of latent tuberculosis.[101–104]

Approximately 25% to 33% of patients may experience recurrent IrAEs after initial resolution of signs and symptoms. Recrudescence of signs and symptoms may occur after drug rechallenge or emerge as an unprovoked pneumonitis, months after drug discontinuation. Life-threatening toxicities involving the lungs, heart, or central nervous system are considered absolute contraindications to drug rechallenge. If clinically significant pneumonitis recurs following reinstitution of the drug, permanent discontinuation of the ICI agent is recommended.

TABLE 63–4 Treatment Guidelines for Immune Checkpoint Inhibitor Pneumonitis

Grade of Pneumonitis	Grade 1	Grade 2	Grade 3	Grade 4
Definition	Asymptomatic chest imaging findings	Mild symptoms that limit ADLs	Severe debilitating symptoms that limit self-care	Life-threatening symptoms
Intervention indicated?	No	Yes	Yes	Yes
FOB, BAL, PFTs	Yes	Yes	Yes, if stable	Yes, when stable
Treatment	• Consider holding drug.	• Hold drug. • Consider hospitalization. • Start steroids (prednisone 1–2 mg/kg/day PO or methylprednisolone 1 mg/kg/day IV). • Consider antibiotics.	• Discontinue drug. • Hospitalize. • Start high-dose IV methylprednisolone. • Add antibiotics.	• Discontinue drug. • Admit to ICU and intubate. • Start high-dose IV methylprednisolone. • Add antibiotics.
Follow-up	• Reassess after 3 weeks. • If completely resolved or non-drug-related: continue treatment. • If worsening. treat as grade 2 or ¾.	• Reassess every 1–3 days. • Symptoms improving: slowly taper steroids. • Symptoms worsening: treat as grade ¾.	• Reassess daily. • No symptom improvement or symptoms worsening after 48 hours: add additional immunosuppressive therapy (infliximab, cyclophosphamide, mycophenolate, tocilizumab).	• Reassess daily. • No symptom improvement or symptoms worsening after 48 hours: add additional immunosuppressive therapy (infliximab, cyclophosphamide, mycophenolate, tocilizumab).
Duration of treatment	N/A	4–6 weeks	4–6 weeks	4–6 weeks
ICI rechallenge?	Yes	May be considered if symptoms resolve to grade 1	No	No

ADL, activity of daily living; BAL, bronchoalveolar lavage; FOB, fiberoptic bronchoscopy; ICI, immune checkpoint inhibitor; ICU, intensive care unit; IV, intravenous; NA, not applicable; PFT, pulmonary function test; PO, by mouth.

RADIATION-INDUCED LUNG INJURY

Clinically significant radiation-induced lung injury is the most common dose-limiting complication of thoracic radiation therapy (RT), occurring in 5% to 20% of patients.[105] Recent advances in radiation techniques and delivery systems, such as proton therapy, three-dimensional conformal RT, intensity-modulated RT, and stereotactic body RT, purport lower lung injury rates while delivering higher target doses of radiation to the lung. Factors associated with radiation delivery (total radiation dose, dose per fraction, volume of irradiated lung, and beam characteristics and arrangements) as well as clinical factors (preexisting lung disease, underlying poor pulmonary reserve, prior radiotherapy, multimodality regiments, rapid steroid withdrawal) all potentiate the appearance and severity of radiation pneumotoxicity. Radiographically apparent lung injury is common with total doses of radiation that exceed 40 Gy and is rare at doses below 20 Gy.[106,107] Hyperfractionated radiation doses delivered to the smallest lung volume is recommended.

Acute clinical radiation pneumonitis, heralded by dyspnea, low-grade fever, and dry cough, develops insidiously over 1 to 3 months after completion of radiation. Radiographic changes typically precede clinical symptoms, appearing 3 to 4 weeks after RT. Discrete ground-glass opacities, ill-defined patchy nodules, or consolidation with air bronchograms and volume loss within the irradiated field are common early findings that evolve over the ensuing 6 to 23 months, leaving a linear scar. Regional fibrosis is seen in nearly all patients, including those without clinical symptoms, and is characterized by the appearance of

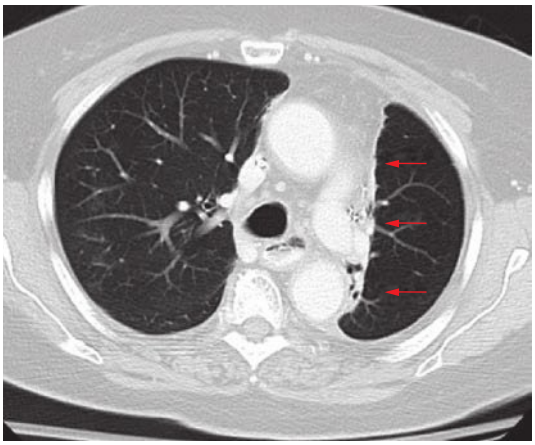

FIGURE 63–7 Radiation fibrosis 1 year after completion of radiation therapy for adenocarcinoma of the lung. Fibrotic changes are demarcated by a linear scar (*arrows*). There is associated significant volume loss of the left lung.

a well-demarcated area of volume loss, linear densities, bronchiectasis, retraction of the lung parenchyma, tenting and elevation of the hemidiaphragm, and ipsilateral pleural thickening within the irradiated field (Fig. 63–7). Postradiation volume loss, bronchiectasis, and consolidation may occur after the newer modes of RT delivery but typically are less extensive than injury patterns after conventional radiation.[108,109]

Radiation recall pneumonitis (RRP) is a rare inflammatory reaction that develops within a previously irradiated field after certain chemotherapy and molecularly targeted therapies. This reaction has been most often observed after taxane- and anthracycline-based therapies. Gemcitabine, etoposide, vinorelbine, trastuzumab, and erlotinib may also trigger this disease.[110–112] The small molecule kinase inhibitors involving the EGFR (erlotinib), VEGF (sunitinib), and mTOR pathways (everolimus) have also been implicated in triggering RRP. ICIs associated with PD-1/PD-L1 axis and CTLA-4 blockade have also been added to the list of triggers.[110,113–122] Clinically, RRP is signaled by dry cough, fever, and dyspnea, and accompanied by ground-glass opacities and areas of consolidation that conform to the prior radiation treatment portal. RRP may develop during the first or subsequent course of therapy with the inciting agent, which may be weeks to years after completion of RT. Drug withdrawal and corticosteroid therapy may mitigate symptoms of radiation pneumonitis but have not been shown to be of benefit in the treatment of patients with radiation fibrosis. Drug reintroduction without reemergence of RRP has been successful in some cases.[112,117]

Pleural effusions may develop as early (within 6 months) and late (1–5 years) sequelae of RT. Effusions are typically small and ipsilateral or bilateral. Reactive mesothelial cells with negative pleural fluid cytology are common. Most RT-induced pleural effusions are asymptomatic, although pleuritic chest pain and dyspnea are occasionally presenting symptoms. Radiation-related OP and EP have been described in patients with breast cancer and may involve nonirradiated areas of the lung.[109,110,123] These lung injury patterns are characterized by migratory pulmonary opacities that develop 1 to 3 months after completing RT. A prior history of asthma or atopy, coupled with blood or tissue eosinophilia, supports the diagnosis of radiation-induced EP. Both lung injury patterns are typically steroid responsive.

NONINFECTIOUS PULMONARY COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

Pulmonary complications remain a formidable threat to the success of hematopoietic stem cell transplantation (HSCT). Posttransplant lung injury occurs in up to 60% of patients as a consequence of direct toxicities from conditioning regimens, delayed bone marrow recovery, prolonged immunosuppressive therapy, and graft-versus-host disease (GVHD). Recipients of allogeneic HSCT are at increased risk of infectious complications, owing to the increased rates of GVHD and the protracted need for immunosuppressive therapy in this group of patients. Antimicrobial prophylaxis has emerged as standard protocol after HSCT, effectively reducing the rates of transplant-related infections. Noninfectious pulmonary complications, however, remain a major cause of post-HSCT morbidity and mortality.[117] Infectious and noninfectious pulmonary complications after HSCT are temporally related to immune recovery and the development of GVHD (Table 63–5).

Early-onset pulmonary complications occur within the first 100 days after transplant and include diffuse pulmonary edema, DAH, peri-engraftment respiratory distress syndrome (PERDS), idiopathic pneumonia syndrome (IPS), delayed pulmonary toxicity syndrome, and PVOD (Table 63–6). Bronchiolitis obliterans syndrome (BOS), cryptogenic organizing pneumonitis (COP), posttransplant lymphoproliferative disorder (PTLD) comprise the late-onset pulmonary complications, which typically occur more than 100 days after HSCT (Table 63–7). Each of these entities is briefly discussed next.

Early-Onset Noninfectious Pulmonary Complications

Early-onset pulmonary complications are characterized by nonspecific symptoms of acute dyspnea,

TABLE 63–5 Infectious and Noninfectious Complications of Hematopoietic Stem Cell Transplantation

Timing After HSCT	Risk Factors	Infectious	Noninfectious
Pre-engraftment (days 0–30)	Conditioning or preparative regimen Neutropenia	Bacterial infections (gram-negative and gram-positive species) Fungal infections (aspergillosis, *Candida*) Respiratory viruses (eg, RSV, parainfluenza, influenza, metapneumovirus, rhinovirus) HSV ARDS caused by sepsis	Pulmonary edema Pleural effusion Engraftment syndrome Diffuse alveolar hemorrhage Transfusion-related lung injury Idiopathic pneumonia syndrome Chemotherapy-induced lung injury Radiation-induced lung injury
Early postengraftment (days 31–100)	Impaired cellular and humoral immunity Delayed lung injury from the conditioning or preparative regimen	Gram-positive bacterial infections Respiratory viruses (eg, RSV, parainfluenza, influenza, metapneumovirus, rhinovirus) Other viral infections (CMV, adenovirus, HSV) Fungal infections (aspergillosis, PJP) Parasitic infections (*Toxoplasma gondii*)	Diffuse alveolar hemorrhage Idiopathic pneumonia syndrome Radiation-induced lung injury Chemotherapy-induced lung injury
Late postengraftment (>100 days)	Delayed immune recovery Immunosuppression Chronic GVHD	Viral infections (CMV, adenovirus, varicella zoster reactivation Fungal infections (aspergillosis, PJP Respiratory viruses (eg, RSV, parainfluenza, influenza, metapneumovirus, rhinovirus) Encapsulated bacteria (chronic GVHD) ARDS caused by infection EBV	Bronchiolitis obliterans syndrome due to chronic GVHD Bronchiolitis obliterans organizing pneumonia Chemotherapy-induced chronic lung injury Radiation-induced chronic lung injury

ARDS, acute respiratory distress syndrome; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplantation; HSV, herpes simplex virus; PJP, *Pneumocystis jiroveci* pneumonia; PTLD, posttransplantation lymphoproliferative disorder; RSV, respiratory syncytial virus.

cough, and fever with associated diffuse pulmonary infiltrates. The exclusion of competing diagnosis such as infection, cardiac disease, and renal failure, along with documentation of diffuse infiltrates, are supportive findings. Diffuse pulmonary edema may develop as a result of increased hydrostatic capillary pressure or permeability pulmonary edema and is one of the most common early complications of HSCT. Hydrostatic and permeability causes of HSCT may coexist and overlap with other early-onset pulmonary complications, which confounds diagnosis. The diagnosis is supported by diffuse bilateral pulmonary infiltrates, with or without bilateral pleural effusions, and coupled with the absence of competing diagnoses, such as infection on diagnostic evaluation. DAH may occur as a result of widespread alveolar injury in association with PERDS, DAD, or IPS or as a separate syndrome. Bronchoscopic findings of DAH include sequential aliquots of progressively bloody BAL fluid. Cytologic evidence of greater than 20% hemosiderin-laden macrophages on BAL fluid is also supportive. Hemoptysis only occurs in approximately 20% to 25% of patients with DAH. DAH may develop independent of thrombocytopenia or coagulopathy. Supportive therapy is standard. The benefits of steroid therapy have not been definitively proven. PERDS may develop after both allo- and autologous transplants and is characterized by fever, hypoxemia, noncardiogenic pulmonary edema, erythematous skin rash, and weight gain arising during the peri-engraftment period. DAH complicates

TABLE 63–6 Early-Onset (<100 Days) Pulmonary Complications After Hematopoietic Stem Cell Transplantation

Parameter	Diffuse Alveolar Hemorrhage	Peri-engraftment Respiratory Distress Syndrome	Idiopathic Pneumonia Syndrome	Pulmonary Veno-occlusive Disease
ncidence	1%–21%	12%–60%	1%–5%	Rare case reports
Transplant type	Autologous = allogeneic	Autologous > allogenic	Allogeneic > autologous	Allogeneic > autologous
Onset	Acute, 1–3 month after HSCT	Acute, within 5–7 days of neutrophil engraftment	1–3 months after HSCT	2–6 months after HSCT
Risk factors				
Clinical symptoms and signs	Cough, progressive dyspnea Hemoptysis: rare (<25%) Progressively bloody lavage fluid on BAL	Fever, dyspnea, dry cough, skin rash, weight gain, edema	Fever, cough dyspnea, hypoxemia	Progressive dyspnea
Histopathologic pattern	≥20% hemosiderin-laden macrophages in BAL fluid	Neutrophilic inflammation on BAL fluid Diffuse alveolar damage (biopsy contraindicated caused by low platelets)	Diffuse alveolar damage	Fibrous intimal proliferation of pulmonary venules; may also involve arterioles
Radiographic findings	Diffuse infiltrates; may be central early on	Bilateral infiltrates; pleural effusions; findings range from mild NCPE to ARDS	Bilateral interstitial infiltrates	Cardiomegaly, enlarged pulmonary arteries on chest radiography or CT
Treatment	Supportive; response to steroids variable	Excellent response to steroids	Supportive; poor response to steroids	Supportive; no benefit from steroids
Prognosis	Less favorable prognosis when advanced; may progress to multiorgan system failure, sepsis, and death	Favorable	Poor	Poor

ARDS, acute respiratory distress syndrome; BAL, bronchoalveolar lavage; CT, computed tomography; HSCT, hematopoietic stem cell transplant; IPS, idiopathic pneumonia syndrome; NCPE, noncardiogenic pulmonary edema.

PERDS in approximately one third of patients.[124—126] Growth factor administration, infusion of increased numbers of CD34-positive cells, prolonged neutropenia, and peripheral blood source of stem cells all confer an increased risk of PERDS. Reductions in morbidity and mortality have been noted after steroid therapy in several small studies.[127,128]

Another early-onset diffuse lung disease, IPS, typically develops 14 to 90 days after transplant. The presence of GVHD, CMV seropositivity, older age, total-body radiation, transplant type, human leukocyte antigen (HLA) disparity, and transplantation for malignancy other than leukemia, are possible risk factors.[129,130] High-dose steroids, broad-spectrum antibiotics, and supportive care are the mainstays of treatment. Mortality rates may exceed 50% at 5 years despite aggressive therapy.

PVOD is a rare complication of HSCT that results in intractable dyspnea associated with severe PH. Symptoms of dyspnea and fatigue develop insidiously several weeks to months after HSCT. Treatment options are limited, with the 2-year mortality rate approaching 100%. DPTS occurs in 29% to 64% of autologous transplant recipients who received BCNU-, cyclophosphamide-, or cisplatin-based pretransplant conditioning regimens.

TABLE 63–7 Late-Onset (>100 Days) Pulmonary Complications After Hematopoietic Stem Cell Transplantation

Parameter	Bronchiolitis Obliterans Syndrome	Cryptogenic Organizing Pneumonia
Incidence (%)	2–30	2
Transplant type	Allogeneic	Allogeneic and autologous
Onset	Late, 4–24 months after HSCT; usually around 1 year	2– 2 months post-HSCT; usually within first 100 days
Risk factors	GVHD	
Clinical symptoms and signs	Cough, progressive dyspnea, wheezing Obstructive findings on PFTs; DLCO may be normal Diagnosis based on clinical, physiological, and radiographic criteria	Fever, dyspnea, dry cough, skin rash, weight gain, edema Restrictive findings on PFTs; DLCO reduced Usually requires surgical lung biopsy for diagnosis
Histopathologic pattern	BO; cellular and constrictive bronchiolitis Neutrophil-predominant BAL fluid	OP; intraluminal organizing fibrosis in distal airspaces; mild interstitial inflammation Lymphocyte-predominant BAL fluid
Radiographic findings	Hyperinflation on chest radiography; otherwise routinely normal; CT findings include mosaic attenuation (early) and air trapping, bronchiectasis (late)	Bilateral, patchy airspace disease with ground-glass appearance; may be nodular
Treatment	Supportive; immunosuppressive therapy; variable response to steroids; poor response to therapy and progressive disease with respiratory failure may occur	Steroid-responsive disease
Prognosis	Less favorable with advanced disease	Favorable; potentially reversible disease

BO, bronchiolitis obliterans; BOS, bronchiolitis obliterans syndrome; BAL, bronchoalveolar lavage; COP, cryptogenic organizing pneumonia; CT, computed tomography; DLCO, diffusing capacity of the lungs for carbon monoxide; GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplant; OP, organizing pneumonia; PFT, pulmonary function test.

This syndrome is heralded by dry cough, dyspnea, and bilateral pulmonary infiltrates, which typically occur 45 days after HSCT. Corticosteroid therapy leads to complete resolution of symptoms in 92% of patients.[131]

Late-Onset Noninfectious Complications

Chronic GVHD, an immunologic posttransplant disorder in which donor cells attack healthy host tissue, is the most common late complication of allogeneic HSCT.[132—134] Involvement of GVHD in the lung results in BOS, a nonspecific lung injury causing inflammation, smooth muscle hypertrophy, and concentric intraluminal fibrosis of the small airways. The clinical hallmark of BOS is airflow limitation (Table 63–8).[132—134] Patients are often asymptomatic during the early stages of BOS, leading to delays in diagnosis. At presentation during late stages of the disease, wheezing, dry cough, and dyspnea on exertion predominate as airflow obstruction progresses. Recurrent sinusitis and antecedent "cold" symptoms are common before diagnosis. Hyperinflation may be seen on plain chest radiographs, which are otherwise normal.[130,135] The lack of a precise definition and uniform diagnostic criteria along with a paucity of knowledge regarding the pathogenesis of BOS and delays in diagnosis represent distinct challenges in management. The National Institutes of Health recently provided consensus guidelines in the diagnosis of BOS, which require (1) evidence of airflow obstruction (FEV_1/FVC [forced vital capacity] <0.7 and FEV_1 <75% of predicted), with evidence of air trapping on PFT; (2) increased residual volume (>120% predicted); (3) air trapping, small airway thickening, or bronchiectasis on expiratory CT or lung biopsy or pathological confirmation of constrictive bronchiolitis; and (4) absence of any infectious process on radiographic, laboratory, or clinical testing.[136] The prognosis of BOS poor, with 5-year survival estimates of only 13%. Immunosuppressive therapy with corticosteroids and calcineurin inhibitors comprises the mainstay of treatment (Table 63–9). Recent studies have demonstrated stabilization of FEV_1 with high-dose inhaled corticosteroids. Small clinical trials and observational studies have suggested a beneficial impact of other agents, including azithromycin, montelukast, azathioprine, sirolimus, and antithymocyte globulin, on lung function.[15,137,138] Early disease recognition is crucial to improvements in therapy and survival.

COP, also known as idiopathic BOOP, is seen almost exclusively among allogeneic HSCT recipients with GVHD. Presenting symptoms include dry cough, dyspnea, and fever, accompanied by a restrictive defect on PFTs and bilateral patchy infiltrates on chest imaging studies. COP is typically steroid responsive, although

TABLE 63–8 Suggested Diagnostic Criteria of Bronchiolitis Obliterans After Hematopoietic Stem Cell Transplantation

1	Allogeneic HSCT
2	Chronic GVHD
3	Insidious onset of dyspnea, cough, and wheezing, usually 100 days after transplantation
4	Normal chest radiograph
5	HRCT of the chest (with inspiratory and expiratory views) showing areas of air trapping on expiratory views (mosaic pattern), hyperinflation, micronodular changes or bronchial dilatation, with no parenchymal involvement
6	PFT showing new onset of airflow obstruction ($FEV_1/FVC < 0.7$ and FEV_1 < 75% of predicted), not responsive to bronchodilators
7	Exclusion of an infectious process by appropriate radiologic, serologic, and microbiologic studies (obtained by sinus aspirate, upper respiratory tract viral screen, sputum culture, or BAL)

BO, bronchiolitis obliterans; BAL, bronchoalveolar lavage; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; GVHD, graft-versus-host disease; HRCT, high resolution computed tomography; HSCT, hematopoietic stem cell transplant; PFT, pulmonary function test.

TABLE 63–9 Suggested Approach to the Management of Bronchiolitis Obliterans After Hematopoietic Stem Cell Transplantation

1	Confirm the diagnosis of bronchiolitis obliterans (see Table 63–8)
2	Systemic corticosteroids (prednisone 1–1.5 mg/kg/day); taper gradually over 6–12 months
3	Immunosuppressive therapy (eg, cyclosporine A or tacrolimus)
4	Maintenance macrolide treatment
5	Inhaled bronchodilators
6	Prophylactic therapy against PJP, fungi, and CMV
7	Antireflux measures
8	Consider inhaled corticosteroids
9	Consider extracorporeal photodynamic therapy
10	Consider IVIGs
11	In advanced cases: • Long-term oxygen therapy • Outpatient pulmonary rehabilitation • Consider lung transplantation

BO, bronchiolitis obliterans; CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplant; IVIG, intravenous immunoglobulin; PJP, *Pneumocystis jirovecii pneumonia.*

no evidence-based guidelines regarding dosage and duration of corticosteroid therapy are currently available. Normalization of chest radiographs and PFTs may be seen within 1 to 3 months of therapy.[134,139—142]

PTLD is a well-recognized complication of both solid organ transplantation and allogeneic HSCT. The disease is characterized by uncontrolled B-cell proliferation of donor-derived, Epstein-Barr virus–infected lymphocytes. Major risk factors include the use of T-cell–depleted donor stem cells, unrelated or HLA-mismatched related donor cells, and antithymocyte globulin predisposes to the development of PTLD. PTLD complicates approximately 1% of allogeneic HSCTs but may increase to 22% in patients with two or more risk factors. The lymph nodes, liver, spleen, and lungs are the primary targets of PTLD. Dyspnea and fever typically develop 4 to 12 months after transplant, accompanied by interstitial and intraalveolar infiltrates and ill-defined nodules. Reduction of immunosuppressive agents and administration of anti-CD20 (rituximab) therapy represent primary therapy.[133,143] The prognosis is generally poor.

VASCULAR DISEASE

VTE is a well-recognized complication of cancer and its therapy. The manifestations of VTE, PE, and DVT are seen in 20% of patients with cancer. Cancer is associated with a four- to sevenfold increased risk of VTE compared with patients without cancer.[144,145] Evidence suggests that tumor type and stage as well as specific cancer therapies influence the absolute risk of thromboembolism. Hematologic malignancies, followed by lung and GI cancer, have the highest absolute risk, especially in the first few months of diagnosis. Furthermore, surgery, immobility, hormonal therapy, growth factors, angiogenesis inhibitors, erythropoietic agents, corticosteroids, and central venous catheters all impact the overall likelihood of thrombotic complications.[146—148] Rates of VTE as high as 28% to 43% have been reported in patients treated with combination antiangiogenic therapies, such as thalidomide and steroids or certain cancer chemotherapies (doxorubicin or BCNU). Many patients, especially those with hematologic malignancies, may have thrombocytopenia in the setting of VTE. In a study evaluating risk factors for VTE in acute leukemia, thrombocytopenia and a cancer diagnosis within 12 months, central venous catheters, hematopoietic growth factors, high-dose corticosteroids, L-asparaginase, and the new immunomodulatory agents were all associated with increased risk of VTE.[149] Unprovoked VTE may herald an impending diagnosis of cancer in patients without known malignancy, primarily in the subsequent 2 years. D-dimer assays and scoring systems developed to estimate the

pretest probability of VTE are neither sufficiently specific nor sensitive enough to rule out VTE in patients with cancer.[148,150] CT pulmonary angiography is the standard imaging technique for diagnosing PE and permits evaluation of competing diagnoses.

Treatment options for PE are based on risk stratification, and the tiers include low-risk PE, intermediate-risk or submassive PE, and high-risk or massive PE.[151] Low-risk PE or those found incidentally on staging scans are treated with anticoagulation. In patients that are hemodynamically unstable, echocardiogram and cardiac biomarkers (B-type natriuretic peptide [BNP], N-terminal pro-BNP [NT-proBNP], troponin I or T) are used to classify massive PE. Significant echocardiographic findings may include right ventricular dilatation, right ventricular hypokinesis, tricuspid regurgitation, septal flattening, paradoxical septal wall motion, PH, and lack of inspiratory collapse of the inferior vena cava.[152] Full-dose thrombolysis may be indicated in massive PE, and other interventions, including surgical embolectomy, inotropic and vasopressor support, pulmonary vasodilator therapy, or mechanical circulatory support devices, may be indicated. For submassive PE, several large evidence-based trials, including Pulmonary Embolism International Thrombolysis Study (PEITHO), no longer support thrombolysis. Catheter-directed thrombolysis and half-dose thrombolysis are still under investigation.[153,154] In all cases, contraindications to anticoagulant therapy should be weighed against the potential benefits of treatment.

Abundant studies have demonstrated superior efficacy and safety of low-molecular-weight heparin (LMWH) over conventional vitamin K antagonists in the management of cancer-related VTE. These studies suggest a lower risk of recurrent VTE without an associated increased risk of major bleeding complications compared with vitamin K antagonists and support LMWH as first-line treatment of patients with cancer-associated thrombosis. Recent trials in patients with cancer have established noninferiority of direct oral anticoagulant therapy (edoxaban, rivaroxaban, apixaban) in patients with cancer with LMWH, but increased bleeding risk was reported with edoxaban and rivaroxaban.[155—158] In those with thrombocytopenia, current guidelines recommend a reduction in LMWH by 50% with a platelet count of 25,000 to 50,000/μL and discontinuation for a platelet count less than 25,000/μL.[152,159—163]

Guidelines for VTE prophylaxis and treatment in the cancer setting have been established. LMWH is the preferred agent based on superior efficacy and safety data. In patients with impaired renal function, unfractionated heparin or fondaparinux should be considered. Recommendations include a 7- to 10-day course of LMWH for patients with cancer undergoing surgery, which should be started preoperatively. Among patients at high risk for VTE, 4 weeks of LWMH is recommended. Thromboprophylaxis is not warranted in the routine management of ambulatory cancer patients. This recommendation is based on analysis of the known risk of bleeding among patients with cancer and potential benefits of anticoagulant therapy in this setting. However, when patients are hospitalized, VTE prophylaxis should be considered. Conversely, prophylactic LMWH is recommended for ambulatory patients with multiple myeloma who are receiving thalidomide- or lenalidomide-based combination therapy. Prophylactic anticoagulation to prevent catheter-associated thrombosis is not recommended. After being established, full anticoagulant therapy should be initiated.

A variety of conditions in the cancer setting may be associated with PH, defined as an elevated mean pulmonary artery pressure of 25 mm Hg or greater at rest. These conditions are represented in all five categories of the revised 2019 World Health Organization (WHO) classification scheme for PH (Table 63–10). For example, chemotherapeutic agents, such as dasatinib and PVOD caused by chemotoxins, thoracic radiation, and stem cell transplantation are known causes of PAH (group 1). Cancer treatment–related left heart disease is a common cause of PH (group 2). Hypoxemic pleuroparenchymal diseases caused by tumor infiltration, infection, and chemotoxicity are well known sources of group 3 PH. Increased rates of acute and chronic PE as well as splenectomy in the cancer setting are associated with chronic thromboembolic PH (group 4). Finally, myeloproliferative disorders and entrapment or compression of large pulmonary vessels by infection and treatment-related mediastinal fibrosis, adenopathy, or neoplasms are recognized risk factors of group 5 PH.[164—171] PH is known to be associated with advanced myelofibrosis, albeit rarely. The cause of PH in this clinical scenario is unknown but is thought to be secondary to the inefficient extramedullary hematopoiesis that occurs as a result of bone marrow fibrosis. Other proposed contributors include porto-PH secondary to organomegaly, pulmonary vascular congestion and obstruction, tumor microemboli, parenchymal lung disease, acute or chronic thromboemboli, and chemotherapeutic agents. In addition, many patients with myelofibrosis-related PH have been found to have elevated filling pressures on echocardiogram, suggesting that in addition to PAH (WHO group 1) and PH related to multiple mechanisms (WHO group 5), left-sided heart disease (WHO group 2) may be the culprit in many of these patients.[172,173] Regardless of the cause, the development of significant PH in cancer portends

a worse prognosis. Dyspnea, nonproductive cough, and hypoxemia develop insidiously in cancer-related PH and may progress to respiratory failure and death. There have been rare case reports of resolution of myelofibrosis-associated PH after HSCT; therefore, this treatment may provide benefits for select patients outside of its anticipated hematologic effects.[172] In most cases, supportive care and treatment of the underlying disease are the mainstays of therapy. The utility of pulmonary vasodilator agents, including treatment strategies that target nitric oxide, endothelin, and prostaglandin pathways, in the management of cancer-related PH has not been definitively studied. Vasodilator therapy in the setting of cancer-related PVOD should be used with extreme caution because fatal pulmonary edema precipitated by vasodilator therapy in this setting has been reported.[164–167]

TABLE 63–10 2019 World Health Organization Classification Scheme for Pulmonary Hypertension

Class	Subclass
1. PAH	1.1 Idiopathic PAH 1. 2 Heritable PAH 1. 3 Drug and toxin induced 1. 4 Associated with 1.4.1 Connective tissue disease 1. 4.2 HIV infection 1. 4.3 Portal hypertension 1. 4.4 Congenital heart diseases 1. 4.5 Schistosomiasis 1′ PVOD and/or pulmonary capillary hemangiomatosis 1″ Persistent pulmonary hypertension of the newborn
2. PH caused by left heart disease	2.1 LV systolic dysfunction 2. 2 LV diastolic dysfunction 2. 3 Valvular heart disease 2. 4 Congenital or acquired left heart inflow or outflow tract obstruction and congenital cardiomyopathies
3. PH caused by lung disease or hypoxia	3.1 COPD 3. 2 Interstitial lung disease 3. 3 Other pulmonary disease with mixed restrictive and obstructive pattern 3. 4. Sleep-disordered breathing 3. 5 Alveolar hypoventilation disorders 3. 6 Chronic exposure to high altitude 3. 7 Developmental lung diseases
4. CTEPH	
5. PH with unclear or multifactorial etiologies	5.1 Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy 5. 2 Systemic disorders: sarcoidosis, pulmonary histiocytosis, lymphangiomyomatosis 5. 3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders 5. 4 Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure

COPD, chronic obstructive pulmonary disease; CTEPH, chronic thromboembolic pulmonary hypertension; HIV, human immunodeficiency virus; LV, left ventricular; PAH, pulmonary arterial hypertension; PH, pulmonary hypertension; PVOD, pulmonary veno-occlusive disease.

MALIGNANT CENTRAL AIRFLOW OBSTRUCTION

Malignant central airway obstruction (MCAO) refers to obstruction at the level of the trachea, mainstem bronchi, or bronchus intermedius. Cough, stridor, wheezing, dyspnea, atelectasis, and recurrent or persistent postobstructive pneumonia are common presenting symptoms. Hemoptysis, which can be massive and life threatening, may also occur. Stridor signals a proximal obstruction at the level of the trachea or larynx, whereas focal wheezing is typically secondary to obstruction distal to the main carina. Tracheal stenosis resulting in airway narrowing of 50% or greater is associated with a 16-fold increase in airflow resistance. Thus, obstructive symptoms typically develop with airway occlusions of 50% or more.[174] Tracheal diameters of 8 mm are associated with dyspnea on exertion, whereas resting dyspnea typically does not develop until tracheal diameters are 5 mm or less. Confounding factors such as chronic obstructive pulmonary disease, mucosal edema, and increased airway secretions may precipitate inexorable dyspnea even in patients with only moderate tumor-related airflow limitation. Patient presentation is influenced by underlying conditions as well as obstruction-related factors such as location and degree of obstruction and rate of development. Compromised airway caliber may be secondary to endoluminal tumor, extrinsic compression, or direct extension of tumor through the airway wall (mixed obstruction). Optimization of therapy is predicated on the location and extent of airway disease and quantification of airflow limitation. Except for rare findings of tracheal deviation on plain films, chest radiographs are of very limited value in defining the anatomic extent of airway tumors. Blunting of the flow–volume loop on PFT is an insensitive signal of upper airway obstruction and typically only occurs once the tracheal caliber is reduced to less than 10 mm (Fig. 63–8).[175] The use of spirometry in patients with severe airway obstruction is not recommended because it may precipitate frank respiratory failure.

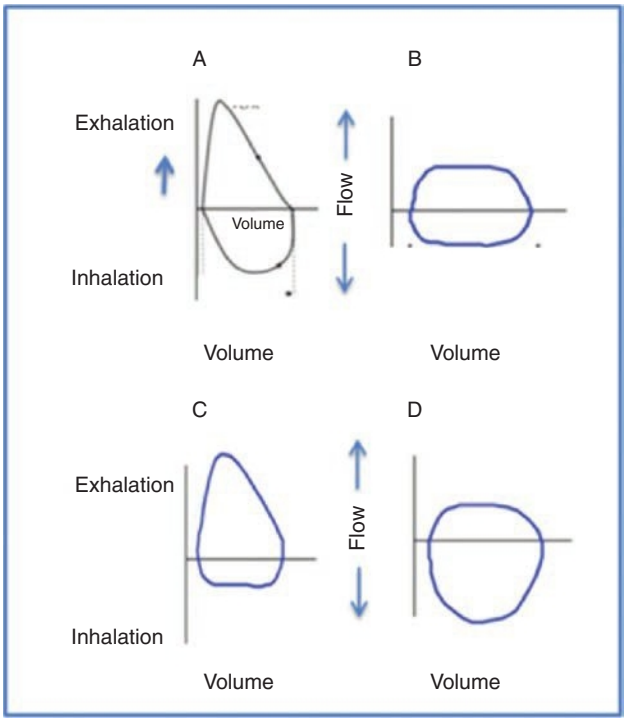

FIGURE 63–8 **Flow–volume loops characteristic of various patterns of upper airway obstruction. A. Normal flow–volume loop. B. Flattening of both the inspiratory and expiratory limbs of the flow–volume loop, consistent with fixed upper airway obstruction. C. Flattening of the inspiratory limb, consistent with dynamic extrathoracic obstruction. D. Flattening of the expiratory limb, consistent with dynamic intrathoracic obstruction.**

Bronchoscopic examination is central to the diagnosis and treatment of MCAO. Characterization and histologic confirmation of the tumor as well as determination of the extent of obstruction attributable to endoluminal or extraluminal disease are important findings that help to guide treatment decisions. Therapeutic strategies for predominantly endoluminal disease include surgical resection and mechanical debulking using the rigid bronchoscope and associated instruments. Endobronchial argon plasma coagulation, laser therapy, electrocautery, microdebrider, and cryotherapy are therapeutic options for predominantly endobronchial disease and provide rapid relief of obstruction when performed during rigid bronchoscopy. Brachytherapy and photodynamic therapy are additional options for treatment of endobronchial disease but typically have a delayed effect. Balloon bronchoplasty, endobronchial stent placement, and RT are reasonable treatment options for patients with predominantly extraluminal disease. A multimodality approach that includes endobronchial tumor debulking and stent placement is common because many patients present with mixed endo- and extraluminal disease (Fig. 63–9). Treatment options are based on the type of obstruction (Figure 63–10).

PLEURAL DISEASES IN THE CANCER SETTING

Nearly 50% of all patients with cancer develop pleural effusions. These may be malignant (MPE), which occur in up to 15% of all patients with cancer, or paramalignant.[176] The later results from direct or indirect effects of tumor on the pleural space and includes causes such as bronchial obstruction, infiltration of mediastinal lymph nodes, superior vena cava syndrome, trapped lung, PE, and atelectasis. Paramalignant effusions occur on the involved hemithorax and are typically small to moderate in size with negative pleural fluid cytology results. MPEs rank second as the leading cause of exudative effusions after parapneumonic effusions. MPEs may be quite large, and in contrast to parapneumonic effusions, pleural fluid cytology results are positive in more than 60% of patients.[177] Malignant pleural involvement may also occur in the absence of pleural fluid in patients with either primary pleural tumors or metastatic disease to the pleura.[178,179]

Fifty percent of all cancer-related pleural effusions are caused by lung cancer. Breast carcinoma and effusions caused by hematologic malignancies, including lymphoma and leukemias, are also common causes. Progressive dyspnea and dry cough are presenting symptoms in most patients and may be accompanied by constitutional symptoms of malaise, anorexia, and weight loss with advanced disease. Preprocedure imaging is an important component of the diagnostic workup and treatment planning. Standard chest radiographs and bilateral decubitus films provide critical information regarding effusion size, position of the mediastinum and diaphragms, presence of fluid loculations, and characteristics of the underlying lung parenchyma. Patients with large pleural effusions and associated contralateral shift of the mediastinum should undergo prompt therapeutic thoracentesis. A centered or ipsilateral shift of the mediastinum with associated pleural effusion may signify frozen mediastinum, tumor encasement of the ipsilateral mainstem bronchus, or extensive parenchymal involvement due to lymphangitic spread of tumor, infection, or other infiltrative lung diseases. Any of these diagnoses may cause ipsilateral opacification of the lung and mimic a large pleural effusion (Fig. 63–11). Pleural effusions in this setting should therefore be approached with caution.[180]

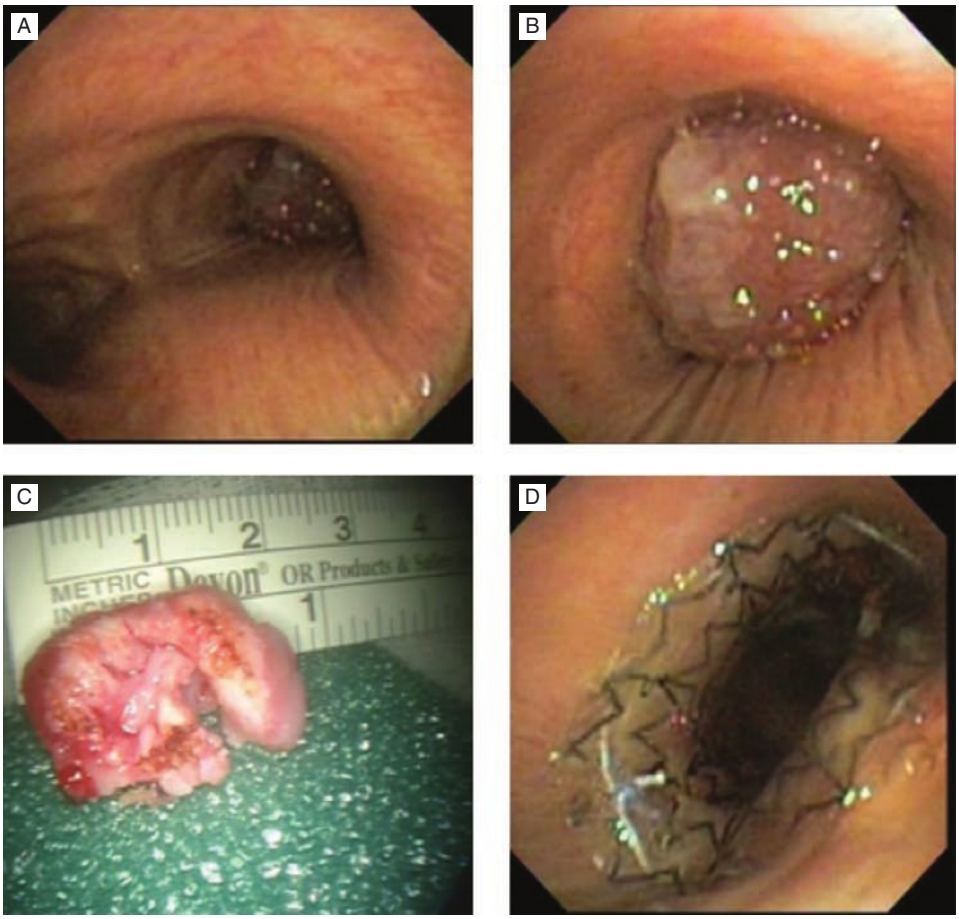

FIGURE 63–9 **A to D. Bronchoscopic images showing complete obstruction of the right mainstem bronchus secondary to an endobronchial tumor (A, B). The large endobronchial tumor was excised tumor using electrocautery (C). This obstruction was managed with a multimodality approach using electrocautery snare followed by endobronchial stent placement (D).**

Ultrasonography is easy to learn and interpret and provides guidance in locating the optimal site for pleural procedures. Pleural ultrasonography also provides valuable information regarding pleural fluid characteristics, including the presence of loculations, fibrin strands, and pleural metastases. CT provides valuable anatomic information of the visceral and parietal pleura, chest wall, lung parenchyma, and mediastinal structures and is particularly useful in characterizing the pleural fluid

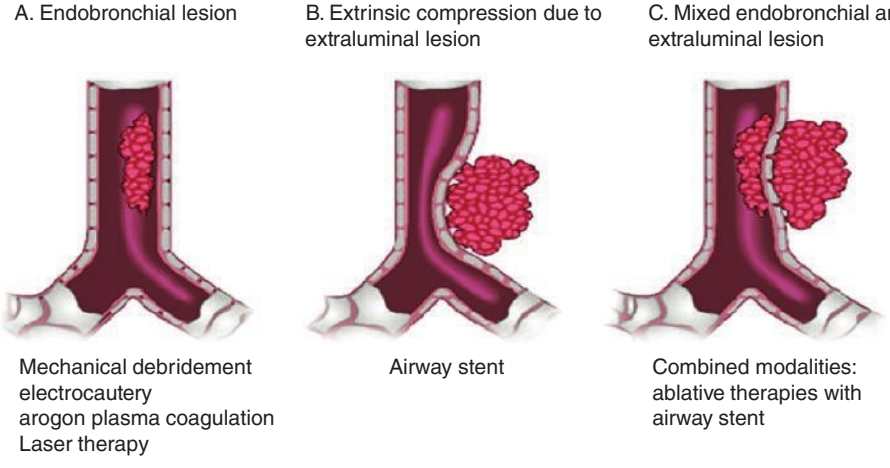

FIGURE 63–10 **Characterization of malignant central airflow obstruction and potential bronchoscopic treatment modalities**

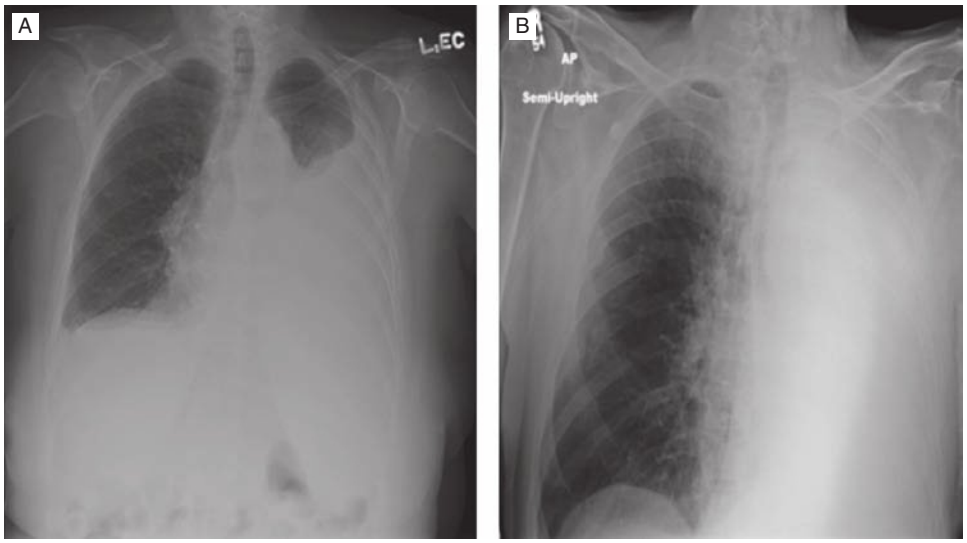

FIGURE 63–11 **A. Chest radiograph with a large left pleural effusion causing compression of the left lung and contralateral shift of the mediastinum. B. Chest radiograph with a large left pleural effusion with ipsilateral shift of the mediastinum in a patient with a central airway obstruction and a nonexpandable lung.**

and identifying competing diagnoses.[181] Findings on positron emission tomography (PET)–CT and conventional CT imaging, such as irregular, thickened, or nodular pleural surfaces, suggest malignancy (Fig. 63–12). Pleural enhancement with IV contrast material is also suggestive of malignancy, although pleural inflammation may be associated with similar findings. Recent studies have shown PET imaging with 18-fluorodeoxyglucose to be useful in delineating pleural tumors and extrapleural extension of disease in patients with malignant pleural mesothelioma (MPM). Magnetic resonance imaging of the pleural space is also valuable in displaying pleural tumors. This imaging strategy provides excellent soft tissue contrast and delineation of extrapleural invasion of the chest wall, spine, nerves, and mediastinal vascular structures.[181] This information is complementary to chest CT imaging and markedly enhances surgical planning for patients with MPM.

Nearly all MPEs are categorized as exudates using Light's criteria.[182] The cytologic or histologic confirmation of malignant cells on pleural fluid or biopsy is key to diagnosis, although pleural cytology results are only positive in 62% of patients.[177] The sensitivity of pleural fluid cytology varies considerably depending on the underlying malignancy with mesothelioma and hematologic malignancies having significantly lower diagnostic yield than adenocarcinomas.[183] Regarding solid tumors, whereas sarcomas, head and neck cancers, and renal cell carcinomas have the lowest sensitivity, the diagnostic yield of pleural fluid cytology from breast, pancreatic, ovarian, and lung cancers is much higher.[183,184] Flow cytometry with identification of tumor markers may improve the diagnostic yield of cytologically negative effusions by 33%. This diagnostic strategy has proved particularly useful when pleural effusions associated with lymphoma, leukemia, or multiple myeloma are suspected.[185,186] A definitive diagnosis is yielded after closed pleural biopsy in only 44% of patients but increases to 77% with the addition of pleural fluid cytology.[177] More recent advances in pleuroscopic and image-guided biopsy techniques have improved the diagnostic yield compared with traditional closed need biopsy in the diagnosis of pleural malignancy. For example, pleuroscopy and CT-guided pleural biopsies exhibit a 95% and 87% sensitivity in the diagnosis of pleural malignancies, respectively. The addition of pleural fluid cytology to pleuroscopy offers only a marginal increase in the diagnostic yield.[185,186]

With few exceptions, the presence of MPE portends a poor prognosis with mean survival measured in months. Treatment is therefore focused on palliation. Factors such as associated symptoms, performance status, volume of fluid evacuated, whether symptom palliation and lung reexpansion were achieved with prior thoracenteses, time course for recurrence, and expected tumor response to systemic therapy should be considered in management options (Fig. 63–13). Among patients with newly diagnosed chemo- or radiosensitive tumors (lymphoma, breast cancer, small cell lung cancer, prostate cancer, thyroid cancer, germ cell cancer), simple thoracentesis while awaiting response to definitive therapy is reasonable. Most MPEs recur within 30 days of the

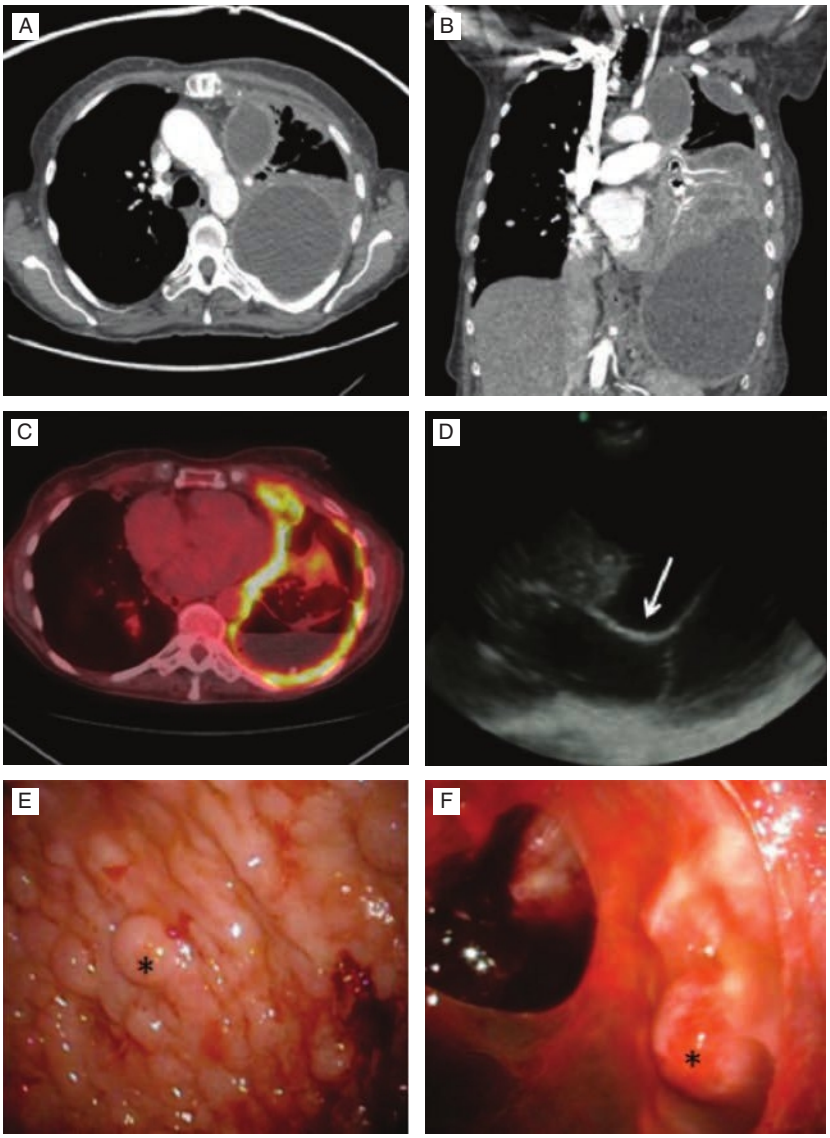

FIGURE 63–12 **Multiloculated pleural effusion on axial (A) and coronal (B) computed tomography (CT) views. C. Classic positron emission tomography–CT appearance in a patient with pleural mesothelioma. D. Corresponding ultrasound image showing loculated pleural fluid. Mesothelioma pleural deposits (E) and significant pleural adhesions (F) visualized during pleuroscopy in a patient with mesothelioma.**

prior thoracentesis. Repeated thoracentesis is also recommended in patients with slowly reaccumulating pleural effusions and a short life expectancy (1–3 months). Poor performance status is predictive of limited survival among patients with recurrent MPEs.[187] Evacuation of pleural fluid is ideally ultrasound guided, which is associated with lower rates of pneumothorax.[188] In recently published guidelines for the management of MPEs, the British Thoracic Society endorses symptom-limited pleural fluid evacuation not to exceed 1.5 L of fluid in one sitting.[189] In our experience, symptom-limited evacuation of up to 2.0 to 2.5 L of pleural fluid in one sitting is safe among patients with contralateral mediastinal shift secondary to a large pleural effusion. Chest pain, cough, and dyspnea are limiting symptoms that should prompt discontinuation of the procedure. Cautious evacuation of large volumes of pleural fluid is recommended in patients with centered or ipsilateral shift of the mediastinum. Pleural pressure measurements during thoracentesis have not been shown to be superior to symptom-limited pleural drainage in reducing the risk of procedure-related complications.[190]

Indwelling pleural catheter (IPC) placement is an increasingly viable palliative option for patients with recurrent MPEs. Patients whose life expectancy exceeds 30 days and those in whom symptomatic

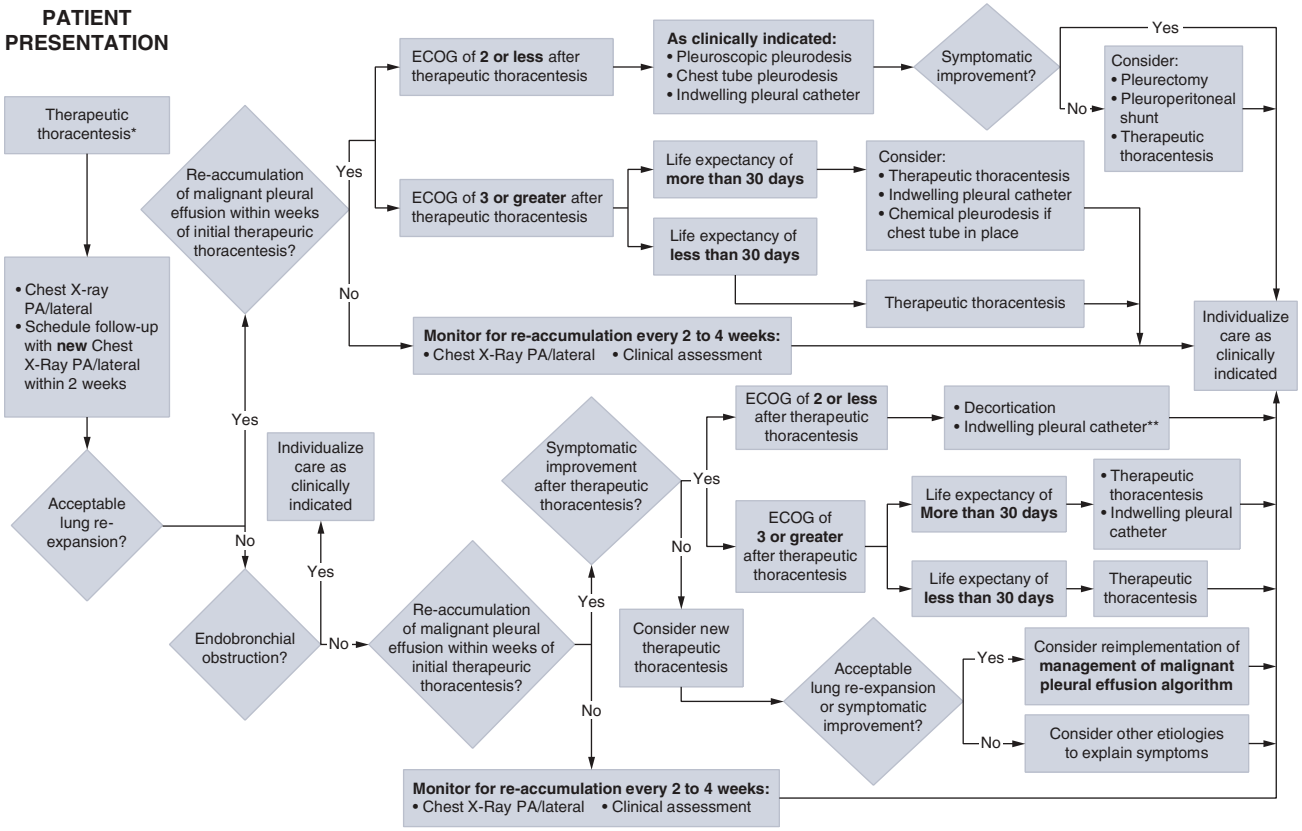

FIGURE 63–13 **Algorithm for the management of malignant pleural effusions. ECOG, Eastern Cooperative Oncology Group; PS, performance status.**

improvement was achieved on prior thoracenteses are ideal candidates for IPC placement. Lung reexpansion after thoracentesis is not a requirement for IPC use because they are also a feasible treatment option for patients with symptomatic trapped lung.[191] Most catheters are placed in the outpatient setting. Designated family members and caretakers are then trained on the proper use of the catheter. Daily home drainage is recommended initially followed by drainage every other day as pleural fluid volume decreases. In our experience, 94% of patients reported symptom relief, and in 52%, effective pleurodesis with subsequent removal of the catheter was achieved. The average time from catheter insertion to removal was 32 days (Fig. 63–14). Empyema and persistent pain at the insertion site were rare complications of IPC placement in our review. Recurrent effusion has also been rarely described in a small group of patients after catheter removal.[192]

Chemical pleurodesis using asbestos-free talc is a widely used strategy in the management of patients with MPE. Several studies have shown talc to be superior to other sclerosants (bleomycin, tetracycline) in achieving pleurodesis.[193] Eligible patients for this procedure should have a good performance status (Eastern Cooperative Oncology Group score, 0–2) and report symptomatic relief and lung reexpansion after prior thoracentesis. Pleuroscopic talc poudrage and talc slurry instillation via small-bore chest tube are both viable methods of chemical pleurodesis with no significant difference in pleurodesis failure rates.[194] The use of an IPC plus talc slurry administration has been evaluated and is also a safe and effective option for the treatment of MPE in outpatients.[195]

The management of recurrent chylous effusions is a particular challenge because of the potential for severe lymphopenia, nutritional depletion, and water and electrolyte loss from prolonged loss of chyle. These effusions, when cancer related, require treatment of the underlying malignancy. Parenteral alimentation, talc pleurodesis, and IPC placement represent reasonable alternatives in the management of recalcitrant effusions.[196] Pleuroperitoneal shunt placement is an attractive treatment option that permits reabsorption of chyle in the peritoneum and mitigates the risk of malnourishment and immune suppression. However, the small-volume shunt removal and increased potential for pump obstruction limits the utility of this treatment

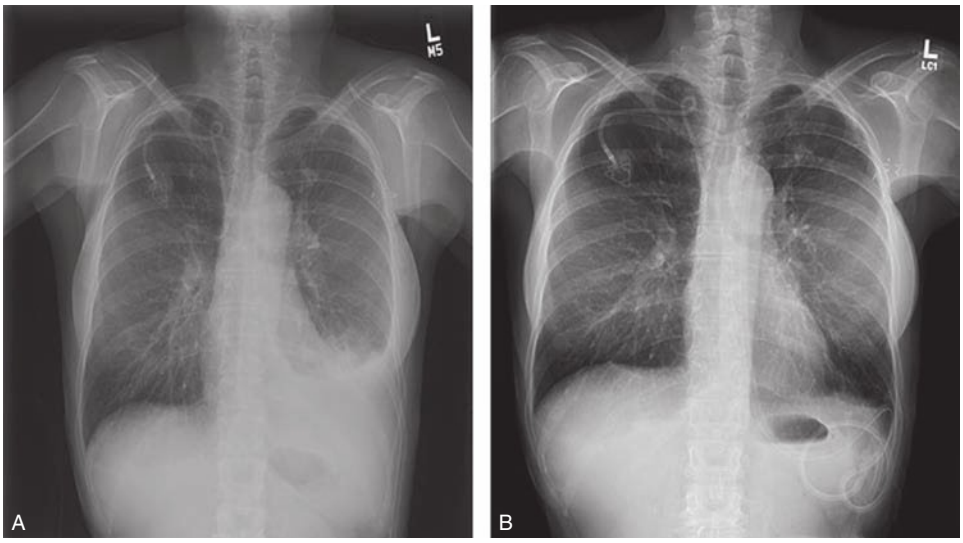

FIGURE 63–14 **A. Chest radiograph before indwelling pleural catheter (IPC) placement showing a left-sided pleural effusion. B. Chest radiograph after IPC placement with resolution of the pleural effusion.**

modality. Embolization of the thoracic duct has not been definitively studied but appears well tolerated.

SLEEP DISTURBANCES IN CANCER THERAPY

Nearly half of all patients with cancer develop sleep disturbances. Insomnia, poor sleep efficiency, early awakening, excessive daytime sleepiness, and restless legs may occur during all phases of cancer care and persist for many months to years after completion of cancer therapy. The biochemical changes inherent to cancer growth, anticancer therapies, and cancer-related symptoms of fatigue, pain, and depression may all adversely impact sleep quality.[197] Sleep disturbances, on the other hand, may have important implications in cancer incidence, treatment, prevention, and survivorship. For example, sleep duration appears to influence cancer risk. Excess cancer prevalence has been demonstrated among insomniacs with sleep times of less than 5 hours per night and patients undergoing 9 or more hours of sleep nightly.[198] In the American Nurses' Health Study, a relative increased risk of breast cancer was demonstrated among nurses working rotating shifts for many years.[199–201] In another study, cancer mortality increased by fivefold among patients with a protracted history of severe sleep apnea.[202] Elevations in inflammatory mediators, such as VEGF, induces disturbed sleep.[203] Sleep loss and, in particular REM (rapid eye movement) sleep deprivation, is hyperanalgesic. Thus, insomnia, which is common in the cancer setting, may confer an increased sensitivity to pain.[204] Sleep-disordered breathing may be increased in the cancer setting because of use of pain medications (eg, opioids) or with certain malignancies.[205] Higher rates of obstructive sleep apnea is seen among patients with head and neck cancers.[206]

Finally, sleep disruption, insomnia, and fatigue may persist after cancer therapy is completed. Cancer-related fatigue and sleep disorders appear to be closely linked, and their prevalence and association may vary greatly during the course of cancer care.[203,207—209] Cognitive behavioral therapy is the treatment of choice for insomnia and suboptimal sleep hygiene, which may improve quality of life and decrease sedative-hypnotic medication use.

SUMMARY

Lung injury associated with cancer therapy may manifest as a diverse spectrum of disorders affecting all components of the respiratory system, including the pulmonary parenchyma, vasculature, airways, and pleura. In addition, cancer and its treatment may profoundly impact sleep hygiene. These disorders contribute substantially to the morbidity and mortality of cancer therapy and may limit cancer care. Early recognition of key clinical, radiologic, and histopathologic features of lung injury and prompt initiation of therapy are key in the successful management of patients with these disorders.

MD ANDERSON PRACTICE TIPS

- Guidelines for the management of DILI caused by conventional chemotherapies and molecular targeted agents are limited and primarily based on expert opinion. Permanent drug withdrawal with or without the addition of systemic glucocorticoids is a frequent management strategy. Optimal dose, timing, and duration of glucocorticoids in the management of patients with DILI have not been elucidated in any prospective controlled trials. In general, 40 to 60 mg of prednisone or its equivalent or weight-based dosing at 0.75 to 1 mg/kg daily is recommended with a taper over a 1- to 3-month time period, depending on response to therapy. With only a few exceptions, drug rechallenge is not recommended.
- Treatment strategies for patients with ICI pneumonitis are guided by CTCAE pneumonitis grades but have yet to be validated in any prospective trials. Treatment ranges from cautious continuation of immunotherapy and monitoring of imaging and symptoms in asymptomatic patients with early (grade I or II) pneumonitis to permanent drug withdrawal, steroid administration, and other immunosuppressive therapies in patients with advanced (grade 3 and 4) disease.
- The use of antimicrobial prophylaxis has resulted in a significant decline in post-HSCT infectious pulmonary complications; however, noninfectious complications remain a major cause of post-HSCT morbidity and mortality. These heterogeneous lung complications are categorized as early (occurring within the first 100 days of HSCT) and late (occurring at day 100 after HSCT or later) events and are influenced by the rate of immune reconstitution and the development of posttransplant GVHD. Prognosis varies depending on the underlying condition.
- Chest radiography has a low sensitivity for diagnosing central airway obstruction (CAO). Therefore, chest CT should be obtained when CAO is suspected. Early referral to a pulmonary specialist is recommended in stable patients with suspected CAO. In unstable or symptomatic patients with advanced disease, emergent referral for further evaluation and airway management is imperative.
- Evaluation and management of pleural effusions is indicated in most patients with treatments tailored by associated symptoms, performance status, size of the effusion, and volume of fluid evacuated during initial drainage. Whether symptom palliation and lung reexpansion were achieved with prior thoracenteses, time course for recurrence, and expected tumor response to systemic therapy are other factors that influence treatment strategies. Optimal management typically involves detailed discussions with the patient by a multidisciplinary team.
- Screening for sleep disturbances in patients with cancer is important given the prevalence of sleep disorders in this patient population. Sleep disturbances may confer increased sensitivity to pain and are closely associated with cancer-related fatigue. As such, sleep hygiene may have important implications in cancer incidence, treatment, prevention, and survivorship.

64 Cancer-Associated Thrombosis

Kelly A. Casteel
Michael H. Kroll

KEY CONCEPTS

- Venous thromboembolism (VTE) is common in patients with cancer and contributes to their morbidity and mortality.
- All hospitalized patients with cancer should be given pharmacologic thromboprophylaxis unless there is a contraindication.
- High-risk ambulatory patients with cancer receiving outpatient chemotherapy can be considered candidates for receiving prophylactic-dose apixaban or rivaroxaban.
- Cancer-associated VTE treatment with anticoagulation is associated with a higher rate of recurrence and bleeding compared with non–cancer-related VTE, so one must fastidiously review the risk–benefit ratio for each patient before beginning anticoagulation.
- Cancer-associated thrombotic microangiopathy is not caused by ADAMTS-13 autoantibodies and does not improve with plasma exchange.
- Routine anticoagulation or antiplatelet therapy for cancer patients with atrial fibrillation or coronary artery disease appears to be safe.

VENOUS THROMBOEMBOLISM

Scope of the Problem

Pulmonary embolism (PE) and deep vein thrombosis (DVT) are manifestations of venous thromboembolism (VTE). Approximately 20% of all VTEs are associated with cancer, and cancer increases the risk for VTE four- to sixfold. Surgery, chemotherapy, hormonal therapy, growth factors, angiogenesis inhibitors, immunomodulators, erythropoietic agents, and central venous catheters (CVCs) contribute to cancer-associated VTE.[1] The risk of VTE is associated with the type of cancer and its clinical stage, with glioblastoma, stomach cancer, pancreatic cancer, lung cancer, gynecologic cancer, and acute leukemia frequently associated with VTE and early-stage breast cancer, prostate cancer, and melanoma least commonly associated with VTE.[1] Cancer-associated VTE is rarely lethal within 6 months of diagnosis and treatment,[2] but it is often undiagnosed, and its onset can be associated with considerable mortality. VTE was the death certificate–attributed cause of death for 0.21% of patients with cancer in a large population-based death certificate review,[3] the objectively documented cause of death among 0.4% of all patients with cancer registered by our institution between 2000 and 2010 (unpublished data), and the cause of death for 5/141 (3.5%) deaths recorded among 4466 community hospital–treated ambulatory patients with cancer.[4]

Diagnosis

Clinical presentations of VTE are not specific. Most patients with DVT have unilateral leg swelling and tenderness, and most patients with PE have abrupt-onset dyspnea and pleuritic chest pain. VTE can be ruled out in about 97% of cases when there is a low Well's score in conjunction with normal D-dimer levels. A higher Well's score along with elevated D-dimers cannot, however, be used to diagnose VTE in patients with cancer, and radiographic studies are required for all patients in whom VTE cannot be ruled out using Well's criteria and D-dimer levels.[5] Doppler with compression ultrasound is the preferred method to diagnose DVT, although magnetic resonance imaging and

computed tomography (CT) may be required in special circumstances, such as internal iliac vein or vena cava thrombosis. CT angiography is the best method for diagnosing PE,[6] and it offers the advantage of providing additional information regarding synchronous thoracic pathology that may confound the diagnosis. Up to 5% of all routine chest CTs done for cancer staging, monitoring, and surveillance show asymptomatic or incidental PEs.[7]

Prevention

Pharmacologic VTE prophylaxis should be considered in every hospitalized patient with cancer for whom there is no contraindication.[8] Contraindications to pharmacologic anticoagulation are absolute (platelets <20,000/μL, recent central nervous system bleed, intracranial or spinal lesion at high risk for bleeding, or major active bleeding: >2 units transfused in 24 hours) or relative (chronic, clinically significant measurable bleeding >48 hours; platelets <50,000/μL; platelet dysfunction [uremia, medications, dysplastic hematopoiesis]; recent major operation at high risk for bleeding; underlying hemorrhagic coagulopathy; high risk for falls; neuraxial anesthesia/lumbar puncture). During hospitalization for nonsurgical patients with cancer, one could use enoxaparin 40 mg subcutaneously (SC) once per day, dalteparin 5000 IU SC once per day, fondaparinux 2.5 mg SC once per day or rivaroxaban 10 mg by mouth (PO) once per day. Another option is the direct oral anticoagulant rivaroxaban 10 mg PO once per extended post hospitalization for up to 31-39 days total.[9]

Patients with cancer undergoing abdominal or pelvic surgery should receive low-molecular-weight heparin (LMWH) prophylaxis extended for 4 weeks.[10] Routine pharmacologic prophylaxis in ambulatory patients with cancer receiving chemotherapy is recommended for patients with myeloma receiving thalidomide or lenalidomide as part of combination chemotherapy, although outpatient pharmacologic prophylaxis, including thromboprophylaxis with rivaroxaban 10 mg or apixaban 2.5 mg po twice a day (BID) can be considered in high-risk patients receiving systemic chemotherapy, such as those with glioblastoma multiforme, pancreatic cancer gastric cancer, or metastatic breast cancer beginning tamoxifen therapy.[8,11]

Treatment

Routine VTE induction followed by maintenance therapy is used to treat patients with symptomatic VTE or incidental PE. Incidental PEs, including those found in the subsegmental branches of the pulmonary artery, appear to have a recurrence risk similar to symptomatic PE and should be managed similarly.[12] There has been a preference for induction and maintenance therapy with a LMWH over warfarin—for example, enoxaparin 1 mg/kg/12 hours or dalteparin 200 IU/kg/24 hours—but most organizations now suggest that a direct oral anticoagulant (DOAC) can be considered. Edoxaban 60 mg PO once per day is begun as maintenance therapy after 5 days of LMWH.[13] Rivaroxaban 15 mg PO BID for 3 weeks followed by 20 mg once per every day[14,15] or apixaban 10 mg PO BID for 1 week followed by 5 mg PO BID[16] can be used during both induction and maintenance. Both edoxaban and rivaroxaban cause more bleeding than LMWH, with almost all major bleeding being gastrointestinal (GI) or genitourinary (GU). Therefore, these DOACs should be avoided in patients with luminal GI or GU malignancies or among those with overt or potential GI or GU hemorrhage.[17] Apixaban does not cause more bleeding than LMWH, and it appears to be the safest DOAC for patients with luminal GI or GU malignancies or GI or GU bleeding.[18]

Unfractionated heparin (UFH) followed by warfarin is preferred for patients with renal failure. Because it is rapidly reversible with a reliable antidote (Table 64–1), UFH is also preferred for patients with nonsevere hemorrhage and all patients with massive PE (defined as associated with systolic blood pressure <90 mm Hg lasting for more than 15 minutes) being evaluated for systemic or local thrombolytic therapy. Thrombolysis must be considered in all cases of massive PE. If thrombolysis is contraindicated, one must evaluate patients with massive PE for treatment with mechanical thrombectomy.[7]

An inferior vena cava (IVC) filter should be placed when anticoagulation is contraindicated. If the contraindication is temporary, a retrievable IVC filter is preferred. If a patient has bleeding that is not reversible or has cancer and is unlikely to survive for more than 6 months, a permanent IVC filter is preferred.[19]

Recurrence

Recurrence of VTE on anticoagulation therapy is common in patients with cancer. The Comparison of Low-Molecular-Weight Heparin versus Oral Anticoagulant Therapy for the Prevention of Recurrent Venous Thromboembolism in Patients with Cancer (CLOT) trial from 2003 showed a best-case scenario of 9% recurrence at 6 months among those treated with LMWH maintenance.[2] The Comparison of Acute Treatments in Cancer Hemostasis (CATCH) trial showed that we have not made great progress in the intervening decade: the recurrence rate was 6.9% at 6 months among patients receiving LMWH maintenance.[20] The only prospective analysis examining 12 months of anticoagulation (in

TABLE 64–1 Coagulation Reversal Recommendations

Vitamin K Antagonist	Reversal Agent	Dosage	Comments
	Vitamin K	Life-threatening bleed: 10 mg IV[62] INR >9 with no bleeding: 5–10 mg PO[62] INR >5 to <9 with no bleeding: 1–4 mg PO[62]	IV and PO are equally effective at 24 hours, but IV is more effective at 6–8 hours.[1] DO NOT administer SC.[1,11,12]
		Recommended for life-threatening bleeds or need for emergency surgery[a]	For prolonged reversal administer with vitamin K:[1] Duration: 12–24 hours[1] **Contraindications:** DIC, recent thrombotic event, HIT with a HIT episode in past 60 days
Warfarin (Coumadin) (Jantoven)	PCC (Kcentra)	**INR** / **Dose (units/kg)** / **Max Dose (units)** 2 to < 4 / 25 / 2500 4–6 / 35 / 3500 > 6 / 50 units/kg / 5,000 units	
Half-life[4]: 36–48 hours			
	FFP	If PCC not available, use FFP. Generally, 15 mL/kg (64,65)[a] 5–8 mL/kg if urgent reversal is required and INR is not supratherapeutic (See dosing calculation on page 9.)	Monitor for volume overload[1] Risk of transfusion complications[1] Thawing of product may result in administration delays[17] Time to normal hemostasis: 2–7 hours[4]
Heparin			
Half-life[4]: 60–90 min (IV) 3 hours (SC)	Protamine 1 mg protamine neutralizes 100 units of heparin	The anticoagulant effect of heparin IV infusion will not be present 3–4 hours after discontinuing IV infusion or 8–12 hours after SC UFH.[66] Administer 1 mg of IV protamine for every 100 units of IV heparin given over the last 2–2.5 hours. Give slowly over 10 minutes or as a continuous infusion over 30 minutes. Administration rates should not exceed 5 mg/min. Single doses **should not exceed** 50 mg. Neutralization of subcutaneously administered heparin may require a prolonged infusion of protamine sulfate because the half-life is longer. Half-life is 10 minutes, so repeat dosing may be needed.	Excessive dosing can potentially lead to increased bleeding. Increased risk for preformed antibodies against protamine sulfate and to have an allergic reactions, including anaphylaxis • Previously received protamine sulfate-containing insulin • Have undergone vasectomy • Have known sensitivity to fish **Possible side effects of protamine:** Severe hypotension, anaphylaxis, dyspnea, bradycardia, flushing, a feeling of warmth, especially when given too rapidly

TABLE 64–1 Coagulation Reversal Recommendations *(Cont.)*

LMWH	Reversal Agent	Dosage	Comments
		Administer 1 mg of IV protamine for each 1 mg of enoxaparin or 100 IU of dalteparin given in the past 8 hours[66] IV slowly over 10 minutes or as a continuous infusion over 30 minutes. Administration rates should not exceed 5 mg/min. Can repeat a second dose of 0.5 mg per 100 units if bleeding continues. Smaller doses of protamine can be given if the time since LMWH is >8 hours. Likely not useful if dose given >12 hours ago. Single doses of protamine **should not exceed** 50 mg. Half-life is 10 minutes, so repeat doing may be needed.	See comments for heparin above
	Protamine		
Enoxaparin (Lovenox) Half-life: 4.5–7 hours	Percent Xa activity neutralizes enoxaparin: 54.2%[2] Dalteparin: 74%[2]		**Possible side effects of protamine:** severe hypotension, anaphylaxis, dyspnea, bradycardia, flushing, a feeling of warmth, especially when given too rapidly
Dalteparin (Fragmin) Half-life: 4–8 hours			
		For refractory life-threatening bleed:	
	PCC (Kcentra)	25 units/kg (maximum, 2500 units) to 50 units/kg (maximum, 5000 units) Consider using ideal or adjusted body weight for obese patients.	**Contraindications:** DIC, recent thrombotic event, HIT with a HIT episode in past 60 days
Pentasaccharide	**Reversal Agent**	**Dosage**	**Comments**
Fondaparinux (Arixtra) Half-life[4]: 15–20 hours	PCC (Kcentra)	25 units/kg (maximum, 2500 units) to 50 units/kg (maximum, 5000 units) Consider using ideal or adjusted body weight for obese patients.	Contraindications: DIC, recent thrombotic event HIT with a HIT episode in past 60 days
	Recombinant factor VIIa (Novo-Seven) Half-life: 2.6–3.1 hours	20–90 mcg/kg IV for one dose[66] Repeat in 2 hours if needed. Round to the nearest 1 mg.	**Monitoring**: monitor for evidence of hemostasis; safe to use in Jehovah's Witness patients

Data from Schulman S. Clinical practice. Care of patients receiving long-term anticoagulant therapy, *N Engl J Med* 2003 Aug 14;349(7):675-83.

>1000 patients with cancer) revealed a VTE recurrence rate at 12 months of about 8% in the DOAC (edoxaban) arm and about 11% in the LMWH (dalteparin) arm.

Optimal management of VTE recurrence remains uncertain. If a patient is using warfarin with in-range international normalized ratio (INR) or a DOAC for which monitoring is generally unavailable, one should switch to an LMWH. If a LMWH and an anti-FXa level drawn 4 hours after injection is not in the therapeutic range, the dose of LMWH should be adjusted, aiming toward the therapeutic peak anti–FXa level. If the anti-FXa level is therapeutic, one can increase the dose of LMWH by 20%, change to another anticoagulant, or place an IVC filter.[21]

Anticoagulation in Patients with Thrombocytopenia

Mild thrombocytopenia (platelets <50,000/μL) is presented as a relative contraindication for anticoagulation by the American Society of Clinical Oncology and the National Comprehensive Cancer Network despite the lack of data about the risk of anticoagulation in patients with thrombocytopenia. There are, however, fairly consistent data that thrombocytopenia preventing pharmacologic prophylaxis is a critical factor in the large risk of VTE and its recurrence among patients with acute leukemia[22] and after stem cell transplant (SCT).[23]

To address this conundrum, the Subcommittee on Haemostasis and Malignancy for the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis has developed consensus guidelines.[24] One recommendation is that patients with chronic thrombocytopenia be given dose-adjusted LMWH, with full-dose LMWH when the platelet count is greater than 50,000/μL; half-dose LMWH when the platelet count is between 25,000 and 50,000/μL; and no anticoagulation when the platelet count is less than 25,000/μL. Such an approach can also be considered for patients with cyclical thrombocytopenia from chemotherapy.

Catheter Thrombosis

Catheter thrombosis may affect almost 50% of patients who have CVCs, although fewer than 5% of catheters are associated with symptomatic occlusive DVTs.[25] In addition to all the other risk factors for DVT development in patients with cancer, the catheter type (peripherally inserted central catheter > centrally inserted catheters > implanted ports) and location (femoral > jugular > subclavian) affect the risk of developing a catheter-related DVT.

There is no evidence that anticoagulation prevents catheter-associated thrombosis, and all guidelines currently recommend against it. The diagnosis and treatment of catheter-associated DVT are, however, similar to the diagnosis and treatment of lower extremity DVTs, with two special considerations. The first is that the catheter can be maintained in place during anticoagulation if it is functional and useful. In this case, therapeutic anticoagulation should be maintained for as long as the catheter is in place. The second is how to manage anticoagulation when a catheter has been removed because it is infected or no longer needed. Clinical guidelines recommend 3 months of anticoagulation after catheter removal.

Bleeding Complications

Bleeding while on anticoagulation is common. During the first 6 months of treatment, about 4% of all patients with cancer will have major bleeding (generally defined as a fall in hemoglobin of 2 g over 24 hours, the need for two units of packed red blood cell transfusion over 24 hours, or bleeding into a body cavity, vital organ or eye), and another 10% will have clinically relevant nonmajor bleeding.[13–18] After the first 6 months, bleeding events decrease, and after 1 year, they appear to remain at a stable level below 1% per year.[13,26]

Bleeding often develops unexpectedly at the beginning of treatment when LMWH unmasks a previously unrecognized bleeding threat.[8] When major bleeding occurs, it is essential to stop anticoagulation, reverse it when appropriate (Table 64–1), and place an IVC filter.

THROMBOTIC MICROANGIOPATHIES

Cancer-associated thrombotic microangiopathies (TMAs) are a group of disorders identified mainly by descriptive clinical characteristics, always involving the presence of circulating schistocytes associated with intravascular hemolysis (elevated lactate dehydrogenase and indirect bilirubin), anemia, thrombocytopenia and when the bone marrow is healthy, elevated reticulocytes. Anemia and thrombocytopenia are the principle clinical manifestations, but there may also be end-organ dysfunction from microvascular thrombosis, particularly in the kidneys. Cancer-associated TMAs are distinguished from disseminated intravascular coagulation (DIC) by normal coagulation studies and D-dimer levels.

Pathogenesis of Cancer-Associated Thrombotic Microangiopathy

The molecular pathogenesis of cancer-associated TMAs is barely understood, and ignorance about pathophysiological mechanisms is coupled to inadequate diagnostic measures and a paucity of effective evidence-based clinical therapeutics. Most of the approaches used derive from those used to manage

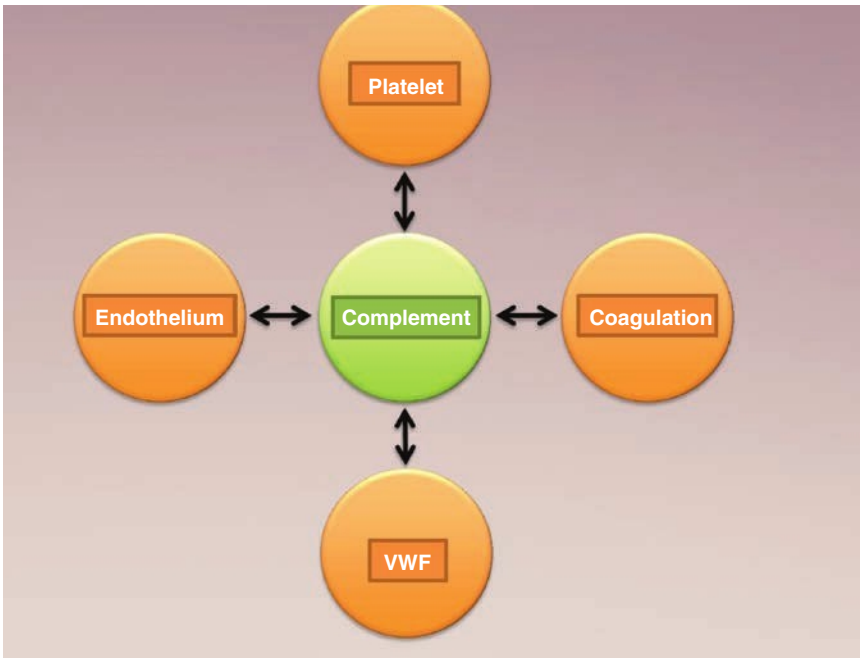

FIGURE 64–1 **Cancer-associated thrombotic microangiopathies represent a pathophysiological nexus involving von Willebrand factor (VWF), platelets, the soluble coagulation system, perturbed vascular endothelium, and the complement system. Identifying and ranking the major predisposing and triggering elements is the clinical challenge that one must confront with each individual case.**

patients with two of the well-characterized TMAs: de novo thrombotic thrombocytopenic purpura (TTP) and hereditary complement-mediated TMA (also referred to as familial atypical hemolytic uremic syndrome [aHUS]).[27] Because some forms of cancer-associated TMA almost certainly result from an overlap of pathophysiological elements present in TTP and complement-mediated TMA (Fig. 64–1), a brief overview of each is presented.

De Novo Thrombotic Thrombocytopenic Purpura

Thrombotic TTP is an autoimmune disorder leading to severely deficient (<10%) activity of the primary von Willebrand factor (VWF) cleaving protease ADAMTS-13 (the 13th member of the protein family designated "a disintegrin and metalloproteinase with thrombospondin-type 1 motif"). Anti-ADAMTS-13 antibodies cause its dysfunction or rapid clearance, and this results in absent cleavage of ultralarge VWF multimers that are synthesized and secreted by vascular endothelium. The ultralarge VWF multimers are excessively adhesive, and when they circulate systemically, they attach to platelet glycoprotein Ib in the microcirculation, leading to in vivo platelet activation and aggregation, microvascular thrombosis, and end-organ ischemia accompanied by microangiopathic hemolytic anemia. This is a hematologic emergency with considerable a mortality rate when it is unrecognized and untreated. Treatment targets the antibody (immune suppression with corticosteroids and urgent plasmapheresis) and restoring normal ADAMTS-13 activity (immediate plasma infusion). Factors separate from ADAMTS-13 def iciency (eg, numerous infections) are involved in triggering the onset and relapse of TTP, suggesting that there is more than a single pathophysiological element driving the development of this TMA.

Complement-Mediated Thrombotic Microangiopathy

aHUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal impairment. It is distinguished from typical hemolytic uremic syndrome by the absence of infection with Shiga-like toxin-producing bacteria.[28] The most common etiologic element in both inherited and sporadic aHUS is a deficiency of the alternative complement pathway regulatory protein factor H. Factor H binds indirectly to endothelial surfaces and engages C3b, serving as an essential allosteric cofactor for C3b cleavage by factor I. Factor I cleavage of C3b shuts down the proteolytic cascade of complement activation, thereby preventing the formation of the membrane attack complex on intact vascular endothelium. In the absence of factor H, there are unregulated complement activation and deposition of the membrane attack complex on the vascular

endothelium, leading to endothelial injury and its shift from an antithrombotic to a prothrombotic surface. The reason why the renal compartment is the primary target for thrombosis in aHUS is poorly understood, although one hypothesis is that the fenestrated endothelium of the glomerulus makes the kidney particularly vulnerable to complement attack.[28] The aHUS is treated with the anti-C5 antibody eculizumab or ravulizumab.

Cross Talk Between von Willebrand Factor, ADAMTS-13, and Complement

A story relevant to the pathogenesis of cancer-associated TMAs is rapidly developing: recent data indicate that de novo TTP involves complement activation and that aHUS involves abnormalities in the VWF–ADAMTS-13 axis.[29,30] Furthermore, mechanisms of cross talk between these two prototypical pathogenic elements have been identified and include direct interactions between factor H, VWF, and ADAMTS-13. These molecular interactions provide a conceptual framework from which to explore mechanisms of cancer-associated TMAs. Innovations in diagnosis and treatment will only become possible when pathogenic elements can be identified and their clinical significance elucidated and ranked.

Syndromes of Cancer-Associated Thrombotic Microangiopathy

There are rare but predictable clinical associations between TMA and some malignancies and their treatments. These may provide general clarity about pathogenesis, and their recognition often provides a useful management strategy for patients with microangiopathic hemolytic anemia and thrombocytopenia, particularly when the TMA is caused by a drug that can be replaced with an effective alternative agent.

Drugs

Several antineoplastic drugs have been repeatedly associated with TMA.[31] These include mitomycin C, gemcitabine, interferons, pentostatin, sunitinib, bevacizumab, oxaliplatin, and docetaxol. Also, TMA is predictably associated with drugs used routinely in the management of SCT: the calcineurin inhibitors cyclosporine and tacrolimus and the mTOR (mammalian target of rapamycin) inhibitors sirolimus and everolimus. End-organ injury, if it occurs, mainly involves the kidneys and is reversible after stopping the drug.[32]

Hematopoietic Stem Cell Transplantation

At least 3% of all recipients of SCT develop TMA, usually within the first year after SCT.[33] Risk factors include conditioning programs (total-body irradiation, busulfan, fludarabine, and platinum compounds), graft-versus-host disease, infections (especially *Aspergillus*, cytomegalovirus, and adenovirus), and medications (especially calcineurin inhibitors). The pathogenesis of post-SCT TMA focuses primarily on vascular endothelial injury (directly from drugs or irradiation or indirectly by inflammatory cytokines) as the trigger (see Fig. 64–1). Genetic or acquired abnormalities of the VWF–ADAMTS-13 axis or complement are theorized as predisposing factors that drive the development of overt TMA in susceptible individuals suffering a triggering event.

Diagnosis is based mainly on clinical judgement, although there are scoring systems that have been weakly validated.[34] Acute renal failure is the most threatening clinical consequence of post-SCT TMA. Treatment with plasma exchange or any other active intervention is rarely effective, but discontinuing a calcineurin inhibitor can often arrest (and sometimes reverse) kidney injury. The long-term prognosis of post-SCT TMA is unfavorable; there are increased risks of hypertension, chronic kidney disease, end-stage kidney disease, cardiac disease, and death.

Paraneoplastic Thrombotic Microangiopathy

Thrombotic microangiopathy may develop in patients with solid tumors. The most likely development pattern for patients is gastric > breast > prostate > lung > lymphoma > unknown primary cancer. Paraneoplastic TMA almost always develops in patients with bone marrow metastases and can involve a DIC-like coagulation picture. It rarely involves any end-organ injury and appears to be treatable only with effective chemotherapy, although plasma infusion followed by plasma exchange (if needed because of TMA progression despite plasma infusion) is often used along with anticancer therapy.[33,35]

Summary

In patients with cancer, TMAs are a heterogeneous group of diagnoses, almost all of which have common clinical correlates and a final common pathway of microvascular thromboses that threaten or injure the kidneys. Dissecting established pathophysiological elements of de novo TTP (VWF and ADAMTS-13) and aHUS (complement over activity), putative pathophysiological elements of chemotherapy and post-SCT TMA (direct endothelial toxicity and cytokine "storms"), and vague pathophysiological elements of paraneoplastic TMA (myelophthisis and coagulation system activation) may someday allow clinicians to establish diagnostic criteria and treatments that are based on a hierarchy of pathophysiological factors driving each individual case.

VASCULAR SYNDROMES

Chemotherapy-Induced Thrombosis

A number of medications used to treat patients with cancer have been documented to increase the risk of venous thromboembolic events. These are reviewed individually. It is worth noting, however, that the use of any chemotherapeutic agent has consistently been demonstrated to increase thrombotic risk. In 2008, Khorana et al[36] developed a predictive model for chemotherapy-associated thrombosis. In their derivation cohort of 2701 patients, 60 patients (2.2%) developed VTE; of these events, 75% of the VTEs occurred within the first two cycles of chemotherapy. A 2009 review identified systemic chemotherapy as carrying a two- to sixfold increased risk of VTE.[37]

The most common oncologic medications that carry an increased risk of thrombosis include tamoxifen, bevacizumab and other angiogenesis-inhibiting tyrosine kinase inhibitors (TKIs), lenalidomide or its derivatives when combined with steroids or chemotherapy, and L-asparaginase.

Tamoxifen, but not an aromatase inhibitor, raises the risk of thromboembolic events, particularly in the first 3 months of use; its procoagulant effect is amplified by coadministration with chemotherapy.[38] Bevacizumab and other angiogenesis-inhibiting TKIs have been associated with an increase in arterial thrombotic events; there are mixed data on whether the risk of venous thrombotic events is also increased.[39] Mechanistically, it is thought that these drugs disturb the endothelial lining of the vasculature, providing a nidus for thrombus formation. Given the risk for both thrombotic and hemorrhagic complications with these medications, prophylactic anticoagulation is not recommended. Thalidomide and its derivatives (lenalidomide, pomalidomide) increase the risk of VTE when administered in combination with steroids or chemotherapy; the highest risk is when thalidomide is combined with doxorubicin. This is thought to be caused by direct endothelial damage caused by both thalidomide and doxorubicin in addition to alterations in the coagulation cascade.[8] Thalidomide alone does not raise the risk of VTE. Patients with multiple myeloma treated with combination therapy containing thalidomide have a risk of VTE approaching 20%. Therefore, pharmacologic VTE prophylaxis is indicated with aspirin, LMWH, or warfarin. The Myeloma Working Group has proposed a risk stratification model, including factors such as obesity, recent surgery, history of VTE, and type of therapy (thalidomide combined with high-dose dexamethasone, doxorubicin, or multiagent cytotoxic chemotherapy) to determine which agent to use for VTE prophylaxis. Patients with no or one risk factor should receive aspirin (81 or 325 mg), and patients with two or more risk factors should receive LMWH (enoxaparin 40 mg subcutaneous daily).[40] L-asparaginase is often used to treat adult acute lymphoblastic lymphoma. Its use carries a small risk of arterial thrombosis but a large risk of VTE (up to one third of patients). The mechanism of these effects may be caused by decreased synthesis of the natural anticoagulant protein antithrombin.[41]

Myeloproliferative Neoplasm–Associated Thrombosis with Attention to Portal Vein Thrombosis and Budd-Chiari Syndrome

The Philadelphia chromosome–negative myeloproliferative neoplasms (Ph^- MPNs), including polycythemia vera (PV), essential thrombocytosis (ET), and primary myelofibrosis (PMF), are clonal disorders of myeloid lineage stem cells associated with *JAK2*, *MPL*, or *CALR* mutations. These disorders carry an increased risk of both arterial and venous thrombotic events, as well as increased risk of hemorrhagic events. The mechanism of thrombophilia in Ph^- MPN is complex. Proposed factors include increased total volume of erythrocytes, activated or adhesive platelets and erythrocytes, inflammation leading to endothelial damage, inhibition of anticoagulant pathways, and secretion of procoagulant factors.[42] Thrombotic events contribute significantly to disease-specific morbidity and mortality, causing 45% of all disease-specific fatal events.[43] Venous thrombosis in an unusual location (ie, portal vein thrombosis [PVT]) may be the presenting symptoms of Ph^- MPN, and *JAK2* mutation testing should be strongly considered in a patient presenting with a first thrombosis in an unusual location.[44]

A number of studies have sought to stratify patients with PV and ET into those with high- versus low-risk of thrombotic events, with conflicting results. Patients older than age 60 years or with a history of thrombosis are considered high risk. High-risk patients should be managed with low-dose aspirin, phlebotomy to a goal hematocrit of less than 45%, and cytoreduction with hydroxyurea or interferon alpha to normalize platelet count (for ET) or if phlebotomy alone is unable to produce the target hematocrit level (for PV).[45] Additional factors to be considered in evaluating the individual patient include *JAK2* mutation status and allele burden, leukocytosis, inflammatory markers, and any history of bleeding, particularly the presence of an acquired von Willebrand syndrome. Traditional risk factors for arterial and venous thrombotic events (smoking, hyperlipidemia, and diabetes and immobility, respectively) should be managed aggressively. The role of ruxolitinib and other *JAK* inhibitors in the prevention of thrombotic events is uncertain at this time.[46]

Management of the acute VTE in a patient with Ph^- MPN includes anticoagulation with LMWH, heparin, fondaparinux, warfarin, or a DOAC.[47,48] The duration

of anticoagulation remains controversial; a minimum of 3 to 6 months is required, with longer duration to be guided by the clinician's estimate of risk of recurrence. Risk of recurrence is influenced by MPN disease burden, advanced age, and prior history of VTE. Bleeding complications must also be considered. If the decision is made to continue anticoagulation beyond 6 months, the risk and benefit of anticoagulation should be reassessed frequently. Aggressive management of the MPN, with attention to achieving goal complete blood cell count values, is an integral component of the management of VTE in the patient with MPN. Concurrent use of anticoagulation and antiplatelet therapy increases the risk of bleeding events.[49] After VTE, monotherapy with an antiplatelet agent reduces the risk of both recurrent venous and arterial events; therefore, a reasonable course of action for the patient with MPN and a new VTE is 3 to 6 months of LMWH followed by long-term low-dose aspirin with optimal cytoreduction. Patient-specific factors (a life-threatening VTE or life-threatening bleeding) must always be considered.

As noted, the diagnosis of MPN may be heralded by development of a VTE in an unusual location, including the portal vein or the hepatic vein; the latter may result in venous congestion and hepatocyte damage (Budd-Chiari syndrome). The management of PVT is dictated by the acuity of the thrombus. Acute PVT, in which symptoms precede the diagnosis of PVT by less than 60 days and there is no evidence of cirrhosis, is managed with therapeutic anticoagulation. The diagnosis is made with abdominal ultrasound, which has a 90% negative predictive value.[50] Patients with chronic PVT should not be anticoagulated because the likelihood of recanalization of the blood vessel in this setting is low, and the sequelae of PVT-related portal hypertension (gastric and esophageal varices) increase the risk of life-threatening bleeding with anticoagulation. Making the diagnosis of MPN at the time of chronic PVT diagnosis may be hindered by portal hypertension causing GI blood loss or hypersplenism, resulting in platelet sequestration, falsely suppressing hematocrit and platelet levels; a high index of suspicion is required.

Budd-Chiari syndrome can be classified as fulminant, acute, subacute, or chronic. Unless there are clear contraindications, anticoagulation should be started promptly on diagnosis and continued indefinitely. Although a stepwise approach is warranted with medical management alone first, a number of interventions for patients with MPN-associated Budd-Chiari syndrome are available including endovascular stenting, transjugular intrahepatic portosystemic shunt, and even orthotopic liver transplant for patients with good-prognosis ET and PV.[50]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired hematopoietic clonal disorder caused by mutation of the PIGA gene, leading to a deficiency of a glycosyl phosphatidylinositol anchor for several proteins, including the natural anticomplement proteins CD55 (membrane inhibitor of reactive lysis) and CD59 (decay accelerating factor).[51] This leads to chronic nonimmune intravascular hemolysis caused by complement activation on the red cell surface. It is diagnosed by blood flow cytometry revealing CD55 and CD59 deficiency on leukocytes and erythrocytes. PNH is associated with cytopenias from bone marrow failure. All patients with PNH have some degree of marrow failure, and about 50% of patients with aplastic anemia and 20% of patients with low-risk myelodysplastic syndrome have detectable CD55- and CD59-deficient blood cells. Thrombosis, particularly thrombosis in unusual sites, including cerebral venous thrombosis, portal venous thrombosis, and hepatic vein thrombosis, is common in patients with PNH, preceding the diagnosis in almost 10% of patients and developing during the course of the disease in about one third of all patients.[52] Management of acute thrombosis is routine anticoagulation, adding anticomplement therapy with eculizumab or ravulizumab for patients with clinically significant hemolysis. Anticoagulation should be continued indefinitely until the patient receives a SCT that eliminates the PIGA mutated clone.

Trousseau Syndrome

Trousseau's sign is the appearance of superficial thrombophlebitis heralding the diagnosis of malignancy, named after the French physician Armand Trousseau, who noted the phenomenon in 1865. Trousseau syndrome is used more broadly to describe the hypercoagulable state associated with malignancy, often described as low-grade DIC. The pathogenesis of Trousseau syndrome is multifactorial and likely to involve all three components of Virchow's triad (stasis of blood flow, activation of the coagulation cascade, and damage to endothelial cells of the blood vessel).[51,52] Mouse models of MET oncogene-driven hepatocellular carcinoma have demonstrated a relationship between MET-driven malignancies and the development of a thrombohemorrhagic phenotype similar to Trousseau syndrome, mediated by cyclooxygenase-2 and plasminogen activator type 1 genes.[53] When Trousseau syndrome appears to be causing microvascular thrombosis with digital, nasal, or earlobe ischemia, low-dose UFH or LMWH may be beneficial.[54]

ARTERIAL THROMBOSIS

Coronary Artery Disease

The management of patients with malignancy-associated thrombocytopenia and acute coronary syndrome

(ACS) poses a unique challenge; the cardioprotective effect of antiplatelet agents must be balanced with the increased risk of bleeding. Two retrospective analyses with a total of 188 patients with thrombocytopenia demonstrated marked improvement in 7-day survival when they received aspirin. Platelet counts in the thrombocytopenic groups ranged from 4000 to 100,000/μL, and no major bleeding events (defined as major GI bleeding, intracranial bleeding, or fatal bleeding) were reported.[55,56] In an appropriately monitored setting and in the absence of clear contraindications, aspirin should not be withheld from patients with malignancy-associated thrombocytopenia and ACS.

Atrial Fibrillation

There appears to be an increased risk of nonvalvular atrial fibrillation for patients with cancer: among all Danes older than 18 years, the incidence of atrial fibrillation was 17.4 per 1000 persons per year among patients with cancer versus 3.7 per 1000 persons per year among noncancer persons.[57] The reasons for this are not clear. Alleged reasons include treatment-induced effects, such as the familiar toxicities of mediastinal irradiation, anthracyclines, trastuzumab, and ibrutinib; heart trauma from surgery, such as lung cancer or esophageal cancer surgery; and recognition bias as the diagnosis of cancer brings individuals under more intense clinical scrutiny.[58] To date, there is no evidence that treatment of cancer-associated atrial fibrillation is associated with worse outcomes: the risk of thromboembolic stroke and anticoagulation-related bleeding appears similar in patients with and without cancer,[58] and cancer patients with atrial fibrillation treated with DOACs had rates of thromboembolism similar to those treated with warfarin with a lower risk of bleeding, including intracranial bleeding.[59]

MD ANDERSON PRACTICE TIPS

- A LMWH such as enoxaparin 40 mg SC or dalteparin 5000 units SC should be give once per day for 28 days to patients receiving abdominal or pelvic cancer surgery.
- These same LMWHs or rivaroxaban 10 mg PO every day can be given to nonsurgical cancer patients who are hospitalized. LMWH is used during hospitalization, but rivaroxaban is extended post discharge for a total of ~ 35 days.
- Consider using thromboprophylaxis with apixaban 2.5 mg PO BID or rivaroxaban 10 mg PO once per day for 6 months to prevent VTE in outpatients receiving treatment for pancreatic cancer, gastric cancer, glioblastoma multiforme, and breast cancer beginning a selective estrogen receptor modulator.
- Cancer-associated VTE can be treated with a DOAC, although edoxaban and rivaroxaban should be avoided in patients with any luminal GI or GU malignancies.
- Patients with thrombocytopenia can be given dose-adjusted anticoagulation, with full-dose anticoagulation when the platelet count is greater than 50,000/μL, half-dose when the platelet count is between 25,000 and 50,000/μL, and no anticoagulation when the platelet count is less than 25,000/μL.
- Patients with myeloproliferative disorder–associated acute splanchnic vein thrombosis should be treated with routine anticoagulation.

Inpatient Supportive and Palliative Care

Ahsan Azhar
Ali Haider
Eduardo Bruera

KEY CONCEPTS

- Inpatient palliative or supportive care service is an interdisciplinary team of palliative care providers, including a physician, counselor, chaplain, social worker, pharmacist, palliative care nurses, and many others, who provide an integrated model of care to advanced cancer patients alongside the oncology teams.
- Supportive care consultation can help identify and manage complex symptom issues like missed delirium and refractory pain in patients with advanced cancer, as well as psychosocial, emotional, and spiritual distress, while reducing the amount of opioids and other psychotropic agents (polypharmacy).
- Early integration of supportive care has improved patient-reported outcomes and discharge outcomes, including an intensive care unit and overall hospital mortality, without increasing length of stay.
- An acute palliative and supportive care unit (PSCU) at a tertiary care hospital is different from an acute inpatient hospice facility, because patients with a prognosis of more than six months can be admitted to a PSCU for the management of physical symptoms and the psychosocial, emotional, and spiritual distress for both the patient and their family.
- An acute PSCU not only provides clinical care and education to the patient and family but also provides opportunities for education of the different disciplines involved in the patient's care as well as research geared toward improving the quality of life of patients, family, caregivers, and care providers.
- The supportive care team, when part of the care continuum, can proactively assist with early identification and clarification of goals of care and completion of advanced-care directives, as well as provide a smoother transition and/or discharge plan for patients with advanced cancer.
- An overwhelming majority of patients with cancer, as well as junior oncology colleagues, feel that they benefit from the integration of an interdisciplinary palliative and supportive care team.

Patients with advanced illnesses such as cancer often experience high physical and psychological symptoms that can affect them throughout the trajectory of their disease.[1–3] The literature has shown that patients with advanced cancer experience an average of 8 to 12 symptoms, suggesting that many symptoms are not recognized by their treating teams and often remain untreated.[1,4] In addition to physical and psychological needs, patients and caregivers often struggle with decision making.[4] Provision of specialized palliative and supportive care services has improved patients' physical, psychosocial, and spiritual well-being.[5–9] The World Health Organization has defined palliative care as:

"An approach that improves the quality of life of patients and their families facing the problem associated with a life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual. … Palliative care is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to understand better and manage distressing clinical complications."[10]

In the last few decades, palliative care has emerged as an interdisciplinary team specialty with expertise in complex symptom management, psychosocial

care, communication, complex decision making, and transition of care.[5] Despite mounting evidence on the effectiveness of palliative care services, the referral of patients often occurs late in their disease trajectory.[5,11] One crucial reason for late referrals is the misconception of palliative care as "end-of-life care"; therefore, oncologists are often reluctant to refer to preserve patients' hopes.[12,13] However, current evidence suggests that palliative care can function along with the oncologic care for improving quality of life.[8,9,14] To overcome some of these barriers, the term "supportive care" instead of palliative care has improved oncologists' comfort to refer patients early in the disease trajectory.[15–17]

MODELS OF PALLIATIVE CARE DELIVERY

Specialist palliative care is delivered by different models of care such as outpatient palliative care, inpatient palliative care that functions as consultative, acute palliative and symptom management units, community-based palliative care services, and hospice care.[5] These models have different structures, processes, location of services, and patient populations (Fig. 65–1).[5] In this chapter, we will discuss different inpatient palliative and supportive care structures, processes, and outcomes.

STRUCTURE AND PROCESSES OF INPATIENT PALLIATIVE AND SUPPORTIVE CARE SERVICES

Inpatient palliative and supportive care is the most prevalent model of palliative care service and is usually delivered in acute care hospitals.[5,18] In the United States, approximately 90% of the National Cancer Institute–designated centers have dedicated inpatient palliative care teams, and up to 56% of non–NCI-designated cancer centers have such services. A palliative care consultant team—including physicians, advanced practice providers, nurses, and members of the psychosocial

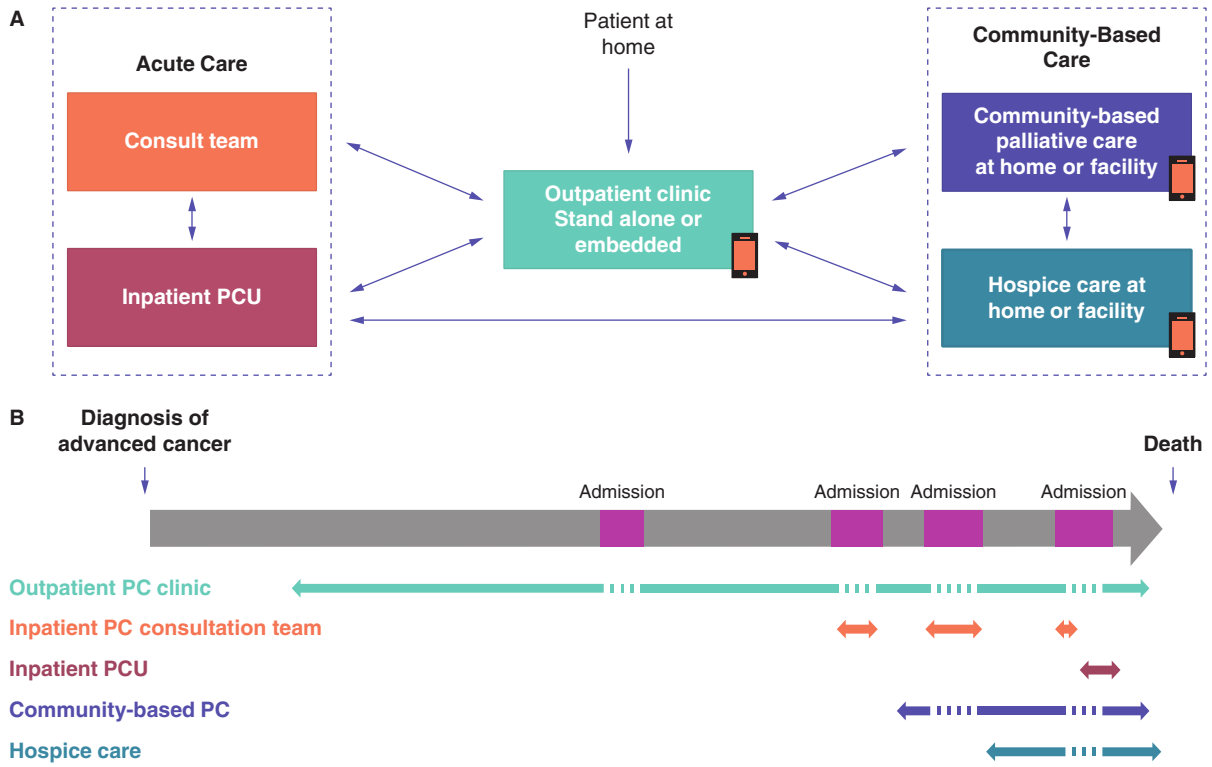

FIGURE 65–1 **Service models of specialist palliative care (PC). A. Care anywhere. Outpatient clinics facilitate access to palliative care in the ambulatory setting while coordinating care with the other models of PC. Inpatient consultation teams and PC units (PCUs) are available at acute care facilities, whereas community-based PC and hospice care allow patients to be cared for in the ambulatory and community setting. The smartphone icon indicates telehealth outreach. B. Care anytime. This figure highlights how the five service models complement one another to provide a comprehensive PC along the entire disease continuum for patients and their families. The arrows indicate the general time frame of patient engagement. (Reproduced with permission from Hui D, Bruera E. Models of Palliative Care Delivery for Patients With Cancer, *J Clin Oncol* 2020 Mar 20;38(9):852-865).**

team such as counselors, psychologists, and social workers—delivers this model of palliative care.[5] Access to palliative care teams in certain centers is available as inpatient consultation as well as outpatient, which provides opportunities for early referral.[19] Despite all this, patients continue to be referred to palliative care in low numbers and late in the trajectory of illness, at an average of 30 to 60 days before death.[19,20] Late referrals often undermine the ability of the palliative care interdisciplinary team to intervene, especially among patients with high symptom burden and caregivers' distress.[20] In a recent retrospective study, Heung et al examined 7322 patients who were referred to inpatient palliative care for the first time; 154 (2%) died within the 24 hours of referral but were found to have a significant amount of distress, indicating a missed opportunity for earlier palliative care intervention.[21]

OUTCOMES OF INPATIENT PALLIATIVE AND SUPPORTIVE CARE SERVICES

Inpatient palliative and supportive care consultation can help identify and manage complex symptom issues like missed delirium and refractory pain in patients with advanced cancer, as well as psychosocial, emotional, and spiritual distress, while reducing the amount of opioids and other psychotropic agents (polypharmacy).[7,22–24] In a recent study of 536 hospitalized patients with cancer, 239 (45%) who received timely palliative care had significantly less chemotherapy in the last two weeks of life and considerably fewer admissions to intensive care units (ICUs) in the last month of life.[25] Delgado et al compared 200 patients with advanced cancer who received palliative care services from the emergency center with those who received palliative care services during inpatient stay; patients who received palliative care had significantly earlier control of their symptoms and a shorter length of stay.[6] In the last decade, several randomized controlled trials have been conducted to examine the benefits of inpatient palliative care.[5,26,27] Grudzen et al examined hospitalized patients with advanced cancer who received palliative care versus the control group and found that the palliative care group was associated with significant improvement of quality of life at 12 weeks compared with the usual care.[26] Although the trend favored the palliative care group, no statistically significant difference was found in secondary outcomes such as rates of depression, ICU admissions, hospice discharge, and overall survival.[26]

Literature has highlighted the benefits of early integration of palliative care with standard transplant care among patients with hematologic care.[14,27] In a recent nonblinded, randomized clinical trial among 160 patients undergoing autologous/allogeneic stem cell transplant, El-Jawahri et al found that patients who received twice-weekly inpatient palliative care reported a smaller decrease in quality of life at two weeks post-transplant versus those who received standard care.[27] Moreover, patients in the concurrent care arm reported lower anxiety, less increase in depression, and less increase in overall symptom burden.[27] Patients' caregivers also reported significantly less depression and post-traumatic stress disorder at 6 months post-transplantation.[28]

According to the American Society of Clinical Oncology clinical practice guidelines, patients with advanced cancer and/or high symptom burden should be considered for a referral to an interdisciplinary palliative care team early in their disease trajectory concurrent with active cancer treatment.[29] More research is needed to find an optimal model of integration of early palliative care among hospitalized patients for symptom management, complex decision making, and survivorship care.

INPATIENT PALLIATIVE AND SUPPORTIVE SERVICE AT MD ANDERSON

Palliative and supportive care services at the MDACC was established 20 years ago and has seen constant growth in its clinical activity, including the inpatient model of delivery.[30] In recent years, most of the patients were initially consulted at the outpatient or inpatient non-ICU setting.[30] It is reassuring that a very low proportion of patients were consulted at the ICU setting, which is generally considered a late referral.[30] From 2011 to 2017, the proportion of first-time referral in the ICU setting has decreased from 2.3% in 2011 to 1% in 2017 versus the non-ICU setting from 97.7% in 2011 to 98% in 2017 ($P < .01$).[30] Unfortunately, despite the continued growth seen in many centers, the existing infrastructure is unable to accommodate universal referral of all hospitalized patients, especially in the oncologic setting.[5,18] The Center to Advance Palliative Care has published several criteria for referral of patients to inpatient palliative care (Table 65–1).[18] These criteria can serve as a general guideline to decide whether patients will benefit from palliative care integration.

HISTORY AND BACKGROUND OF THE INPATIENT PALLIATIVE CARE UNIT

Cicely Saunders, a nurse and a social worker who became a physician, having worked with patients with advanced cancer treating their pain and other symptoms from 1957

Table 65–1 Referral Criteria for Inpatient Palliative Care Consultation Teams for Patients with a Life-Limiting or Life-Threatening Condition

Primary Criteria[a]	Secondary Criteria[b]
The surprise question: You would not be surprised if the patient died within 12 months or before adulthood	Metastatic or locally advanced incurable cancer
Frequent admissions (eg, more than one admission for the same condition within several months)	Admission from long-term care facility or medical foster home
Admission prompted by difficult-to-control physical or psychological symptoms (eg, moderate to severe symptom intensity for 24–48 hours)	Elderly patient, cognitively impaired, with acute hip fracture
Complex care requirements (eg, functional dependency; complex home support for ventilator, antibiotics, and feedings)	Long-term home oxygen use
Decline in function, feeding intolerance, or unintended decline in weight (eg, failure to thrive)	Out-of-hospital cardiac arrest
	Current or past hospice program enrollee
	Limited social support (eg, family stress, chronic mental illness)
	No history of completing an advanced-care planning discussion/document

[a]Global indicators that represent the minimum that a hospital should use to screen patients at risk for unmet palliative care needs.
[b]More specific indicators of a high likelihood of unmet palliative care needs and should be incorporated into a systems-based approach to patient identification if possible.
Data from Weissman DE, Meier DE. Identifying patients in need of a palliative care assessment in the hospital setting: a consensus report from the Center to Advance Palliative Care, *J Palliat Med* 2011 Jan;14(1):17-23.

to 1967 at St. Joseph's Hospice, laid the foundation of the St. Christopher's Hospice in London in 1967. Saunders appreciated the importance of teaching and research in the hospice care setting and, on her advice, in 1974, Florence Ward, then the dean of the School of nursing at Yale University in New Haven, Connecticut, founded the Connecticut hospice.[31]

During the same time, the first hospital-based palliative care service was founded by a Urology Surgeon, Dr Balfour Mount, in 1974. This was part of the research and teaching structure at the Royal Victoria Hospital of McGill University in Montréal, Canada. Dr Mount was the first to use the term *palliative care*,[32] demonstrating the value of a hospital-based palliative care service, which he called the "palliative care unit." Its primary purpose at that time was to perform research and education for control of symptoms, mainly pain. Following the same model of inpatient palliative care in 1974, St Luke's Hospital in New York City created a working palliative consultation team.[31]

THE ACUTE PALLIATIVE AND SUPPORTIVE CARE UNIT AND HOW IT DIFFERS FROM A HOSPICE INPATIENT UNIT

An acute palliative and supportive care unit (PSCU) in a hospital setting (also known as a tertiary care Palliative Unit) differs in many ways from an inpatient hospice care unit. The main distinction is its being designed for the care of distressed patients with an advanced illness like cancer with poor prognosis (perhaps terminal; however, meaning more than six months and not necessarily actively dying patients).[33] It is a hospital inpatient facility with designated beds, where care is provided by a highly specialized interdisciplinary team lead by a palliative care physician (who works in conjunction with an inpatient palliative care program, including a consultation team with or without an outpatient clinic).[34,35]

The unit is considered an interdisciplinary care unit to meet the needs of patients and families while addressing complex problems: physical, psychosocial, and spiritual. It offers a full range of diagnostic and interventional procedures geared toward palliation of symptoms while providing access to different support services and specialty and subspecialty consultations. A *Do Not Resuscitate* (DNR) order may not be a prerequisite for admission to such a unit. However, it is of utmost importance to have clarity of goals of care between all parties involved about the intent and duration of the interventions being offered.

OBJECTIVES OF AN ACUTE PALLIATIVE AND SUPPORTIVE CARE UNIT

At its core, a PSCU is primarily a unit for clinical care of distressed patients[36] and families. Its primary role is to assess and treat the most complex patients with advanced cancer, considered terminal in most cases, with and without complex family dynamics (whole-person care). It may involve challenging discharge planning near the end of life.

Another critical role of such a unit is the education of physicians and other disciplines, along with research aimed at the identification and management

of complex situations in such patients. The role of an interdisciplinary team to care for this patient population is of paramount importance.

GUIDELINES FOR ADMISSION TO AN INPATIENT PALLIATIVE AND SUPPORTIVE CARE UNIT

The following two main categories of patients comprise the vast majority of patients with advanced illness, along with their families (Fig. 65–2). They may be candidates for transfer to the PSCU. They are mostly near the end of life (with advanced, refractory cancer with limited or no anticancer treatments available) but are not necessarily actively dying. These include patients and family members who are:

1. Extremely distressed, with refractory symptoms near the end of life.
2. Facing difficulty in transitioning to comfort or end-of-life care

The PSCU serves to control their special (and complex) symptoms and counseling needs. These patients and their families need to accept the role that the PSCU fulfills so that the problem of unfulfilled expectations is not created (ie, the focus of the PSCU is not to treat cancer but increase the quality of life and comfort of the patient and assist the family in coping). In addition, such patients with advanced cancer at the end of life do not benefit from attempts at resuscitation, so that "no CPR" (a DNR) would be appropriate. They do not have to agree to go to hospice; however, it may be helpful to explain that this is usually the option recommended for such patients.

3. The third category is a small, select groups of patients who are early in their disease trajectory, who may have special problems (usually refractory symptom control) that are not resolvable on the regular floor under the guidance of the mobile consult team and would be better addressed in the PSCU. The patients may wish to recieve full resusitation and return to the primary oncologist for further cancer-directed treatment. Such patients are an exception to the usual end-of-life care that the PSCU provides and benefit from the symptom control expertise and the interdisciplinary team approach present on the unit. This group is a tiny percentage of the total number of patients admitted to the unit served by our current palliative care model.

Generally, the following types of patients and families are not considered as candidates for transfer because the scope of the PSCU is limited in their case and they can be transitioned to comfort measures either on the primary floor or outside under hospice care:

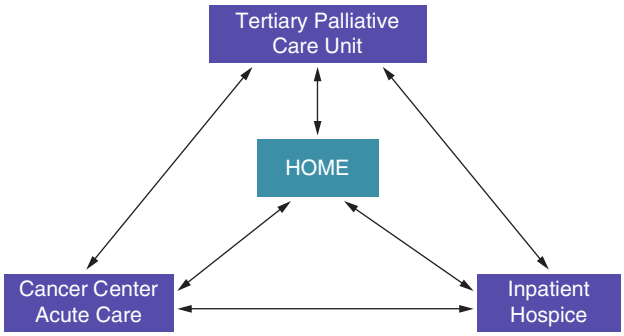

FIGURE 65–2 Service delivery locations for acute symptom management in patients with advanced cancer near the end of life.

1. Patients and families that are managing well and prefer to go directly to the hospice.
2. A comatose patient with a family who is coping well. If they were to be transferred to the PSCU, the team's only next step would be to transfer to hospice, which in the majority of cases can be offered and arranged directly from their primary oncology floor.
3. The patient is dying (or may soon be) and they wish to be "full code" despite ongoing discussions.
4. The patient is intubated and on a ventilator.
5. The patient is under 18 years of age.
6. The primary team does not agree with transferring the patient to the PSCU.

SERVICES AVAILABLE IN PALLIATIVE AND SUPPORTIVE CARE UNITS

In addition to the core interdisciplinary team (comprised mainly of a board-certified palliative care physician, junior physician or trainee, advanced practice provider, palliative nurse, nursing assistants/patient care technicians and Patient Scheduling Coordinators (PSCs), palliative pharmacist, chaplain, social worker, counselor, case manager, physical and occupational therapist, dietician, research staff, and volunteers), some other services available for the patient and their family may include Pets Are Wonderful Support, aromatherapy, music therapy, massage therapy, availability of artist-in-residence (legacy therapy), caregiver support groups and family care conferences.[37] The interdisciplinary team at the PSCU, which continually provides psychosocial, spiritual, and emotional support to the patient and family will recommend the involvement of different specialists for these additional services. Based on available resources, the patient's condition and tolerance, and goals of care discussions,

the interventions available may include but are not limited to palliative radiotherapy, limited duration of transfusion and antibiotics support, hydration, procedures for achieving palliation of symptoms like a colostomy, venting tube, intraperitoneal and intrapleural catheter, interventional pain procedures (cordotomy, nerve block, vertebroplasty), as well as oxygen supplementation, opioids, antiemetics, and laxatives.

SEVERE SYMPTOM DISTRESS: ROLE OF PALLIATIVE SEDATION NEAR THE END OF LIFE AND AN ACUTE PSCU

The interdisciplinary model of care in the PSCU under the leadership of the palliative physician, with specialty trained palliative nurses, plays an essential role in the delivery of interventions like palliative sedation for the management of refractory and distressing issues like terminal delirium, refractory dyspnea, and pain near the end of life, mainly for patients who are actively dying.[38–44]

ROLE OF THE PSCU IN IMPROVING PATIENT-REPORTED OUTCOMES AS WELL AS DISCHARGE OUTCOMES

Various studies have shown improvement in patient-reported outcomes when they are treated by an inpatient palliative care service, including an inpatient PSCU.[2,5,34,45–51] Mortality rates in the PSCU vary owing to multiple factors.[52–54] However, the role of the PSCU is of paramount importance in reducing inpatient hospital mortality because from 40% to 70 % of patients admitted to the PSCU are able to be discharged from the hospital (mostly to hospice care), which helps reduce emergency center readmissions and the ICU census.[48,54–57]

ROLE OF THE ENVIRONMENT

The acute PSCU is poised to provide a unique level of care,[34,35] mainly because of the interdisciplinary model of team integration, but also from the exceptional environment (with the incorporation of soothing, ambient lighting and music)[58–60] it provides to patients and families under care of the team. It offers opportunities for better assessment, improved symptom control, better family satisfaction with care, better bed utilization, and decreased cost of care.[34,53,61] Chai et al stated: "A dedicated unit offers direct control over the implementation of clinical recommendations, the presence of skilled interdisciplinary staff, and a care setting designed for the needs of seriously ill patients. Under circumstances of difficult-to-control symptom distress, family exhaustion, or lack of adequate community support services, a palliative care unit may provide the safest and highest quality of care."[62]

Patients with advanced cancer (and their families) near the end of life face many distressing symptoms and challenges.[45] Unfortunately, only a small proportion of comprehensive cancer centers and community-based cancer centers in the nation have inpatient PSCUs.[19,20] The acute PSCU can be a fantastic resource as an integral part of the inpatient palliative care service,[34,47] not just for managing complex and challenging situations but also for providing a platform on which to conduct sensitive clinical research[63–65] in this patient population, and to provide education and training for the various disciplines involved in the provision of such vital care.

MD ANDERSON PRACTICE TIPS

- Familiarity with the inpatient palliative or supportive care team structure and function can be useful for the referring teams. It is an interdisciplinary team of palliative care providers, including a physician, counselor, chaplain, social worker, pharmacist, palliative care nurses, and many others, alongside the oncology teams, who provide an integrated model of care to patients with advanced cancer.
- Consultation with inpatient supportive care service can help identify and manage complex symptom issues like missed delirium and refractory pain in patient with advanced cancer, as well as psychosocial, emotional, and spiritual distress, while reducing the amount of opioids and other psychotropic agents (polypharmacy).
- Early integration of supportive care has improved patient-reported outcomes and discharge outcomes, including ICU and overall hospital mortality without increasing length of stay.
- An acute PSCU at a tertiary care hospital is different from an acute inpatient hospice facility, because patients with a prognosis more than six months can be admitted to a PSCU for the management of physical symptoms and help navigating the psychosocial, emotional, and spiritual distress for the patient and their family.

MD ANDERSON PRACTICE TIPS

- An acute PSCU not only provides clinical care and education to the patient and family but also provides opportunities for education of the different disciplines involved in the patient's care, as well as research geared toward improving the quality of life of patients, family, caregivers, and care providers.
- The supportive care team, when part of the care continuum, can proactively assist with early identification and clarification of goals of care, completion of advanced-care directives, and providing a smoother transition and/or discharge plan for patients with advanced cancer.

Integrated Outpatient Supportive Care

Akhila Reddy
David Hui
Eduardo Bruera

KEY CONCEPTS

- Interdisciplinary palliative care improves the quality of life of patients and families by focusing on alleviation of physical, psychosocial, and spiritual distress.
- The literature consists of a variety of outpatient palliative care models with different team composition, the timing of referral, and the place of delivery.
- Outpatient palliative care provided by an interdisciplinary team and earlier in the disease trajectory is generally more beneficial than that provided by a single discipline or later in the disease trajectory.
- Automatic referrals to palliative care can increase both the volume and timeliness of referral.
- Standalone clinics are more suitable for larger centers than multiple embedded clinics.
- Ultimately, no one model fits all, and each institution needs to determine the optimal model based on patient population, infrastructure, staff, and resource availability.

Palliative care is "an approach that improves the quality of life of patients and their families facing the problem associated with a life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual."[1] According to the World Health Organization, palliative care "is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications."[1]

Palliative care first started in the community with the hospice movement. It evolved over the past six decades to offer care in acute care facilities by providing inpatient consultations and palliative care units.[2] In 1990s, Edmonton, Canada, established one of the first palliative care clinics, providing outpatient care to patients in the ambulatory setting.[3,4] This represented a significant shift in paradigm because patients at palliative care clinics generally had better performance status and fewer acute symptom distress than patients at other palliative care settings (ie, palliative care inpatient consultation teams, palliative care units, and home palliative care programs and hospices).[5] Palliative care clinics allowed patients to be referred earlier in the disease trajectory while they were actively receiving cancer treatments. As a result, these patients could be followed longitudinally by the palliative care team, with many more opportunities to optimize care. The focus of care also shifted from dealing with acute symptom crisis at the end-of-life care to anticipatory care to address chronic symptoms (eg, fatigue, nutrition, function) through education and monitoring, and timely serious illness conversations to enhance illness understanding and facilitate care planning.[6] As a result, an increasing number of cancer centers now offer outpatient palliative care services. For example, 67% of the National Cancer Institute (NCI)-designated cancer centers in the United States reported having outpatient palliative care clinics in 2009, and this number had increased to 98% in 2018.[7]

The literature for outpatient palliative care has grown substantially over time.[8] Timely referral of cancer patients to outpatient palliative care leads to

enhanced symptom management, decreased rates of depression, greater patient and caregiver satisfaction, better illness understanding, improved quality of end-of-life care, and overall survival compared with oncologic care alone.[9–11] This chapter covers three key aspects: (1) a synopsis of the literature on outpatient palliative care, (2) models of outpatient palliative care delivery, and (3) a description of the outpatient palliative care clinic at MD Anderson Cancer Center.

LITERATURE ON OUTPATIENT PALLIATIVE CARE

In 2004, Rabow et al conducted a controlled trial comparing the outcomes of 50 patients seen by an outpatient palliative care team with 40 control patients seen by an outpatient general internal medicine clinic over 12 months.[12] Patients were eligible if they had a diagnosis of cancer (33%), advanced chronic obstructive pulmonary disease or heart failure, and a life expectancy of 1 to 5 years. The palliative care team consisted of three physicians, a social worker, nurse, chaplain, pharmacist, psychologic art therapist, and volunteer coordinator. The primary outcome was pain, which did not differ between the study groups. However, dyspnea, sleep, anxiety, and spiritual well-being improved in the palliative care group and decreased in the control group. There were also significantly fewer urgent care visits.

In 2009, the Project ENABLE II study was published by Bakitas et al. This randomized clinical trial assigned 322 patients with advanced solid tumors to either a telephone-based nurse-led palliative care intervention or usual care alone.[13] The three coprimary outcomes were the quality of life, symptom burden, and resource use. The telephone-based nurse-led palliative care intervention was associated with a significant improvement in the quality of life and mood, but not symptom burden or resource use. Of note, a small proportion of patients in both the intervention group (26%) and usual care group (32%) received a referral to specialist palliative care.

In 2010, Temel et al reported the findings of a groundbreaking clinical trial that randomly assigned 151 patients with metastatic non–small-cell lung cancer to specialist outpatient palliative care or usual care provided by an oncology team.[14] Patients were eligible if they were within 8 weeks of cancer diagnosis and had a performance status of 0 to 2. The palliative care intervention included monthly clinic appointments provided by palliative care physicians and advanced practice nurses. At 12 weeks, patients in the palliative care group had a significantly higher quality of life, lower depression scores, and improved quality of end-of-life care compared with usual oncologic care. There was also a significant overall survival benefit in post-hoc analysis. In a subsequent secondary analysis, the palliative care group was also found to have greater illness understanding, which was associated with less chemotherapy use at the end of life.[15]

These findings were consistent with a large cluster-randomized trial by Zimmermann and colleagues in 2014.[16] Four-hundred sixty-one patients with cancer from 24 medical oncology clinics were enrolled and randomly assigned to oncologic care with or without outpatient palliative care. The palliative care intervention involved monthly followed by a palliative care physician and nurse in a standalone clinic. At 3 months, there was a trend toward improvement in the quality of life (Functional Assessment of Chronic Illness Therapy–Spiritual Well-Being Scale [FACIT-Sp]) and symptom burden (Edmonton Symptom Assessment Scale [ESAS]) favoring the palliative care group, which became statistically significant at 4 months.[16] Palliative care was also associated with increased patient satisfaction. A secondary analysis found that patients with higher symptom burden were more likely to benefit from palliative care (personal communication).

In 2014, Tattersall et al randomly assigned 120 patients with metastatic cancer and a life expectancy of less than 12 months to usual care with or without a palliative care nurse consultant.[17] It is important to note that the intervention only consisted of a brief introduction to palliative care services with limited follow-up. The investigators found no significant difference in the primary outcome of quality of life over 12 months; moreover, patients in the palliative care group had worse physical symptom scores, worse psychological distress scores, and worse survival compared with the control group.

Bakitas et al reported findings from the Project ENABLE III study in 2015 that involved 207 patients with advanced cancer to examine the effect of a telephone-based nurse-led palliative care intervention.[18] Compared with the Project ENABLE II study, this study had a waitlist design, and the structured intervention included an initial in-person visit and more weekly sessions. Neither quality of life nor mood differed between the palliative care intervention and usual care groups. Interestingly, a greater proportion of patients in the palliative care group were still alive at the one-year survival marker.

In 2016, Temel et al published a confirmatory trial that included 191 patients with metastatic lung cancer and 159 with incurable noncolorectal gastrointestinal malignancies.[19] It adopted a similar design to their original trial with the same palliative care team intervention. The primary outcome (Functional Assessment of Cancer Therapy—General [FACT-G]) had a nonstatistically significant improvement at 12 weeks in the palliative care group compared with usual care, which became

significant at 24 weeks. Subgroup analysis revealed that patients with lung cancer had a greater benefit than patients with gastrointestinal malignancies.

Maltoni et al from Italy also reported their findings in 2016.[20] This randomized clinical trial assigned 207 patients with advanced pancreatic cancer to either palliative care or usual oncology care.[20] It had a similar design to the original Temel trial; however, palliative care was delivered by physicians only instead of by an interdisciplinary team (IDT). Quality of life at 3 months was the primary outcome and was significantly better in the palliative care group compared with the control group. Secondary outcomes, including depression, anxiety, a majority of the end-of-life care metrics, and overall survival did not differ significantly between the two groups.[21]

Another European trial was reported in 2017.[22] This Danish study by Groenvold et al enrolled patients with high symptom burden and randomly assigned them to palliative care intervention or usual care. The palliative care intervention involved physicians, nurses, and allied health professionals providing a consultation but limited follow-up visits. The primary outcome, palliative care need, did not differ significantly between groups; however, this measure has not been validated. The secondary outcomes also did not differ significantly, except for nausea.

In Brazil, do Carmo et al conducted a three-arm randomized trial in 2017 comparing palliative care plus a psychology intervention, palliative care, and usual care alone.[23] However, this study was terminated prematurely after enrolling 63 of 150 planned patients, and no difference in study outcomes was reported.

Vanbutsele et al from Belgium conducted a randomized study in 2018. Both outpatients and inpatients were eligible for this study, provided they were within 3 months of a diagnosis of advanced solid tumor or progression and had a life expectancy of 6 to 24 months.[24] One-hundred eighty-six patients were enrolled. The palliative care intervention was predominantly nurse based, and palliative care physicians were only available on an as-needed basis. At 24 weeks, the palliative care group had a statistically significant improvement in the primary outcome, quality of life at 12 weeks (global health status in European Organisation for Research and Treatment of Cancer Quality-of-Life Questionnaire Core 30 [EORTC-QLQ-C30]). Secondary outcomes including overall survival, symptoms, mood, and illness understanding did not differ between groups.

The Italian group reported the findings of a randomized study involving advanced gastric cancer in 2018.[25] With 186 patients enrolled, no significant differences were found between the two study arms in quality of life, mood, the aggressiveness of care near the end of life, and survival.[25]

MODELS OF OUTPATIENT PALLIATIVE CARE DELIVERY

Taken together, the above clinical trials varied widely in regard to the patient population, intensity of intervention, and outcomes. This diversity in the literature helps to inform which elements of outpatient palliative care delivery are more essential.[26] In this section, we will discuss the three key elements of outpatient palliative care clinics, including team composition, the timing of referral, and location of care.

Team Composition

No clinical trials have directly compared interdisciplinary and single-disciplinary palliative care teams. However, studies that included an interdisciplinary palliative care team providing in-person longitudinal care were generally associated with more consistent and positive outcomes relative to nurse-led telephone-based interventions[13,18] and physician-only interventions.[20,25] What is the definition of an IDT? In an international Delphi study, the consensus was that an interdisciplinary palliative care team should consist of at least physicians, nurses, and psychosocial professionals (eg, psychologist, social worker, chaplain).[27]

Palliative care delivered by an IDT is likely more beneficial versus that of a single discipline because patients' supportive care needs are interconnected, necessitating an IDT to address the multidimensional aspects of suffering. For example, total pain may have physical, emotional, social, spiritual, and informational components.[28] To manage pain effectively, a team approach may include physicians to make the proper diagnosis and prescribe appropriate therapies, nurses to provide education and nonpharmacologic strategies, physical and occupational therapists to improve function, psychologists and counselors to provide psychotherapy to alleviate emotional distress and to strengthen coping strategies, chaplains to discuss sources of spiritual pain, and social workers to provide financial support and maximize care access. However, it is important to note that different interventions may be appropriate in different settings. For instance, it may be difficult for patients in rural areas to attend an outpatient palliative care clinic when the closest is hundreds of miles away. In a resource-limited setting, a telephone-based nurse-led intervention would be the most appropriate model to provide outpatient palliative care.

Timing of Care

A majority of the randomized trials above showed that patients referred to specialist palliative care earlier in the disease trajectory generally had better outcomes than patients who either had delayed or no palliative

care. For example, a study at MDACC found that timelier referral (>6 months before death) was associated with lower rates of hospitalization, emergency department visits, and intensive care unit (ICU) admissions in the last 30 days of life compared with later referrals.[29] A systematic review in patients with cancer also showed that earlier referral was associated with improved outcomes.[10] However, it is currently not possible to universally refer patients within the first few months of their advanced cancer diagnosis to specialist palliative care because of the limited palliative care workforce. Furthermore, some patients with cancer may have limited supportive care needs and/or they have been adequately addressed by the oncology team.

In contrast to *early* palliative care, *timely* palliative care involves identifying patients with the greatest supportive care needs and referring them to palliative care in a timely fashion.[6] Theoretically, this approach has several advantages. First, it would align care needs with the provision of specialist palliative care, thus allowing the timing of involvement to be more personalized. Second, it would triage scarce palliative care resources. Third, it may uncover supportive care needs during initial screening. Fourth, it could help to streamline the processes of care while ensuring equal access. Four key components are needed for automatic referral to facilitate timely palliative care[30]:

(1) Systematic screening of supportive care needs in the oncology outpatient clinic. For example, symptom assessments can be conducted using the ESAS, which documents the intensity of 10 or more symptoms using 0–10 numeric rating scales.[31] ESAS is validated, available in different languages, and simple to use, making it an ideal tool for rapid screening.

(2) Referral criteria that both the oncology and palliative care teams agree can be used to identify patients most appropriate for specialist palliative care intervention. An international consensus panel has identified 11 criteria that could be useful to trigger a referral (Table 66–1).[32] Interestingly, nine of these criteria were needs-based, and two were time-based criteria. This set of criteria may represent a starting point for institutions to further tailor based on the availability of palliative care services and the desired level of supportive care services. In a retrospective study, the use of these criteria improved the timing of referral by approximately 2 months to more than 1 year.[33]

(3) Finally, successful application of these criteria will result in more and earlier referrals. Thus, the outpatient palliative care programs should have adequate staffing, space, and resources to support sustainable growth.

Table 66–1 International Consensual Referral Criteria for Outpatient Palliative Care[30,32]

Criteria
1. Severe physical symptom(s), eg, pain ≥7/10
2. Severe emotional symptom(s), eg, depression ≥7/10
3. Request for hastened death
4. Spiritual or existential crisis
5. Assistance with decision making/care planning
6. Patient request
7. Delirium
8. Brain or leptomeningeal metastases
9. Spinal cord compression or cauda equina
10. Within 3 months of diagnosis of advanced/incurable cancer for patients with median survival 1 year or less
11. Diagnosis of advanced cancer with progressive disease despite second-line systemic therapy (incurable)

Location of Care

In addition to team composition and timing of referral, another variation of outpatient palliative care delivery involves the location of delivery: patients may be seen at a standalone outpatient palliative care clinic, a palliative care clinic embedded within an oncology clinic, or remotely via telehealth. In a 2018 survey of NCI-designated cancer centers in the United States, 83% of the existing palliative care programs reported having standalone clinics, and 39% had embedded clinics. In contrast, 41% and 30% had standalone clinics and embedded clinics at non–NCI designated cancer centers.[7]

Standalone palliative care clinics represent the standard of care. To date, randomized controlled trials of outpatient palliative care clinics have mostly tested this model of care.[7,34] Standalone clinics allow all the palliative care resources to be consolidated in one place, providing centralized access to patients referred from different oncology services. Patients with cancer can access comprehensive supportive care services all in one location. However, unlike in embedded clinics, an encounter with palliative care is separated in space and time from the oncology visit. This can be partially addressed by booking the palliative care appointment on the same day as an oncology visit. The outpatient palliative care clinic at MDACC has successfully operated under this model of care, which is described in detail below.

A large proportion of cancer centers in the US offer embedded clinics, defined as "the palliative care team and the oncology team sharing the same clinic space and seeing the same patients on the same day."[26] Embedded clinics offer several advantages over standalone clinics, including convenience for patients and more opportunities for communication and collaboration between the oncology team and the palliative care team. To date, no randomized controlled trial has compared the outcomes

between embedded specialist palliative care clinics and standalone clinics or usual care. Several retrospective cohort studies have reported mixed outcomes compared with historical data or concurrent control.[35–39] In general, embedded clinics were associated with increased referral and timelier access to palliative care.[36,37,39] These embedded clinics are generally staffed by one to two members of the palliative care team, such as a physician,[36,39] a nurse practitioner,[35,38] and/or a psychosocial team member.[37] Embedded clinics are likely more suitable for smaller cancer centers because it is difficult to place a palliative care team in every oncology clinic (eg, thoracic, breast, gastrointestinal, genitourinary, gynecologic etc). Moreover, it is not often feasible to ensure the presence of a large interdisciplinary palliative care team at an oncology clinic because of limited space.

Telehealth has the potential to bring even more outpatient palliative care access to patients via video conference technology.[26] Compared with in-person visits or home visits, they can minimize the need for travel for patients and palliative care teams, respectively, thus cutting time and cost. It should be noted that telehealth technologies are mostly used to augment, instead of replace, in-person visits. Variations of telehealth interventions include video visits with or without remote physical examination capabilities, smartphone apps, and remote symptom monitoring.[40,41] Some setups involve patients (mostly in rural areas) attending a telehealth facility, and other programs can be delivered at home. Several nurse-led palliative care telehealth interventions discussed above have shown some benefits in randomized trials as discussed above.[13,18] However, there remains a paucity of studies examining outcomes associated with telehealth interventions by an interdisciplinary palliative care team.[42] A large noninferiority randomized trial is underway that compares palliative care delivered by either telehealth (with the first consultation being in person) with standard in-person visits.[43]

MD ANDERSON OUTPATIENT PALLIATIVE CARE PROGRAM

The Supportive Care Center (SCC) in MDACC was started in 1999 by Dr Eduardo Bruera, Chair, Palliative, Rehabilitation, and Integrative Medicine. The last few years have seen increased integration of supportive/palliative care with routine oncologic care in the US.[7] This increase is driven by growing evidence that early integration of palliative care can improve quality of life, symptom management, patient/family satisfaction, and patient experience while reducing aggressive end-of-life care and emergency room and ICU visits, and decreasing cost of care.[10] The increased integration has also been quite significant at MDACC, as demonstrated by our growth and steady increase in the total number of referrals every year.[44] To sustain the growth and to be able to accommodate the consults within 2 weeks of the request, a satellite supportive care center was started in 2014.

STRUCTURE OF THE SUPPORTIVE CARE CENTER

The SCC is staffed by 10 Registered Nurses (RNs), 4 Medical Assistants (MAs), 7 Patient Service Coordinators (PSCs), 3 counselors, a social worker, and a pharmacist. Other members of the IDT, such as the nutritionist, chaplain, and case manager, are available to assist as needed. There are a total of four physician templates daily, and an additional physician is available to help with phone calls, triages, and walk-ins, and also fulfills the role of the physician on call for the SCC. The SCC is not staffed with any advanced practice providers.

The SCCs have a total of 17 examination rooms along with a family counseling room. Because of the symptom distress experienced by the patients referred to the SCC, each of the examination rooms are furnished with a hospital bed, two comfortable chairs for visitors, and a computer and stool for the clinician (Fig. 66–1). It must be noted that the supportive care team does not use the computer in the room. A survey conducted showed that our patients (72%) preferred their doctors not to use the computer in the room.[45] The waiting room in the SCC is seldom used because many patients experience symptom distress or body image issues, or they use assistive devices and are promptly taken into the comfortable examination rooms rather than remain in the outside waiting room.

The SCC also has lights that have a pink hue, known to alleviate anxiety, and soft, soothing music is always played to help keep the patients relaxed and at ease. More than 70% of our patients surveyed preferred music in patient care areas.[46] The examination rooms have television screens with content displaying the SCC staff and clinicians they will see that day, and personal information such as "favorite food," "favorite movie," or "favorite book" listed underneath their picture and title. Patients have expressed that seeing this information on the screens while waiting for the provider to come in helps ease their anxiety related to the visit.

Along with the staff and clinician bios, the patients also watch 2-minute educational videos regarding exercise, cancer pain management, opioid use, constipation management, spirituality, preparation of advanced-care directives, and so on, while waiting for their clinical team. The patients and caregivers also have access to restrooms within a few steps

FIGURE 66–1 Examination room at MD Anderson Cancer Center's Supportive Care Center.

of the examination rooms. Because of the sensitive nature of specific discussions and to allow for split visits, a large family counseling room is available. During these split visits, the clinicians or counselors or other members of the IDT can meet separately with the caregivers to counsel them for emotional distress or end-of-life care planning or direct hospice referral.

The SCC welcomes same-day/walk-in patients and caregivers in severe distress, and they are seen without an appointment. New patient consults are also seen the same day for symptom distress after a physician-to-physician referral from other primary oncology centers. Approximately 30% of the patients seen in the SCC are those without any prior appointments. Allowing walk-in visits is vital in preventing avoidable visits to the emergency department, or even hospitalization, and also to help alleviate any distress in patients, both physical and psychosocial.[47,48] In addition, a total of 80 to 100 phone calls, messages, faxes, and prior authorization requests are received daily and promptly addressed by two dedicated telephone nurses.[49] Telephone calls by nurses and calls and telehealth visits by our counselors are also conducted proactively for any patients and families in high distress.[41]

The SCC successfully piloted video visits between physicians and patients during the Covid-19 pandemic in 2020, serving approximately 1000 patients within 2 months of implementation.

DELIVERY OF CARE AT THE SUPPORTIVE CARE CENTER

The SCC receives patients from medical oncology, radiation oncology, gynecological oncology, surgical oncology, and also from other downstream centers.[50] A patient visit to the SCC involves an interdisciplinary approach to care.[51] First, the medical assistant takes the patient to a room after recording the patient's vital signs. The RN then conducts a comprehensive assessment of symptoms using the Edmonton Symptom Assessment Scale- Financial and Spiritual (ESAS-FS) as a guiding tool.[31,52–54] The ESAS-FS is a symptom assessment scale where 12 primary physical, psychosocial, and spiritual symptoms are scored by the patient on a scale of 0–10. The RN also administers the Memorial Delirium Assessment Scale to screen for delirium, which is highly prevalent in patients with advanced cancer.[55] Other tools administered by the RN are the Cut-down Guilty Annoyed and Eye-Opener-Adapted to Include Drugs (CAGE-AID) questionnaire and Screener and Opioid Assessment for Patients with Pain (SOAPP), which are validated tools to screen for alcohol and substance abuse and enable the team to evaluate the risk for opioid abuse.[56] The RN also conducts an assessment of performance status based on the patient's reported functional ability.[57] Included in the RN's evaluation is a brief overview of coping strategies, sources of physical and emotional support for the patient, any worries/fears, presence of anhedonia or suicidal thoughts, medication review, falls assessment, and presence or absence of advanced-care directives. After receiving a report from the RN, the physician then visits with the patient and determines a plan, which may include extensive opioid and other medication management, counseling, and the involvement of other members of our IDT, such as the counselor, pharmacist, dietician, social worker, or chaplain.

Approximately 54 appointments are scheduled daily between the four physicians, and the walk-in physician sees an additional 8 to 12 walk-in patients. The counselors are involved in 15 to 20 patient visits and the pharmacist in about 8 to 10 patient visits daily. More than 50% of the patients visiting the SCC are seen by our counselor at least once, and 30% are seen more than once. Counselors conduct home outreach telephone/video follow-up counseling for patients, especially for those with transportation and distance barriers.[41]

At the end of every visit, the patient is provided with our contact information, including our after-hours and

weekend on-call pager information. Patients calling with severe symptom distress are asked to walk into the clinic the same day or the following day if adjustments and assistance are not feasible over the phone. About 30% of our patients use the phone triaging program; uncontrolled pain, nausea, constipation, and counseling are the main reasons.[51]

All follow-ups are scheduled in coordination with other appointments at MDACC, so the patient and family can minimize transportation efforts. This is especially important because the majority of our patients have advanced cancer and rely on instrumental aid and caregivers to bring them to their appointments. To accommodate a patient on a day and time best suited for them, the focus is on providing easy access rather than continuity with the same physician. Patients are informed that they may not be able to see the same supportive care physician for follow-up, although they have the choice of seeing the same physician if they return on their clinic day. However, because of the uniform practice guidelines in the SCC, lack of continuity is not foreseen as a significant concern by both patients and physicians.

Our SCC has a specialized interdisciplinary program called Compassionate High Alert Team (CHAT), which aims to address nonmedical opioid use in patients, assist clinicians, and ensure patient safety.[58] Advances in cancer treatments, improved cancer survival rates, and early referrals to supportive care can result in more patients receiving opioids, and for a longer duration, which may increase the risk for aberrant opioid use among patients. Our SCC has an elaborate screening process to include clinical interviews and tools like CAGE-AID and SOAPP. Along with these tools, a review of national prescription drug monitoring programs and random urine drug testing is part of routine care.[56,59] If aberrant opioid behavior is recognized, the CHAT is activated. Members of CHAT include physician, nurse, pharmacist, counselor, patient advocate, and social work. A team approach that emphasizes patient safety is followed. Our CHAT approach has resulted in significantly reduced frequency in aberrant behavior and aberrant opioid use among patients.[58] This successful CHAT approach is now being implemented in other centers in the US.[60]

Our SCC also has a clinic that aims to identify patients at risk for cachexia early and to intervene using a multidisciplinary approach.[61,62] Our SCC provides an ideal platform to train palliative care, medical oncology, and internal medicine trainees, along with introducing our way of care delivery to numerous observers and visitors from around the world.[63] For many trainees, our SCC is the first exposure to palliative care. Trainees that experienced a rotation with our palliative care team were more knowledgeable with a higher understanding of palliative care principles and strongly believed in referring patients to us early in the disease course.[64] In addition, our SCC is the home for an extensive palliative care research program, enrolling patients in multiple clinical trials and surveys, and is the most academically productive team in the field of palliative and supportive care in patients with cancer.

Despite increased integration and high utilization of SCC, 21% of our patients surveyed perceived that their consult to SCC happened late or too late.[65] Patients experience a significant decrease in numerous symptoms even after a single visit with the SCC team.[66] Patients referred early to outpatient supportive care at MDACC have significantly fewer emergency department visits, hospital admissions, ICU admissions, and hospital deaths.[29] An SCC must be an integral part of all cancer centers to deliver high-quality, patient-centered care to patients with cancer and their families.[67]

MD ANDERSON PRACTICE TIPS

- Consult supportive care for all patients with metastatic/advanced cancer and those with limited-stage cancer that has a poor prognosis.
- Consult supportive care for all patients with physical and psychosocial symptom distress irrespective of the cancer stage or prognosis.
- Supportive care can help not only distressed patients but also their caregivers and family.
- Patients exhibiting signs of aberrant opioid use will need an urgent referral to supportive care for specialized interdisciplinary care.
- Supportive care can help in goals-of-care discussions and timely referrals to hospice. Communication between the primary oncologist and palliative care team, along with the documentation in the electronic health record by the primary oncologist outlining the goals of treatment and prognosis, is beneficial.
- A referral to supportive care can improve patient and family satisfaction with care, patient experience, quality of life, physical and emotional symptoms, and healthcare utilization outcomes at the end of life.

KEY CONCEPTS

- Cancer rehabilitation is a medical subspecialty practiced by physical medicine and rehabilitation (PM&R) physicians, also known as physiatrists. Cancer physiatrists practice in a variety of settings to address a wide array of diagnoses and impairments, with the end goals of optimizing independent function and quality of life.
- The four phases of cancer rehabilitation as described by Dietz in 1980 are: preventive, restorative, supportive, and palliative. These concepts help cancer physiatrists frame their functional assessment and treatment goals when working with cancer patients and their treating oncologic teams.
- The Karnofsky Performance Scale and Eastern Cooperative Oncology Group Scale of Performance Status are widely used as overall functional assessment tools but are limited by overgeneralization and poor correlation with cognitive status. The Functional Independence Measure or the Boston University Activity Measure for Post-Acute Care used by rehabilitation professionals are more comprehensive tools to assess current function and changes over time.
- Neurorehabilitation broadly includes any impairment or functional deficit that results from compromise of the central nervous system (CNS) resulting from direct tumor invasion or as a byproduct of cancer treatment. These can include cognitive deficits, motor impairments, neuropathy, apraxia, ataxia, dysphagia, aphasia, spasticity, or bowel/bladder dysfunction. Depending on the severity or complexity of the impairment, comprehensive evaluation by a cancer rehabilitation physician may be beneficial.
- Musculoskeletal rehabilitation broadly includes any impairment or functional deficit that results from compromise of the musculoskeletal system (bone and/or surrounding soft tissue) resulting from primary, secondary, or metastatic tumor invasion, or as a byproduct of cancer treatment. Topics addressed include amputee care, radiation fibrosis, general musculoskeletal diagnosis and treatment, wound care, bone health, and exercise guidance. Depending on the severity or complexity of the impairment, comprehensive evaluation by a cancer rehabilitation physician may be beneficial.
- There is a growing body of evidence demonstrating that moderate to vigorous exercise confers some protection against several different types of cancer. Along these same lines, "prehabilitation" is an emerging field of interest in oncology. By improving physical function, optimization of nutrition, gaining muscle mass and strength, improving body composition, providing tobacco and/or alcohol cessation counseling, and managing mood before planned cancer treatment, studies have shown improved patient outcomes and reduction in healthcare costs by decreasing length of stay, reducing post-treatment complications, and reducing hospital readmission rates.

GENERAL PRINCIPLES

Cancer and its treatments are a major cause for impairments and disability. As cancer treatments have become increasingly successful and have improved survival, there has been an increasing focus on quality of life and rehabilitation in particular. Cancer rehabilitation is practiced by physical medicine and rehabilitation (PM&R) physicians, also known as physiatrists, in a variety of clinical settings including outpatient clinics, oncology wards, inpatient rehabilitation units, skilled nursing facilities, nursing homes, long-term acute care centers, palliative care units, and hospices. Common diagnoses addressed include asthenia, deconditioning, hemiplegia, spinal cord injury, peripheral neuropathy, somatic and neuropathic pain, steroid myopathy, lymphedema, bowel/bladder management, limb amputation, and limb dysfunction.

The major goal of cancer rehabilitation is to improve quality of life by minimizing the disability caused by cancer and its treatments and decreasing the "burden of care" needed by patients with cancer and their caregivers. The more patients can do for themselves, the less assistance they will require from those around them, and thus they are able to maintain more personal dignity.

In 1978, Justus Lehmann, supported by the National Cancer Institute screened 805 randomly selected patients with cancer, identifying multiple problems in the cancer patient population amenable to rehabilitation interventions along with barriers limiting the delivery of rehabilitation care. More than 40 years later, many of Lehmann's remediable cancer rehabilitation problems and barriers to rehabilitation care remain the same (Table 67–1).[1]

These problems are familiar to physiatrists because many are also found in traditional rehabilitation patients without cancer. Lehmann also described major barriers to the delivery of cancer rehabilitation care including the lack of identification of these problems by oncologists and the lack of referral to rehabilitation professionals for intervention. In addition, there are multiple patient-related factors that can affect the successful rehabilitation of the patient with cancer. Several reported by DeLisa include reduced life expectancy, extensive comorbidities, degree of pain, the dynamic nature of cancer lesions, the demands of anticancer therapies, and the desire to spend remaining time with loved ones.[2]

Phases of Cancer Rehabilitation

In 1980, Dietz categorized cancer rehabilitation into four stages: preventive, restorative, supportive, and palliative.[3] Preventive rehabilitation, more recently coined "prehabilitation," occurs before an intended treatment with the aim of preventing loss of function or disability. In 2001, Courneya described a similar concept called "buffering," whereby a patient with cancer performs exercises and undergoes therapies to increase their physical and functional reserves before cancer treatment.[4] Although the concept of prehabilitation is not unique to cancer, research in the field of oncologic surgery has intensified and results suggest better medical and surgical outcomes with prehabilitation programs.[5–9] An example of prehabilitation would include exercise and nutrition counseling, pre-amputation residual limb care education, and practicing ambulation with a walker for a patient with a lower-extremity sarcoma pending surgical intervention.

Restorative rehabilitation occurs in patients who are believed to be disease free or will have an anticipated relatively stable disease course. In the previous example, a patient with lower-extremity sarcoma with no known metastatic disease after amputation undergoes prosthetic rehabilitation. These first two stages are not significantly different from conventional non-oncologic rehabilitation. Fortunately, as survivorship has increased, restorative rehabilitation has become more prominent in addressing issues in this population, including disability, return to work, and lymphedema management.

For patients in whom we are unable to achieve or maintain a state of remission, supportive rehabilitation is performed to sustain function and provide symptom management. Similar to the example above, a patient with metastatic sarcoma may be provided therapies and durable medical equipment (DME) to promote functional independence while receiving chemoradiation.

Unfortunately, patients may succumb to their malignancy or its accompanying morbidities, and efforts to maximize function may require a transition to focusing on quality of life. Palliative rehabilitation

Table 67–1 Remediable Rehabilitation Problems and Barriers to Delivery of Care[1]

Remediable Rehabilitation Problems		Barriers to Delivery of Rehabilitation Care
Psychological/psychiatric impairments	Lymphedema management	Lack of identification of patient problems
Generalized weakness	Musculoskeletal difficulties	Lack of appropriate referral by physicians unfamiliar with the concept of rehabilitation
Impairments in activities of daily living	Swallowing dysfunction	Patient too ill to participate
Pain	Impaired communication	Patient denies need
Impaired gait/ambulation	Skin management	Cancer prognosis too limited
Disposition/housing issues	Vocational assessments	Rehabilitation unavailable
Neurologic impairments	Impaired nutrition	No financial resources
Vocational assessments	Lymphedema management	
Impaired nutrition		

is provided to reduce discomfort and improve independence in patients with advanced disease. Again, an example scenario is a patient with sarcoma, and advancing metastatic disease may have failed multiple treatment regimens and now requires rehabilitation to return home with some degree of assistance. The emphasis of palliative rehabilitation is typically to get the patient home into a safe environment, focusing on family and transfer training. Higher-level goals such as performing household chores and mobility for longer distances should be addressed as an outpatient.

The last two stages described by Dietz[3] are relatively unique to cancer rehabilitation. The typical course for a patient in conventional rehabilitation (for example post-stroke) is continued improvement after the inciting event. In the cancer patient with persistent disease, however, the battle continues with brief victories followed by declines as the disease progresses (Fig. 67–1).[10]

Multiple studies have established a need for rehabilitation in the cancer patient population.[11,12] Functional improvements of cancer rehabilitation patients have been demonstrated in a number of settings including inpatient[13–16] and palliative care,[17,18] on a consultation basis,[19] in a hospice setting,[20,21] and for outpatient settings.[22] The maintenance of physical activity and exercise has been implicated in increasing survival, with the greatest quantity of evidence in patients with breast or colon cancer. Multiple mechanisms may exist, and some have proposed these findings to be related to levels of insulin/c-peptide, along with the positive effects of buffering on physiologic reserves, potentially allowing for more treatment.[23,24] Cancer physiatrists must also address medical sequelae and complications that are unique to this patient population. These comorbidities may serve as a significant challenge and require frequent communication between the primary oncology and rehabilitation teams as the transfer rate from inpatient rehabilitation to acute care teams has been shown to be quite high compared with other rehabilitation diagnoses.[25]

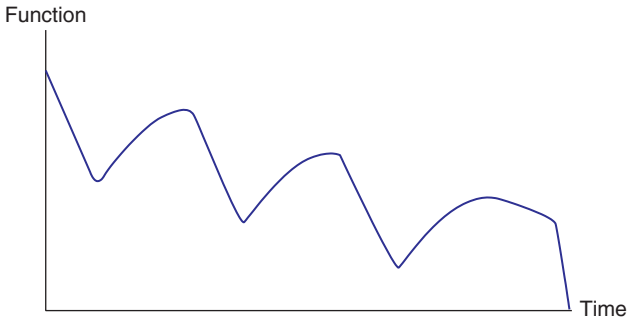

FIGURE 67–1 Functional changes over time typically seen in patients receiving cancer treatment.

FIGURE 67–2 The interdisciplinary rehabilitation team.

Rehabilitation often begins when a patient is admitted into the hospital. As a holistic medical specialty that accounts for medical needs while focusing on a patient's functional issues, physiatrists will ask a series of detailed social questions of patients and their caregivers. This comprehensive evaluation identifies a patient's current functional level, strength, cognition, availability of supervision or assistance upon discharge, accessibility of home conditions, and financial resources. Based on the patient's impairments and the aforementioned practical considerations, realistic and suitable rehabilitation goals are set. If a patient is medically stable with unmet functional and safety goals, their activity tolerance and performance trajectory are used to guide determination of the appropriate intensity and setting for additional rehabilitation.

Rehabilitation goals are formulated and fulfilled by a comprehensive interdisciplinary team of health care professionals, including the physiatrist, rehabilitation nurse, physical therapist, occupational therapist, speech-language pathologist (SLP), dietitian, pharmacist, chaplain, social worker, and case manager. Each member of the team has specific expertise to support the patient with a care plan of maximizing medical stability, function, financial resources, and caregiver involvement for a discharge that is as safe and meaningful as possible (Fig. 67–2).

Rehabilitation at MD Anderson

At MDACC, the cancer rehabilitation practice includes eight physiatrists, and a rehabilitation therapy staff consisting of SLPs and more than 100 physical therapy (PT) and occupational therapy (OT) clinicians. Rehabilitation therapists see more than 300 inpatients and 100 outpatients per day. Patients with a variety of tumor types are seen—the most common being brain, spine, lung, breast, hematologic, genitourinary, gastrointestinal, and head and neck tumors. The most common inpatient rehabilitation diagnoses include asthenia, gait abnormality, dyspnea, hemiparesis, spinal cord injury, and neurogenic bowel and bladder.

Common outpatient rehabilitation diagnoses include lymphedema, myofascial pain, rotator cuff dysfunction, peripheral neuropathy, radiation fibrosis, and low back pain. Inpatient and outpatient electromyograms are performed for neuropathic and myopathic diagnoses. Spasticity management with oral medications and chemodenervation using botulinum toxin injections is also a major focus.

Functional Metrics

When describing a cancer patient's functional status, the Karnofsky Performance Scale (KPS)[26] or Eastern Cooperative Oncology Group Scale of Performance Status[27] are often used. These scales have historically been the most widely used scales in oncology patients both clinically and in research, with various ways in which the scales have been mapped to correlate with each other. They are quick and easy generalized measurements of a patient's function. Weaknesses of these scales include overgeneralization (unable to measure specific tasks) and poor correlation with cognition.[28,29]

In rehabilitation, the outcome scale most often used is the Functional Independence Measure (FIM) (Fig. 67–3). This multidimensional scale addresses 18 items from a scale of 1 (total assistance) to 7 (complete independence). Items are subdivided into self-care, sphincter control, transfers, locomotion, communication, and social cognition. Subscale or aggregate scores are also often useful. It is a common language used in inpatient rehabilitation settings, and it is used to measure changes in functional status during the course of rehabilitation. Criticisms of the scale include that it is too long, too general, and omits items that are important for specific populations, such as those with spinal cord injuries.[30] The Boston University Activity Measure for Post-Acute Care (AM-PAC), developed in 2004, is being used more widely in rehabilitation setttings.[31] The Six-Clicks Basic Mobility and Daily activity are currently used in the MDACC inpatient setting. The Computer Adaptive Test version of this scale selects items from three main domains of basic mobility, daily activity, and applied cognition to match a patient's functional ability, thereby reducing the total number of items on the assessment while increasing the measure's validity.[32]

NEUROLOGICAL CANCER REHABILITATION

Although comprising a relatively small subset of the overall cancer population, patients with malignancy involving the brain or spinal cord often have considerable rehabilitation needs and make up a significant portion of cancer rehabilitation practice. These groups closely resemble their noncancer counterparts in terms of impairments and functional deficits that physiatrists commonly manage. Several key factors must be considered during rehabilitation of the patient with malignancy involving the central nervous system (CNS).

BRAIN TUMORS

Primary brain tumors, although they account for less than 2% of all malignancies, are the second leading cause of death from neurologic disorders after stroke.[33] One-half to two-thirds of intracranial tumors have been reported to be primary tumors.[34] In addition to primary brain tumors, brain metastases are estimated to occur in 20% to 40% of patients with cancer. Most of the metastases are located in the cerebral hemispheres, followed by the cerebellum, and then the brainstem. The incidence of brain tumor metastases is rising possibly because of the increasing length of survival in patients with cancer,[35] increasing ability to diagnose a tumor with improved radiographic imaging,[36] and possibly recent chemotherapy agents that may weaken the blood brain barrier.[37]

Normal brain parenchyma can be destroyed or compressed by the tumor, and the location of the tumor determines the resultant neurologic deficit. Surgical resection may exacerbate these deficits by creating inflammation or peritumoral infarct.[38] Radiation treatment has long been an integral part of brain tumor treatments and often results in collateral damage. Early acute radiation leukoencephalopathy is likely caused by increased cerebral edema. Late-delayed radiation reactions include focal cerebral radiation necrosis, diffuse cerebral radiation injury, and combined-therapy diffuse white matter injury/leukoencephalopathy. Clinical diffuse cerebral radiation injury has been reported in 2% to 5% of patients with metastases and 19% of 1-year survivors after whole brain radiation.[39,40]

Another etiology of significant neurologic deficits that can be challenging to diagnose and manage is leptomeningeal disease (LMD). Leptomeningeal metastases have been reported to occur in up to 10% of breast and lung cancer, melanoma, and acute lymphoblastic and myeloid leukemias, and up to 20% of primary CNS or ocular lymphomas, and non-Hodgkin lymphomas.[41] The presence of LMD is often a poor prognostic indicator of survival, and rehabilitation goals should be set accordingly. However, it has been demonstrated that patients with LMD can still benefit from comprehensive inpatient rehabilitation.[41]

The most common neurologic deficits in patients with brain tumors include impaired cognition (80%), weakness (78%), visual-perceptual deficits (53%), sensory loss (38%), and bowel/bladder dysfunction (37%). Other less common deficits include cranial

nerve palsy, dysarthria, dysphagia, aphasia, ataxia, and diplopia. Approximately 75% of patients with brain tumors have three or more concurrent neurologic deficits, and 39% have five or more deficits.[42] Because of the diverse nature of these neurologic deficits and their impact on functional performance and activities of daily living (ADLs), comprehensive multidisciplinary inpatient rehabilitation is often necessary.

Patients with brain tumors have similar efficiencies of functional improvement when compared with their traumatic brain injury and stroke counterparts, without much variability between tumor types. Lengths of stay tend to be shorter among patients with brain tumors, potentially because of a need to return patients home sooner given their shorter life expectancies.[43–47] Nonetheless, patients with brain tumors often have progressive disease resulting in gradual functional decline and present unique challenges for physiatrists.

CANCER-RELATED SPINAL CORD INJURY

Primary spinal cord tumors such as meningiomas, neurofibromas, and gliomas are relatively rare, and the majority of tumors involving the spinal cord are metastatic. Ninety-five percent of metastatic lesions are extradural, often arising from the vertebral body and compressing the anterior spinal cord. Most spinal cord metastases originate from primary tumors of the breast, lung, and prostate. Other tumors that metastasize to the spine include renal, melanoma, myeloma, and thyroid. Approximately 70% of spinal metastases occur in the thoracic spine, which has higher vascular flow and a smaller ratio of canal-to-cord diameter than the other two major spinal segments,[48] making it uniquely vulnerable to metastatic lesions.

Common presenting symptoms include pain worse at night and lying in the supine position. Weakness and sensory loss, along with the development of bowel or bladder incontinence, may indicate spinal cord compromise. Rapid progression of paraparesis over only a few hours indicates arterial compromise by tumor invasion or pressure; slowly evolving symptoms suggest gradual cord impingement and may respond to systemic steroids and/or radiotherapy, potentially alleviating pain and improving neurologic function.[49]

If a tumor involves two or three columns of the spine, spinal stability is of concern and initial treatment is aimed at stabilization of the spinal column. Surgical consultation is prudent in cases of neurologic compromise, pathologic fracture and dislocation/spondylolisthesis, failure of radiation therapy, and rapidly progressive myelopathy. If operative intervention is not recommended, prescription of an appropriate spinal orthosis may limit the degree of movement at various spinal levels.

Once spinal stabilization is achieved, comprehensive inpatient rehabilitation can address the impairments, functional limitations, and disabilities associated with spinal cord compression and injury caused by cancer. Individuals with nontraumatic spinal cord injuries can achieve significant gains in FIM scores during inpatient rehabilitation.[16] It has also been suggested that because of the limited prognosis of cancer patients with spinal cord compression, an expedited inpatient rehabilitation stay with the focus on family training and home safety should be emphasized.

Neurologic Motor Impairment

Motor impairment with hemiparesis, paraparesis, quadriparesis, ataxia, and apraxia may yield an unsafe gait pattern, increased risk for falls, and a need for inpatient rehabilitation. During inpatient rehabilitation, PTs provide hands-on analysis and treatment of a patient's bed and wheelchair mobility, transfers, and gait with or without an assistive device (eg, single-point cane, quad cane, rolling walker, hemi-walker, and wheelchair). Occupational therapists simultaneously aid vital recovery of other activity limitations, commonly addressing basic ADLs including dressing, bathing, toileting, grooming, and eating. Once a patient is functionally safe with or without an assistive device, they may be discharged home with outpatient rehabilitation prescribed to maximize functional gains and advance patient goals.

The stroke recovery pattern is often used as a guide for patients with brain tumors but does not always correlate. In stroke patients, the recovery of strength occurs in a proximal-to-distal fashion, with flaccidity and decreased muscle tone progressing to spasticity and increased muscle tone. Spasticity of affected limbs can evolve into flexor or extensor synergy patterns, and recovery of movement may plateau at any stage or progress to isolated coordinated volitional motor movement.[50,51] Neuromuscular facilitation techniques applied by PTs and OTs promote working with or against these patterns to optimize functional recovery of impaired extremities.

In cases of moderate neuromuscular weakness, functional electrical stimulation can be incorporated into a rehabilitation program. Using a low-level electrical current to stimulate motor or reflex sensory nerves, coordinated muscle contraction may produce purposeful, functional movements in paretic or paralytic muscles.[52] In addition, orthotic devices may be prescribed to support weak limbs and prevent secondary complications. An example would be an ankle-foot orthosis provided to prevent falls by stabilizing the ankle and knee during ambulation in a patient with ankle dorsiflexor weakness (foot drop). Another example would

be a lapboard while a hemiparetic patient is seated[53] to prevent painful shoulder subluxation caused by loss of motor control of the shoulder stabilizers including the deltoid and supraspinatus muscles.[54]

Apraxia and Hemispatial Neglect

Apraxia, hemisensory deficit, and homonymous hemianopsia may also be seen with hemiparesis. Visual or somatic hemineglect is more frequently seen when the nondominant cerebral hemisphere is affected and has a negative effect on sitting balance, visual perception, wheelchair mobility, safety awareness, and risk of falling. Patients with neglect have difficulty with hygiene and self-care activities, especially on the affected side. Rehabilitation programs must address the issues of apraxia and hemispatial neglect through focused measures led by SLPs, OTs, and PTs. Family training and education are important in this setting as well.

Ataxia

Cerebellar ataxia may be seen with mass effect within the posterior fossa, paraneoplastic cerebellar degeneration, and with high-dose administration of cytarabine or 5-fluorouracil.[55,56] Involvement of the cerebellum can produce intention tremors, dysmetria, and dysdiadochokinesis as patients lose the ability to coordinate agonist and antagonist muscle groups.[57] Response to pharmaceutical management is often poor; consequently, PT and OT are often mainstays of treatment. Therapies may include the teaching of compensatory techniques, weighted tools or wraps to reduce oscillations, and gait training with appropriate assistive devices for balance and safety.[58]

Aphasia

Depending on its location, a tumor may be associated with deficits in speech, which can vary in severity and type. SLP practitioners can diagnose the type of aphasia from a comprehensive neurologic examination including speech comprehension, fluency, and repetition. These include Broca, Wernicke, anomic, global, conduction, and the transcortical motor and sensory aphasias. A speech pathologist may implement treatment approaches including melodic intonation therapy, Amer-Ind Code treatment, functional communication treatment, stimulation approach, and Promoting Aphasics' Communication Effectiveness therapy.[59]

Cognitive Deficits

Cognitive deficits often are more problematic than motor deficits and may vary significantly. They can arise from direct injury to the brain tissue as a result of the tumor itself, from surgical resection, radiation, chemotherapy, depression/anxiety, and medications such as steroids, analgesics, and anticonvulsants.[36] Impairments most commonly seen involve limited memory and attention, decreased initiation, and psychomotor retardation.[60]

The physiatrist evaluates cognition as part of their examination, formulating a rehabilitation program involving all therapy disciplines. Specific deficits in language and cognition can be further delineated through specific testing performed by a SLP. The occupational therapist may also incorporate cognitive rehabilitation as part of a patient's plan of care. In some cases, formal neuropsychological testing may be of great value, especially if a patient wishes to return to work.

Dysphagia

A disruption in the swallowing process may also occur in patients with brain tumors or head and neck cancer caused by either direct tumor burden or as a byproduct of treatment. It is important to diagnose dysphagia because serious potential complications, such as malnutrition and aspiration pneumonia, can be devastating if dysphagia remains undetected. If dysphagia is suspected, a speech pathologist is consulted for bedside evaluation, and daily swallowing exercises are incorporated. Additional treatments include dietary modifications and facilitation techniques.[61] Video fluoroscopic evaluation may help guide food and liquid consistency restrictions (for example, puree, semisolid, or solid foods; or liquids with various degrees of thickening agents).

Compensatory strategies include proper head and trunk positioning, which for most patients is to be seated upright with head midline, trunk erect, and the neck slightly flexed forward. Other techniques include the chin-tuck method and head turning and tilting during swallowing. Regular follow-up to assess for dysphagia improvement is required and may be done by clinical examination or radiographic study. If improvement is noted, the diet may be advanced appropriately.

Spasticity

Spasticity is defined as velocity-dependent resistance to passive movement across a joint. It is an abnormality involving increased muscle tone and is one of the positive findings of upper motor neuron syndrome that can affect patients with brain tumors and cancer-related spinal cord injury. Spasticity must be distinguished from soft tissue contractures, which can result from chronic scar tissue formation and may arise from various causes, including uncontrolled spasticity. Spasticity can affect a patient's gait pattern, ADLs, and hygiene performance, and in severe cases may cause

pain and joint contracture. In some cases, however, spasticity may be beneficial, as when a patient may use knee extensor spasticity to assist in transferring from a sitting to a standing position. Goals of spasticity treatment include decreasing pain, improving hygiene, enhancing the efficiency of gait and transfers, minimizing contractures, and improving self-care.

Treatment measures for spasticity include physical and medical interventions. Proper positioning, passive range-of-motion exercises, serial casting, splints, and braces are some of the physical interventions used in treating spasticity. Oral medication options may include tizanidine, dantrolene sodium, and baclofen, but dosing is often limited by the side effects of excessive drowsiness and cognitive changes.[62] Localized treatment options such as botulinum toxin injections, phenol injections, or implantable intrathecal baclofen pumps may be useful if skilled physicians and follow-up resources are available.

Bladder Management

For all cancer patients with neurologic involvement and those with profound deconditioning, it is prudent to evaluate for signs of bladder dysfunction. One should maintain a low clinical threshold for working up a urinary tract infection. Furthermore, postvoid residual bladder scans can be performed to evaluate for complete bladder emptying.

If the pontine micturition center is preserved, patients with brain tumors and spinal cord injuries often have upper motor neuron bladder dysfunction, which is characterized by bladder hyper-reflexia, low postvoid residual volumes, high bladder pressures, diminished bladder compliance, reflex or urge incontinence, and complete emptying.[63] Persistent areflexia and retention may occur with bilateral brainstem lesions[61] or lesions involving the sacral micturition center, resulting in overflow incontinence and lower motor neuron bladder dysfunction. Patients with complete spinal cord lesions may have reflex incontinence and incomplete voiding caused by detrusor-sphincter dyssynergia.[63] In many cases, a mixed picture of the aforementioned bladder dysfunctions may occur. In complex cases that are difficult to manage, a urology consult for a formal urodynamics study should be considered.

Treatment should be directed at the cause of bladder dysfunction. Using a bedside commode or urinal is of benefit for patients with weakness or a limited ability to safely ambulate to the bathroom. A timed voiding program is useful for those with functional incontinence caused by hyper-reflexic urgency. An intermittent catheterization program may be necessary if postvoid residual volumes are persistently elevated above 150 mL. Anticholinergic medications such as oxybutynin or tolterodine tartrate or β-3 adrenergic agonists such as mirabegron can be used for persistent incontinence in the setting of a hyper-reflexic detrusor[61] to decrease detrusor tone and allow for greater bladder storage capacity; then an intermittent catheterization program can be instituted. Trial of an α-adrenergic agent (such as tamsulosin or terazosin) may be conducted in patients with urinary retention, but resting and orthostatic blood pressures should be monitored upon initiation and dose titration.

An intermittent catheterization program initially involves daily measurements of postvoid residuals (volume of urine remaining in the bladder after a void). If postvoid volumes are elevated, the patient is catheterized every 4 hours. Goals may vary but catheterized volumes should not exceed 500 mL. If the volumes remain consistently low, the frequency of catheterization can be decreased to every 6 hours.

It is important to note that in the cancer population, life expectancy often plays a part in rehabilitation management. Intermittent catheterization may be the preferred method of management for many patients, but an indwelling catheter, or a condom catheter for men, is sometimes used for ease and comfort in patients with limited prognosis or difficulty catheterizing themselves.

Bowel Management

Typically, with lesions above the conus medullaris, an upper motor neuron bowel dysfunction is present, with the muscles of the external anal sphincter and pelvic floor becoming spastic. The connection between the spinal cord and the colon remains intact, and stool can be propelled by reflex activity. With lesions below the conus medullaris, an areflexic lower motor neuron bowel dysfunction is present, with the myenteric plexus intrinsically moving stool slowly.[64]

A complicating matter in patients with cancer is opioid-induced constipation. This and other premorbid factors and current bowel function must be ascertained before instituting a bowel program. Often a plain radiograph of the abdomen is obtained to assess for obstipation before beginning a bowel program. If obstipation is present, suppositories or enemas can be given to clean out the bowels and evacuate the rectal vault.

The goals of a bowel program are to prevent fecal impaction and to facilitate efficient bowel evacuation on a routine schedule compatible with one's daily activities. A bowel program begins with a proper diet, including adequate amounts of fluid and fiber order to create soft, bulky stools that can decrease bowel transit time. In contrast, fatty foods can increase transit time. Medication options may include stimulant or osmotic laxatives, as well as adjunctive suppositories and enemas.

In stepwise fashion, a sample bowel program begins with an abdominal radiograph to determine whether evacuation by enema is necessary; then an appropriate diet is begun, along with stool softeners or stimulants. To take advantage of the gastrocolic reflex, the patient is transferred to a commode or toilet approximately 30 minutes after a meal, preceded by placement of a suppository 10 minutes before. In addition, manual digital stimulation 20 minutes after suppository insertion can be incorporated to induce the rectocolic reflex.[63]

MUSCULOSKELETAL CANCER REHABILITATION

Bone and Soft Tissue Tumors

Primary bone tumors are rare, with the majority arising in the lower limbs. Osteogenic sarcoma is the most common primary bone tumor, representing 20% of all malignant primary bone tumors, with 75% occurring in children.[65] Survival rates have increased from 20% to 70% with the implementation of chemotherapy and limb-sparing surgeries.[65] Grade of severity is based on biopsy results.[66] Anatomic setting and metastases are evaluated by imaging, with lung metastases being most common; based on this information, a surgical plan is devised.[66] No difference in survival has been shown between neoadjuvant chemotherapy followed by surgery versus surgery and adjuvant chemotherapy.[66] Notably, osteogenic sarcoma tends to be less radiation-sensitive as well.[66]

Primary malignant chondrosarcomas are not chemotherapy-sensitive, and wide excision is the treatment of choice.[66] These patients may undergo several types of surgery, including allografts and endoprostheses. Hemipelvectomy and sacrectomy are less common but are often seen at MDACC. There are two types of hemipelvectomy—internal and external—and four types of pelvic resection: iliac (type I), periacetabular (type II), pubic bone (type III), and sacrum (type IV), with combined resections possible.[67] Complications such as hematoma, delayed skin healing, and/or orthostasis caused by delayed mobility may be seen. It is key to communicate with the surgical teams regarding weight-bearing and range-of-motion precautions because this will impact a patient's rehabilitation course and length of stay.[68] Depending on musculature and nerves affected, as well as type of reconstruction, rehabilitation diagnoses may include lower limb weakness, sensory impairment, and neurogenic bowel and bladder. Multiple studies have shown that sparing of S3 spinal nerves results in less bowel dysfunction and sparing of L5/S1 spinal nerves results in improved motor function.[68,69]

Bony Metastases

Bony metastases are most common in the axial skeleton, followed by long bones, skull, ribs, and pelvis.[70] Skeletal-related events include pain, pathologic fracture, hypercalcemia, and spinal cord compression caused by bony metastases; this can result in significant loss of quality of life and function.[66] Bony metastases must be on the differential diagnosis in a patient complaining of localized bone pain. Lytic lesions can be seen with multiple myeloma, renal, lung, and thyroid cancers.[66,70] Blastic lesions can be seen with prostate cancer and mixed lesions with breast cancer.[66,70] Imaging recommendations are based on the type of cancer and location of pain, with magnetic resonance imaging preferred for spine and radiograph preferred for multiple myeloma lytic lesions, but definitive diagnosis requires biopsy. Treatment can be operative for impending pathologic fractures or nonoperative to halt progress and prevent fractures. Systemic hormones, chemotherapy, radiation therapy (often the treatment of choice for radiosensitive tumors), protected weight bearing, and external immobilization are all nonoperative interventions.[66,70] Except for lymphoma and some testicular germ cell tumors, treatment is generally palliative to relieve pain, prevent fractures, prolong survival, and improve quality of life.[66,70]

Rehabilitation of Bone Lesions

These patients often undergo PT and OT, and the physician needs to provide appropriate weight-bearing precautions, range-of-motion restrictions, positioning recommendations, and what resistance exercises to avoid (for instance, axial loading is generally preferred over eccentric exercise). By using an assistive device such as a walker, the patient may be able to offload weight to allow them to ambulate more independently without increasing fracture risk. Spinal precautions are recommended in those at risk for or with pathologic fractures and include no bending, lifting greater than 5 pounds, or twisting. A thoracic lumbar sacral spinal orthosis may need to be considered. It is also important to educate patients and family on the risks of immobility, including pressure ulcers, thromboembolic events, muscle contracture/weakness/atrophy, and osteopenia or osteoporosis.[66,70]

Amputee Care

Depending on the level of involvement of a bony tumor, amputation may be considered the best option for resection of the tumor. Amputation may provide the best outcome for the patient with bone or soft tissue sarcomas, but generally less than 10% of patients will require amputation.[66] Often, primary bone sarcomas

with fracture require immediate amputation to control tumor spread, especially in patients who present with advanced spread.[66] Below-knee amputation may be performed for distal lower-extremity tumors because of its superior function and decreased residual disability.[66] In addition, infection, limited or nonresponse to treatment, necrosis, or inadequate tissue for limb salvage may lead to amputation. In general, the more proximal the amputation, the more energy expenditure is required to ambulate with a prosthesis. After amputation, a patient generally remains non–weight bearing on the affected limb for 6 weeks, depending on wound healing. During this time, patients should receive PT and OT under the supervision of a physiatrist and orthopedist to focus on building independence, strengthening muscles for pregait and weight-bearing activities, and education on appropriate range of motion. Edema and residual limb shaping for prosthetic fitting is achieved first by wraps and then shrinker socks once appropriate. Patients may report phantom sensation and/or phantom pain. This can be treated by pharmacologic interventions, such as gabapentin, duloxetine, and pregabalin, as well as nonpharmacologic techniques, such as desensitization, edema management, and mirror therapy. Central pain syndrome may occur in patients as well. Neuromas may develop at distal limb sites and can be treated with anesthetic blocks to provide relief. Patients who have undergone external hemipelvectomy or sacrectomy may require additional education on sitting balance and use a prosthesis for sitting. Rotationplasty is primarily seen in children with growth potential to avoid above-the-knee amputation.[66] These patients may require later limb-lengthening surgeries and coordinated care with orthopedics, prosthetics, physiatry, and PT. For the upper extremity, forequarter amputation is removal of the shoulder and ipsilateral arm.[66] Postoperative care requires significant work on balance and ADLs with OT. An upper-extremity prosthesis can provide significant cosmetic and functional benefit to the patient.[66]

Radiation Fibrosis

Radiation fibrosis occurs as a result of tissue damage from radiation therapy.[71] Radiation fibrosis syndrome (RFS) is defined as the "clinical manifestations of progressive fibrotic sclerosis that can result from radiation treatment."[72] Because of abnormal accumulation of thrombin in extravascular and intravascular compartments, there may be tissue sclerosis in skin, muscle, nerve, viscera, tendon, ligament, and bone.[72] RFS may occur differently in each person because of susceptibility of underlying tissues to the effects of radiation.[72] Much of the literature has been focused on radiation-induced fibrosis in those who received mantle radiation for Hodgkin lymphoma as well as in breast cancer patients who received chest wall and supraclavicular radiation, but symptoms are also seen in patients with gastrointestinal and lung cancer. Patients with head and neck cancer also exhibit significant morbidity from radiation-induced fibrosis with neck posturing (such as dystonia or torticollis), trismus, and shoulder impairment. Temporally, effects can be seen during or immediately after radiation (acute), up to 3 months from completion (early-delayed), or more than 3 months from completion (late-delayed).[73] Patients can present with "myelo-radiculo-plexo-neuro-myopathy" caused by the significant impact on each respective component of the neuromuscular chain.[72] Patients may experience lower-extremity weakness and spasticity with myelopathy; upper or lower-extremity radiculopathy; plexopathy involving the trunk, divisions, or cords; peripheral neuropathy related to terminal branches involved; and myopathy affecting local muscles within the radiation field.[72] Electromyography/nerve conduction studies and magnetic resonance plexus imaging may be helpful in evaluating the extent of involvement. Unfortunately, RFS is not reversible, with prevention being the first step to avoiding it.[74] As technology continues to improve, the frequency of radiation-induced fibrosis may decrease. Treatments aimed at targeting matrix synthesis and use of biologics to prevent fibrosis are being explored.[74] Pentoxifylline with vitamin E has been shown to improve tissue compliance in patients with breast cancer.[75] Research is ongoing for hyperbaric oxygen and anticoagulation.[66] Most of all, education must be provided to patients by physiatrists, PT, and OT focused on stretching the involved muscles, strengthening both affected and unaffected sides, and orthoses. SLP treatments for patients with trismus include progressive jaw-opening exercises and orthoses. Botulinum toxin injections can treat spasticity and spasms of muscle, including cervical dystonia, trismus, chest wall and paraspinal spasms, and focal neuropathic pain disorders.[66]

REHABILITATION OF GENERALIZED DECONDITIONING AND ASTHENIA

Generalized weakness, deconditioning, and asthenia are common problems in patients with cancer that can require cancer rehabilitation intervention. Asthenia is a combination of weakness and decreased exercise tolerance arising from several factors including muscle wasting, disuse atrophy, malnutrition, anemia, and cardiac or pulmonary comorbidities. Functional impacts of asthenia can include difficulty with transfers, ambulation, ADLs, and balance, as well as a risk for falls.

Rehabilitation treatment can begin with increased sitting time and gentle range-of-motion exercises. This is followed by a progressive increase in physical activity

dose, duration, and intensity, along with instruction in energy conservation and balance training. It is also important to address other potential contributing medical conditions, such as anemia, malnutrition, sleep, pain, and mood disorders. Short-term inpatient rehabilitation can be effective in improving functional status after an acute decline. Outpatient rehabilitation may help maintain or more gradually improve functional performance. However, if the primary malignancy progresses, functional performance will likely deteriorate.

Muscle Atrophy

Muscle atrophy commonly occurs in patients with cancer. There are three types of muscle fibers. Type I muscle fibers are the slow-twitch oxidative metabolism fibers, which have slow fatigability and are used for prolonged activity. Type IIB fibers are the fast-twitch fibers, which use glycolytic anaerobic metabolism and have rapid fatigability. Type IIA is an intermediate fiber.

Prolonged bed rest can result in muscle atrophy and weakness. In a classic study by Muller, the muscles of a person on strict bed rest can lose approximately 1.0% to 1.5% of their initial muscle strength per day of bed rest, corresponding to approximately a 10% loss of strength per week.[76] Antigravity muscles like the gastrocnemius and back extensor muscles tend to lose strength disproportionately, with larger muscles losing strength more quickly than smaller muscles, often leaving handgrip strength unaffected.[77,78] Type I fibers are more affected than type II fibers.[79]

These effects on muscles can be counteracted by a daily stretching program, which delays muscle atrophy.[80] In addition, daily isometric muscle contractions of 10% to 20% of maximal tension for 10 seconds can help maintain muscle strength.[76] Electrical stimulation of muscles can also be used. In general, it may take two or more times as long as the period of immobilization to recover muscle strength.[81]

Cardiovascular Effects

There are deleterious cardiovascular effects from prolonged bed rest as well. Cardiac deconditioning may lead to resting tachycardia. After a period of bed rest, the heart rate can increase by about one-half beat per minute each day for the first 3 to 4 weeks of immobilization.[82] In addition, there are decreased diastolic filling times. This results in decreased myocardial perfusion, decreased stroke volume with submaximal and maximal exercises, decline in cardiac output at submaximal exercise, and deleterious hemodynamic and orthostatic changes.

The treatment of adverse cardiovascular effects from prolonged immobilization is mainly aimed at prevention. Sitting in a chair prevents deterioration of maximum oxygen consumption and orthostatic intolerance. Isometric exercise minimizes decreases in maximum oxygen consumption.[83] Cardiovascular deconditioning can be reversed by progressive increase in activity and regaining of upright posture. Orthostatic intolerance can be helped by range-of-motion exercises, abdominal strengthening, leg exercises to reverse venous stasis, and progressive ambulation. In addition, supportive treatments for orthostatic intolerance include the use of a tilt table, compressive garments such as leg stockings and abdominal binders, and medications such as ephedrine, midodrine, and fludrocortisone acetate.

Thrombotic complications, such as the development of a deep venous thrombosis (DVT) or a pulmonary embolism (PE), are also risks of immobility. Virchow's triad of hypercoagulability, endothelial injury, and stasis of blood flow are factors that acutely ill or postoperative cancer patients share that can contribute to clot formation. At times, rehabilitation begins after a prolonged state of immobility and it is imperative that we take measures to prevent DVT or PE development. Patients should be mobilized, encouraged to ambulate, provided with external intermittent leg compression devices, and administered low-dose anticoagulation when contraindications are not present.[84]

Joint Contractures

Another risk of prolonged bed rest and immobility is joint contracture, an abnormal limitation of passive joint range of motion. Typical contractures from immobilization include hip and knee flexion, ankle plantarflexion, elbow flexion, and internally rotated shoulder contractures. Contractures are treated with stretching, range-of-motion exercises, and soft tissue manipulation. For more severe cases, deep heating followed by range-of-motion exercises and serial casting may be necessary. One goal of nursing and inpatient rehabilitation services should be to prevent joint contractures before they occur. Hip flexion contractures can be prevented by occasionally lying in a prone position and avoiding overly soft mattresses. Dorsiflexion exercises, pressure relief ankle-foot orthoses, and footboards can help prevent ankle plantarflexion contractures.

Bone Health

Immobilization can also affect the bones. Wolff's law states that the ratio of formation to resorption is influenced by the stresses to which bones are subjected. The primary stress on most bones is weight bearing, which results in buildup of bone; a lack of stress on bones leads to a predominance of bone resorption. When a patient is immobilized in bed, extended periods of

non–weight bearing can lead to disuse osteoporosis. This is best treated with preventive measures such as active muscle contraction and active weight-bearing exercises. Exercises conducted in bed are not particularly effective and out-of-bed-to-chair activities are encouraged as soon as possible.[84]

Return to Primary Acute Care Service

It has been shown that cancer rehabilitation inpatients are transferred back to the primary acute care service more frequently than noncancer patients.[85] The medical fragility of these patients has led to interest in identifying predictors of medical complications while on inpatient rehabilitation. Published research has identified several factors in general oncology patients[25,86] and more specific groups including patients with lymphoma,[87] leukemia,[88] and hematopoietic stem cell transplant.[89] The presence of antimicrobial agents, elevated creatinine, and thrombocytopenia at the time of inpatient rehabilitation transfer have been identified as possible predictors of transfer back to the primary acute care service. These issues highlight the importance of maintaining continuous open communication with oncologists and surgeons during inpatient rehabilitation.[25]

EXERCISE IN CANCER

In the past, treatment algorithms for cancer patients did not incorporate physical exercise as an important component of care. Recently, studies have emerged substantiating the short- and long-term benefits of a well-constructed exercise program. Along the time spectrum of cancer prevention, treatment, and survivorship, patients benefit from an individualized exercise regimen at each stage.

As the prevalence of cancer grows, researchers have emphasized prevention strategies. According to the International Agency for Research on Cancer, obesity and a sedentary lifestyle may contribute to a quarter of new cancer cases. Women are at greatest risk with nearly three times the rate of overweight- and obesity-related cancers.[90]

In addition to reducing the burden of primary risk factors, physical activity may serve as a cancer prevention strategy by improving musculoskeletal strength, endurance, balance, and flexibility, while indirectly enhancing the performance of the body's cardiovascular, pulmonary, neurologic, and immune systems. Previously, the strongest evidence for cancer risk reduction via physical activity had been for colon cancer; a systematic review cited a 40% to 50% risk reduction with exercise.[91–93] The Physical Activity Guidelines Committee from the US Department of Health and Human Services in 2018 identified six additional cancers that may have reduced incidence with increased physical activity: breast, renal, endometrial, bladder, esophageal (adenocarcinoma), and gastric.[94,95] The World Cancer Research Fund/American Institute for Cancer Research concluded that there was strong to probable evidence for risk reduction in colon, postmenopausal breast, and endometrial cancers with moderate to vigorous physical activity, and probable evidence in premenopausal breast cancer with vigorous physical activity.[96] Thus, the emerging evidence demonstrating the protective properties of moderate to vigorous physical activity reinforces the importance of public education and execution of this risk-reducing strategy. The American Cancer Society updated their Diet and Physical Activity Guidelines in 2020, in which they again recommend that adults engage in 150 to 300 minutes of moderate-intensity aerobic activity per week, 75 to 150 minutes of vigorous-intensity aerobic activity, or an equivalent combination for cancer prevention. They also note that achieving or exceeding the upper limit is optimal. Children and adolescents should engage in at least one hour of moderate or vigorous physical activity weekly.[97]

In addition, there is an increasing body of research demonstrating improved cancer- and treatment-related symptoms with moderate increases in activity.[1] Rehabilitation regimens including a combination of aerobic and resistance training have demonstrated improvements in body weight, body composition, flexibility, strength, fatigue, depression, anxiety, self-esteem, perception of well-being, lymphedema, bone health, sleep, functional capacity, and health-related quality of life including role functioning and social functioning.[98–102] Many patients with cancer experience significant weight loss, particularly loss of lean muscle mass. This problem may be exacerbated by hormone or chemotherapy treatments and contribute to generalized weakness and fatigue. Sixty-three men with prostate cancer receiving androgen-deprivation therapy were enrolled in a randomized controlled trial; participants performed at least 150 minutes of moderate-intensity aerobic and resistance exercise training during a 3-month period. Compared with the control group, the exercise group had preserved appendicular lean mass and prevented gains in whole-body fat and trunk fat mass. Between-group analyses also demonstrated significant improvements in peak oxygen consumption, muscle strength, cholesterol levels, sexual function, and fatigue.[100]

Exercise may also improve cancer survival. Preliminary epidemiologic data comparing high versus low physical-activity levels has shown 40% to 50% relative risk reductions in mortality in breast, colon, and prostate cancers.[95] In patients with metastatic colorectal cancer, exercise volumes of more than 9 metabolic equivalent hours per week was associated with reduced treatment complications and exercise volumes of at

least 18 metabolic equivalent hours per week was associated with improved progression-free survival.[103] In a prospective trial that enrolled 1340 patients with breast cancer, patients who met the Physical Activity Guidelines before and 1 year after diagnosis had significant reductions in hazards of recurrence and mortality.[104] Even lower to moderate volumes of exercise were associated with improved survival.[104] In a 17-year survival study conducted in a cohort of 830 patients with stage II–IV prostate cancer, postdiagnosis total activity (high vs low) was associated with a significantly lower all-cause mortality risk and postdiagnosis recreational activity (high vs low) was associated with a significantly lower prostate cancer–specific mortality risk.[105] Furthermore, in another trial examining the associations of pre- and postdiagnosis recreational physical activity in 5807 patients with cancer, those who were habitually active had a 39% decreased hazard of all-cause mortality and a 36% decreased hazard of cancer-specific mortality. Moreover, patients who were previously inactive and began exercising after treatment also had a survival advantage.[104]

Safety of Exercise in Cancer

Although the reasons may be multifactorial, patients may not partake in regular exercise activity because of patient and provider fears.[106] Cheville interviewed a group of patients with advanced non–small-cell lung cancer and identified exercise barriers, which included fear of harm and a lack of direction from their physician.[106] Patients were less receptive to guidance from ancillary health professionals, but an early expert consultation with a physiatrist may prove helpful in formulating an individualized rehabilitation program with medical monitoring, identifying and managing impairments and psychosocial barriers, and therapy (if needed) oversight.

Rehabilitation programs involving exercise are generally safe and with proper precautions, adverse events are limited to musculoskeletal injuries, which are typically treated conservatively. Breast cancer survivors are among the most common population studied for exercise and in this group, there is concern that resistance exercise causes exacerbation of lymphedema.[107] However, the evidence suggests that breast cancer survivors undergoing a strength-training protocol demonstrate a reduced risk of lymphedema exacerbations, while improving strength and bone mineral density.[108,109]

Prescribing Exercise in Cancer

With increasing data supporting the benefits of exercise along the cancer diagnosis and treatment continuum, there has been an emerging need for expert clinical exercise guidelines. In 2018, the American College of Sports Medicine (ACSM) International Multidisciplinary Roundtable on Physical Activity and Cancer Prevention and Control brought together experts from 20 international organizations.[101] These experts found that the 2010 ACSM exercise guidelines may have been unachievable for cancer survivors with physical limitations and that health benefits could be achieved with a lower dose of exercise. Thus, the updated guidelines recommend that cancer survivors engage in at least 30 minutes of moderate-intensity aerobic exercise at least three times per week, for at least 8 to 12 weeks. In addition, cancer survivors should engage in strengthening exercises at least two times per week, using at least two sets of 8 to 15 repetitions of weights at 60% or more of their one-repetition maximum. Figure 67–4 outlines programming models on how exercise can be administered.[110] Unfortunately, the literature supporting specific exercise prescriptions for different cancer types is limited, but the updated 2018 ACSM exercise guidelines provide for structure and flexibility in formulating exercise programs for cancer survivors with functional impairment, to ones who are currently physically active.

In recent years, the literature has demonstrated improved cancer outcomes in patients participating in an exercise program. Exercise has been shown to be safe and effective in managing symptoms, body composition, strength, endurance, and well-being. Future steps in exercise oncology include testing different exercise prescriptions and determining the optimal doses of aerobic and strengthening exercise to further improve oncology outcomes.

PREHABILITATION

Prehabilitation, also known as "pretreatment optimization" or "pretreatment conditioning," is an emerging field in oncology. Patients with cancer are fraught with fatigue, muscle wasting, and functional impairments, which are caused by the cancer itself or sequelae of cancer treatment. Cancer prehabilitation is the initial and essential segment in the cancer rehabilitation continuum of care.[111] The goals of prehabilitation may include improving physical function, optimization of nutrition, gaining muscle mass and strength, improving body composition, tobacco and/or alcohol cessation counseling, and managing mood (stress, anxiety, depression). Thus, the prehabilitation period is an ideal time to document patients' baseline level of function, identify impairments, and formulate an individualized plan to minimize anticipated treatment-related declines in function. Figure 67–5 shows how prehabilitation may be unimodal in its goal and treatment outcome, or multimodal, depending on the needs of the patient population. Oncology prehabilitation programs have typically included any combination of exercise,

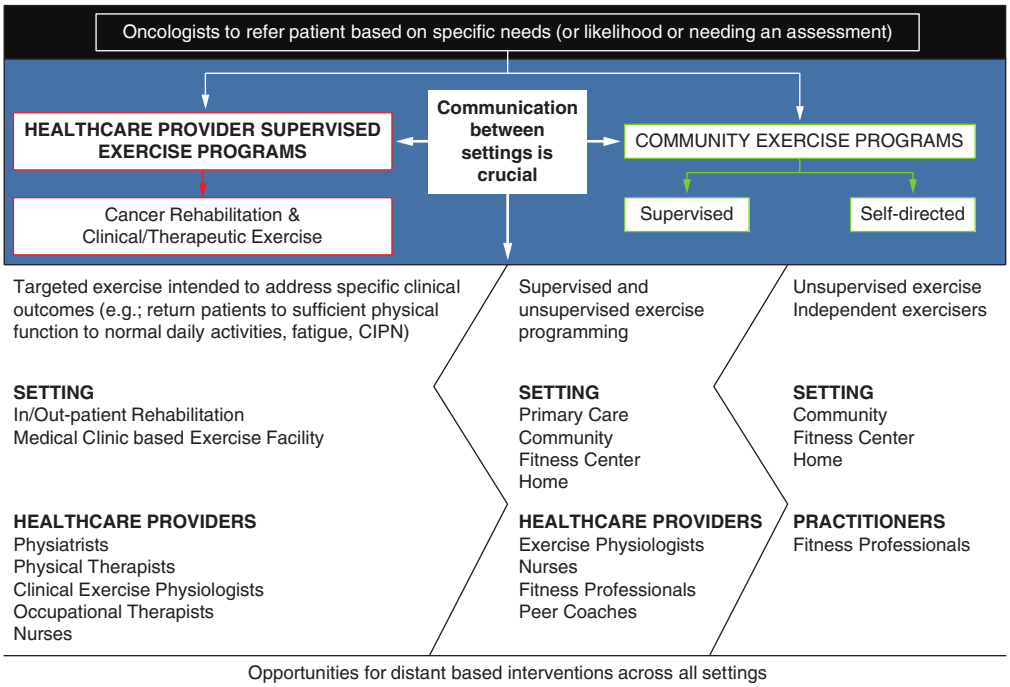

FIGURE 67–4 Different programming models for the referral of patients and delivery of exercise prescriptions.[110] CIPN, chemotherapy-induced peripheral neuropathy. (Reproduced with permission from Schmitz KH, Campbell AM, Stuiver MM, et al: Exercise is medicine in oncology: Engaging clinicians to help patients move through cancer, *CA Cancer J Clin* 2019 Nov;69(6):468-484.)

nutrition, and/or psychology, including stress-reduction strategies. Because of the multimodal programming and because patients often have functional impairment, it is beneficial to have physiatrist oversight for prehabilitation. At MDACC, prehabilitation is offered to patients who may have impairments or are at high risk of functional decline with treatment. Referrals are made to the PM&R, clinic where patients are evaluated by a physiatrist, physical therapist, and if indicated, a counselor (Fig. 67–6). In general, exercise interventions may be delivered by a physical therapist, occupational therapist, certified exercise trainer, or exercise physiologist. The exercise prescription should include a combination of aerobic and strengthening exercises and should often follow, and may exceed, the ACSM exercise guidelines for cancer survivors.[101] In a single-arm study demonstrating feasibility of exercise in 50 patients with potentially resectable pancreatic cancer, preoperative exercise resulted in improved functional capacity and lower limb strength, and physical activity was associated with improved health-related quality of life.[112]

Along with improving patient outcomes, prehabilitation may improve healthcare costs by decreasing length of stay, reducing post-treatment complications, and reducing hospital readmission. In a randomized trial that enrolled 101 patients with lung cancer in a 7-day high-intensity inpatient prehabilitation exercise program, the intervention group had a significantly lower incidence of postoperative pulmonary complications, shorter length of stay, and shorter postoperative stay when compared with the control group.[113] In a multidisciplinary prehabilitation program for elderly patients (≥75 years of age) with stage I–III colorectal cancer compared with historical controls, prehabilitation was associated with reduced cardiac postoperative complications, shorter length of stay, and trend toward lower 1-year mortality.[114] In a small cohort of patients with locally advanced esophageal cancer undergoing multimodal prehabilitation (physical exercise, nutrition optimization, and psychosocial support), patients had fewer admissions during neoadjuvant treatment and reduction in the hospital readmission rate.[115]

Because of improved cancer detection and increasingly effective cancer therapies, there is a growing population of cancer survivors who benefit from optimization of physical activity throughout the continuum of their cancer care via prehabilitation or rehabilitation programs.

PRACTICAL ASPECTS OF CANCER REHABILITATION

Lymphedema

Malignancy (including breast, melanoma, gynecologic, lymphoma, and urologic cancers) is the most common cause of secondary lymphedema in the United States. Lymphedema can be caused by a combination of the patient's cancer, along with its surgical and radiation

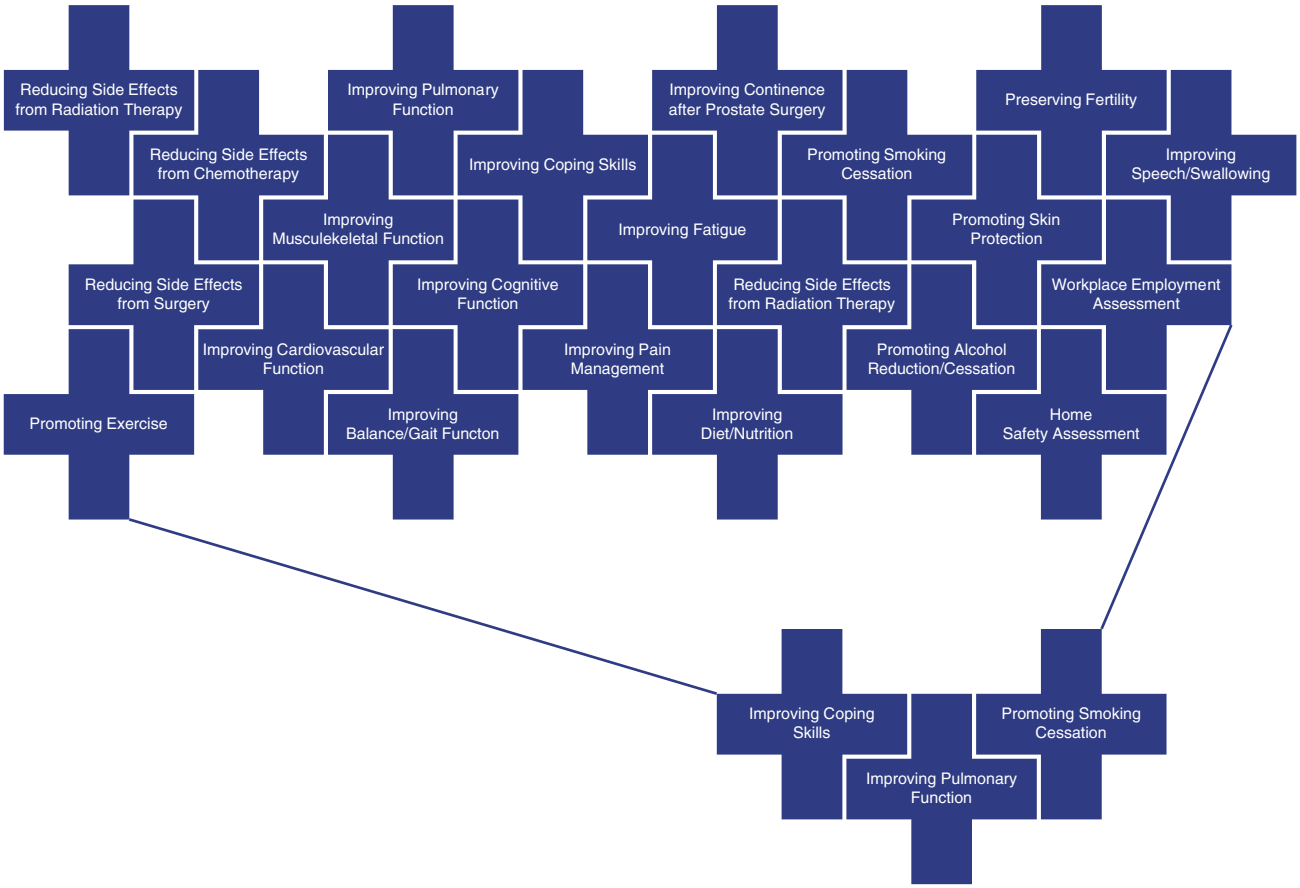

FIGURE 67–5 Examples of components of unimodal or multimodal prehabilitation programs. Pieces of this puzzle can be put together to design a prehabilitation program addressing the specific needs of the patient. (Reproduced with permission from Silver JK, Baima J. Cancer prehabilitation: an opportunity to decrease treatment-related morbidity, increase cancer treatment options, and improve physical and psychological health outcomes, *Am J Phys Med Rehabil* 2013 Aug;92(8):715-727.)

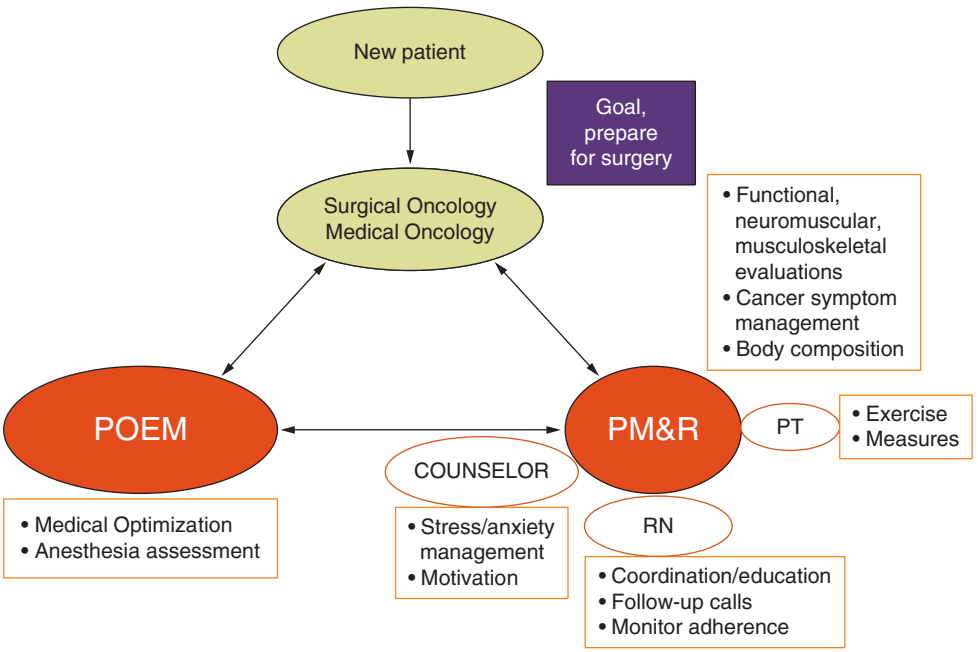

FIGURE 67–6 The MDACC model of prehabilitation with oversight by PM&R to address functional issues to prepare patients for their cancer treatments. PM&R, physical medicine and rehabilitation; POEM, Perioperative Evaluation & Management (includes internal medicine and the anesthesia assessment clinic); PT, physical therapist; RN, registered nurse.

treatments. Breast cancer is the leading cause of upper-extremity lymphedema in the US and develops in 2% to 40% of patients after surgery, radiation, or both.[116,117] The majority of cases are diagnosed clinically, but the differential diagnosis may include DVT, venous insufficiency, myxedema, lipedema, heart failure, kidney failure, and hypoproteinemia. In cases difficult to diagnose, lymphoscintigraphy is the gold standard imaging modality.

Treatment typically starts with one or more conservative techniques, such as manual lymph drainage, compression garments, and pneumatic compression devices. Patients are taught a home lymphedema care regimen to perform daily over several sessions by lymphedema-certified physical or occupational therapists. Periodic follow-ups with measurements are conducted to ensure adherence to the prescribed regimen and to track any changes in their lymphedema. Progression can be measured by volumetric/circumferential measurements, bioelectric impedance, tonometry, and/or perometry. In severe or refractory cases, surgical options such as microsurgery (eg, lymph node transfer or lymphovenous anastomosis/bypass), liposuction, and debulking may be considered.

Pressure Ulcers

According to the National Pressure Ulcer Advisory Panel (NPUAP), a pressure ulcer is an area of unrelieved pressure over a defined area, usually over a bony prominence, resulting in ischemia, cell death, and tissue necrosis. Incidence of pressure ulcers in the acute care setting is 7% to 9%; long-term care incidence is estimated to be between 3% to 31%; home care estimates incidence at 0% to 17%. Patients with cancer have several risk factors that place them at risk of pressure ulcer development (Table 67–2).

The NPUAP staging system for pressure ulcers includes the following:

- Stage I: intact skin with nonblanchable redness of a localized area, usually over a bony prominence.
- Stage II: partial-thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough.
- Stage III: full-thickness tissue loss, subcutaneous fat may be visible, but bone, tendon, or muscle is not exposed.
- Stage IV: full-thickness tissue loss with exposed bone, tendon, or muscle.
- Unstageable: full-thickness tissue loss with slough or eschar covering the wound bed—may become stageable once slough or eschar diminishes to reveal wound bed.
- Deep tissue injury: localized discolored intact skin or blood-filled blister caused by damage of underlying soft tissue from pressure or shear forces.

Table 67–2 Risk Factors for Pressure Ulcer Development

Impaired proprioception	Decreased activity	Impaired mobility
Decreased nutrition	Friction/shear forces	Advanced age
Male gender	Low body-mass index	Urinary or fecal incontinence
Fever/sepsis	Hypotension	Dehydration
Anemia	Immunosuppression	Renal failure

The mainstay of pressure ulcer treatment is the offloading of pressure. This is accomplished by a turning schedule at least every 2 hours while the patient is in bed and frequent position changes up to every 15 minutes when they are seated in a chair or wheelchair.

Other interventions include the use of appropriate support surfaces for the bed and wheelchair, nutritional consultation, PT and OT for mobility issues, and addressing incontinence. Topical dressings may be used based on wound characteristics (Table 67–3). Surgical treatment can include sharp debridement of devitalized tissue if the patient's immune status allows, and plastic surgery intervention may include flap coverage. If available, wound care nursing specialists can also assess the wound and help guide treatment recommendations.

Pressure ulcer healing will also depend on improvement in the patient's overall health and medical condition. Healed ulcers can have decreased tissue tolerance and are at risk for reinjury without ongoing prevention measures. Patients should be monitored throughout cancer treatment for signs of skin compromise or wound degradation.

Thrombocytopenia

Thrombocytopenia, along with the suppression of other blood cell lines, is commonly seen in patients with cancer. These findings are especially frequent in patients receiving chemotherapy or extensive irradiation, with resulting myelosuppression, bone marrow infiltration, and splenomegaly. Hematologic malignancies introduce a variety of associated complications that previously limited implementation of intensive rehabilitation programs with patients at greatest risk. A rehabilitation or exercise program in a severely thrombocytopenic patient remains somewhat controversial, with the major concern being development of a spontaneous bleeding event (eg, intracranial hemorrhage).

Dimeo et al monitored patients during a 6-week intensive aerobic exercise program after high-dose chemotherapy and autologous stem cell transplantation.

Table 67–3 Examples of Wound Dressings

Wound Characteristic	Type of Topical Dressing
Scant or small amounts of drainage	Foam dressing, hydrocolloid, gel/gauze dressing, composite dressing, transparent film
Moderate drainage	Foam dressing, calcium alginate, or hydrofiber
Deep wounds	"Filler" dressing followed by a cover dressing
High drainage	Negative pressure drainage management system, calcium alginate/foam dressing combination, and increased frequency of dressing changes

The investigators did not exclude for neutropenia, anemia, or thrombocytopenia, but they observed no adverse effects. Based on this initial study, the authors proposed using lower limit thresholds of 20,000/μL for platelet counts and 1500/μL for leukocyte counts for safely engaging in a rehabilitation program.[118] With platelet counts over 5000/μL, another study found fatal intracranial hemorrhage in only 1 of 92 patients receiving chemotherapy.[119]

No clear guidelines exist but one recommendation is to allow nonresistive activities and ambulation at platelet counts above 5000/μL and light resistive exercises with counts above 10,000/μL.[120] In addition, platelet transfusions with counts below 10,000/μL should be performed in patients undergoing comprehensive rehabilitation. Clinicians use these values to guide the therapy intervention but apply clinical judgment about how strictly to adhere.

Durable Medical Equipment

Patients with cancer may have a number of rehabilitation-related DME needs, both as inpatients and outpatients. Many are covered by Medicare and third-party payors when patients demonstrate the appropriate need. These can include but are not limited to orthotic (arm, leg, back, and neck braces) and prosthetic prosthetic limbs canes, commode chairs, continuous passive motion machines, crutches, patient lifts, reachers, tub benches, walkers, wheelchairs, and power mobility devices. Table 67–4 lists several commonly prescribed pieces of equipment with a few of their most common indications. Many variations exist within the categories of orthotics and DMEs mentioned. Thus, consultation between a trained physiatrist, therapist, and orthotist may be required to ensure adequate performance, safe mobility, and optimization of self-care.

Survivorship

As of January 2019, it is estimated that there are 16.9 million Americans who are cancer survivors. That number is expected to increase to 26.1 million by 2040.[121] A cancer survivor is any person diagnosed with cancer, from the time of initial diagnosis until his or her death.[122] This definition includes patients receiving active treatment for malignant disease. The number of long-term cancer survivors without evidence of disease is also growing, and these long-term

Table 67–4 Commonly Prescribed Orthotics and Durable Medical Equipment

Prescribed equipment	Common indications
Ankle foot orthosis (AFO)	Ankle dorsiflexion weakness or "foot drop"
Neutral wrist hand orthosis	Median neuropathy at the wrist or "carpal tunnel syndrome"
Shoulder sling	Hemiparesis with shoulder pain caused by glenohumeral subluxation
Thoracic Lumbar Sacral Orthosis (TLSO)	Mild spinal instability or vertebral compression fractures
Rolling walker	Impaired mobility, balance, or proprioception
Hemi-walker	Hemiparesis with impaired mobility or balance
Manual wheelchair	Unsafe gait, poor endurance
Bedside commode	Impaired transfers to/from toilet
Sliding board	Impaired transfers in/out of bed or chair
Tub transfer chair	Impaired transfers in/out of shower
Shower chair	Poor endurance, impaired ADLs
Reacher	Impaired mobility or ADLs

survivors are left with a multitude of disabilities acquired during their cancer treatment. Rehabilitation can help patients with hemiparesis,[123] neuropathy/plexopathy,[124] myopathy,[125] chronic fatigue,[126] RFS,[127] postmastectomy pain syndrome, cognitive deficits,[128] lymphedema,[129] spasticity,[130] cervical dystonia,[131] trismus,[132] and chronic musculoskeletal pain.[72] Once the focus has shifted from surviving cancer to recovering quality of life, rehabilitation often plays an integral role. The bulk of the growth in the field of cancer rehabilitation over the past several decades has been surrounding the growth in the numbers of long-term cancer survivors. This rehabilitation is predominantly provided in outpatient clinics.

Eliminating Barriers

Physiatrists are optimally trained to facilitate a patient's transition from illness and its associated medical care to home with functional restoration. With the appropriate tools and resources, physiatrists can modify, support, or eliminate impairments. In general, musculoskeletal injuries are among the most common causes of disability and contribute to a great deal of functional impairment. In a population of patients with cancer, these injuries may be overlooked because of the presence of more serious illnesses, but a well-trained physiatrist is equipped to detect, diagnose, and treat them. If resolution of an impairment is feasible and presents relatively low risk, treatment should be pursued to alleviate activity limitations (Table 67–5). If treatment is inappropriate or not feasible, a physiatrist may employ alternative strategies, such as orthotics or DMEs, to reduce the burden of activity limitations and participation restrictions.

Employment-Related Disability Management and Return to Work

It has been reported that 38% of cancer survivors are of working age.[133] Increasing survivorship among patients with cancer has led to an increased focus on a return to work and disability. Survivors frequently wish to return to work for continued insurance benefits, income, and self-esteem. Quality of life assessments also show that employed cancer survivors have a higher quality of life. Employment provides a sense of normalcy and control when cancer takes control away from other aspects of their lives.[134] However, many cancer survivors are unable to work secondary to the effects of chemotherapy or radiation, delayed recovery after surgery, the tumor itself, and symptoms associated with the tumor. Survivors may report an inability to return to work for a variety of reasons including fatigue, physical limitations, emotional problems, changing personal priorities, cognitive deficits, awkward interaction with coworkers, and unsympathetic employers.[135]

Twenty percent of patients with cancer report some cancer-related disability. However, most employed patients with cancer do return to work after treatment. At 1 year, 73% are employed, and 84% are employed at 4 years post-treatment. Patients with CNS, head and neck, and stage IV hematologic cancers had the highest risk of disability. Risk factors for not returning to work include older age, female gender, lower level of education, and more physically demanding work. Of note, 87% reported that their employer was accommodating.[136] Of employed cancer survivors, 54% reported having to adjust their work schedule during their cancer treatment.[137]

The Americans With Disabilities Act of 1990 brought legislative protection to cancer survivors with disabilities by requiring employers to make "reasonable accommodation" for employees with disabilities and preventing discrimination in pay, hiring, firing, fringe benefits, and working conditions. It also requires employers to make accommodations for family members that are not an "undue hardship." Accommodations can include extended leave, flexible work schedules, permitting working from home, changing work environment, and allowing rest periods during the day.

If there is uncertainty about whether a cancer survivor can return to work, several options are available. If the primary concern is energy and endurance, the cancer survivor's hours can be started slowly and gradually increased each week, with the patient reporting any difficulties to the physician. When issues of coordination, strength, or endurance are uncertain, a functional capacity evaluation can be performed by an occupational or physical therapist. The evaluation can be useful for determining tolerance for lifting, bending, squatting, walking, and/or prolonged standing or sitting. Often the therapist is able to replicate the duties of the patient, simulate the work environment, and recommend ergonomic or environmental modifications as necessary.

When a return to work is not feasible, physicians may be asked to play a role in supporting claims for disability. Impairment and disability evaluations can often by complicated by considerable variation between objectively measured impairments and subjectively reported disability. Psychological, social, and behavioral factors must be recognized as significant contributors to the relationship between impairment and disability.

REHABILITATION AT THE END OF LIFE

Mackey described caregiver concerns, which can include fear of hurting the patient physically by moving them, fear of hurting themselves when moving or transferring the patient, and a lack of clarity regarding

Table 67–5 Adjunctive Diagnostic and Therapeutic Interventions That May Be Employed by a Trained Physiatrist[a]

Procedure	Indication	Common sites
Botulinum toxin injection for chemodenervation	Upper motor neuron or mixed motor neuron injury leading to spasticity or dystonia	Shoulder internal rotators Upper and lower extremity flexors Lower extremity adductors
	Migraine headache	Facial and suboccipital musculature Sternocleidomastoid, scalene, trapezius, levator scapularis musculature
	Spasmodic torticollis	Muscles of mastication Shoulder adductors and internal rotators
	Trismus Post-mastectomy syndrome Post-radiation muscle spasms	Location dependent
Phenol injection for chemical neurolysis	Upper motor neuron or mixed motor neuron injury leading to spasticity or dystonia	Terminal motor branch of femoral, obturator, tibial nerves
	Painful neuroma	Morton (intermetatarsal) neuroma Post-amputation neuroma
	Trigeminal neuralgia	Terminal branch of trigeminal nerve
	Spasmodic torticollis	Sternocleidomastoid, scalene, trapezius, levator scapularis musculature
Corticosteroid injection	Arthritis	Shoulder or knee joints
	Rotator cuff tendinopathy	Subacromial or glenohumeral space
	Bursitis	Subacromial, knee, or trochanteric bursae
	Adhesive capsulitis	Shoulder
	Carpal tunnel syndrome	Wrist
Hyaluronic acid injection	Degenerative arthritis	Knee joint
Trigger point injection	Muscle spasm with painful trigger points	Trapezius, levator scapularis, rhomboid musculature
Prolotherapy	Tendinopathy	Achilles or patellar tendons
	Fasciitis	Plantar fascia
	Enthesopathy	Origin of extensor carpi radialis brevis (ECRB) musculature for "tennis elbow"
Electrodiagnostic study	Foot drop Carpal tunnel syndrome Ulnar neuropathy Radiculopathy Brachial plexopathy Guillain-Barre syndrome Peripheral mono- or polyneuropathy of unknown origin	Nerve conductions and needle electromyography of upper and/or lower extremities +/- paraspinal musculature
Diagnostic dynamic ultrasound	Tendinopathy	Rotator cuff, Achilles, gluteus medius, patellar tendons ECRB
	Enthesopathy	Subacromial, greater trochanteric, pes anserine bursae
	Bursitis	Popliteal fossa
	Baker's cyst Carpal tunnel syndrome	Median nerve proximal to and within carpal tunnel

[a]Not intended to serve as an exhaustive list.

how hard to push the patient. Family education in transfer training and positioning can decrease caregiver stress of providing care as well as the patient's concern about being a burden.

In the end-of-life setting, the practices of cancer rehabilitation and palliative care share several similarities. Both support quality of life and strive to relieve discomfort. The framework for intervention can be similar with a multidisciplinary team to comprehensively assess and treat the patient. Both have an emphasis not only on the disease process, but also on physical symptoms, limitations of the patient, and how to improve or relieve them. Both also emphasize the family in patient care and education. Rehabilitation interventions at the end of life can include mobility and ADL training, positioning and pressure relief techniques, chest physiotherapy, swallow therapy, edema management, physical modalities to treat pain, and bracing and splinting to relieve pain and assist with mobility.

FUTURE OF CANCER REHABILITATION

Cancer rehabilitation has suffered from under-referrals by oncologists and lack of availability at many cancer centers.[138] Cancer rehabilitation education is still lacking in PM&R departments.[139] However, the field has experienced tremendous growth and increasing acceptance over the past decade. Cancer rehabilitation has become increasingly viewed as important by physiatry academic departments across the United States.[138] Furthermore, cancer rehabilitation research publications have grown at a significantly faster rate than the whole field of rehabilitation.[140] However, more research is needed, and discussions among cancer physiatrists are ongoing to establish core services offered by cancer rehabilitation professionals, because this is still widely variable across healthcare systems.

MD ANDERSON PRACTICE TIPS

- Physiatrist-led rehabilitation programs should be included at comprehensive cancer centers. Rehabilitation services include PT, OT, and speech-language pathology. Referrals to these specialists may be considered at any point in the continuum of care.
- Prehabilitation has emerged as an important step in improving outcomes in surgical oncology patients and most often include physical-activity recommendations, nutrition optimization, and/or psychosocial interventions.
- The Boston University Activity Measure for Post-Acute Care (AM-PAC) is widely used in rehabilitation for monitoring physical function, including mobility and ADLs. The Six-Clicks Basic Mobility and Daily Activity assessments are quick to administer and may be helpful tools to monitor for changes in function in hospitalized patients, and signal the need for closer intervention.
- Neurorehabilitation for patients with malignancy involving the brain or spinal cord is key in facilitating recovery. Functional outcomes in this patient population are similar to what is seen in noncancer neurorehabilitation patients.
- If a patient has painful or function-limiting radiation-induced muscle fibrosis, a consultation to a physiatrist experienced in cancer rehabilitation is warranted. Treatment options include PT, OT, topical medications, optimization of oral pain medications and muscle relaxants, and procedures such as trigger point injections or chemodenervation with botulinum toxin.
- As per the American College of Sports Medicine's 2019 update, cancer survivors should engage in at least 30 minutes of moderate-intensity aerobic exercise at least three times per week, for at least 8 to 12 weeks. In addition, cancer survivors should engage in strengthening exercises at least two times per week, using at least two sets of 8 to 15 repetitions of weights at 60% or more of their one-repetition maximum. Referral to a rehabilitation or oncology exercise specialist is recommended if there are safety concerns.

68 Pain Management and Symptom Control

Kaoswi K. Shih
Rony Dev
Shalini Dalal

KEY CONCEPTS

- Patients with cancer experience multiple symptoms that are often under-reported and not alleviated. Symptoms are often interrelated and can be both physical and/or psychological.
- Pain expression can be modified by cognitive and psychological factors associated with advanced disease or the dying process.
- A thorough psychosocial history, assessment of mental status, and screening with risk assessment tools for nonmedical opioid use is critical before prescribing opioid analgesics.
- Fatigue is the most common symptom in patients with advanced cancer and its treatment is challenging in later stages of disease. Patients and families benefit from education about the burdens of both physical and emotional fatigue. It can be helpful to modify daily activities and rest to accommodate for symptoms of fatigue as well as optimizing nutrition and hydration.
- Dyspnea is often an indicator of poor prognosis in advanced cancer. Initial management includes treating underlying causes medically when able. Palliative measures to reduce the sensation of air hunger include low flow supplemental oxygen for those with hypoxemia, opioids, or corticosteroids.
- Anorexia and weight loss are a result of systemic inflammation and inadequate caloric intake because of cancer and are often difficult to reverse. Psychosocial support for cachectic patients and their family caregivers can help diminish patient-family distress.
- Advanced care planning can decrease anxiety and suffering of patients and families as well as ensure autonomy for patients, especially if they become unable to express informed consent. However, it is an ongoing process that is best started early, revisited periodically, and incorporates room for change owing to unforeseen changes in the patient's clinical condition.

Cancer is frequently associated with a multitude of distressing physical and psychosocial symptoms that can occur throughout the disease trajectory.[1] Access to a multidisciplinary supportive care team is imperative for patients with cancer experiencing multidimensional symptoms including pain, lack of energy, fatigue or drowsiness, dry mouth, dyspnea, anorexia and weight loss, insomnia, changes in mood, constipation, and delirium.[2] Without optimal symptom control in patients, administration of anticancer therapies may be delayed or discontinued, quality of life will be diminished, and unnecessary suffering will increase (Fig. 68–1).

CANCER PAIN

Forty-two percent of patients seen in the outpatient cancer center[1] and 50% of hospitalized patients with cancer have been reported to have uncontrolled pain.[3] In patients with cancer, pain may be the only symptom present before diagnosis and can indicate the recurrence and/or spread of disease.

As many as 30% to 50% of patients receiving active anticancer therapy experience pain.[1] Pain resulting from the tumor burden occurs in approximately 65% to 85% of patients with advanced cancer.[4] In addition, cancer treatment with chemotherapy, radiation, or surgery accounts for the remaining etiology of pain in approximately 15% to 25 % of patients. Three percent to 10% of patients with cancer have chronic nonmalignant pain syndromes similar to the general population (eg, low back pain associated with degenerative disc disease).[5]

Cancer pain can be described by its timing including acute versus chronic, intermittent versus continuous, as well as by its intensity or severity. Pain can be further

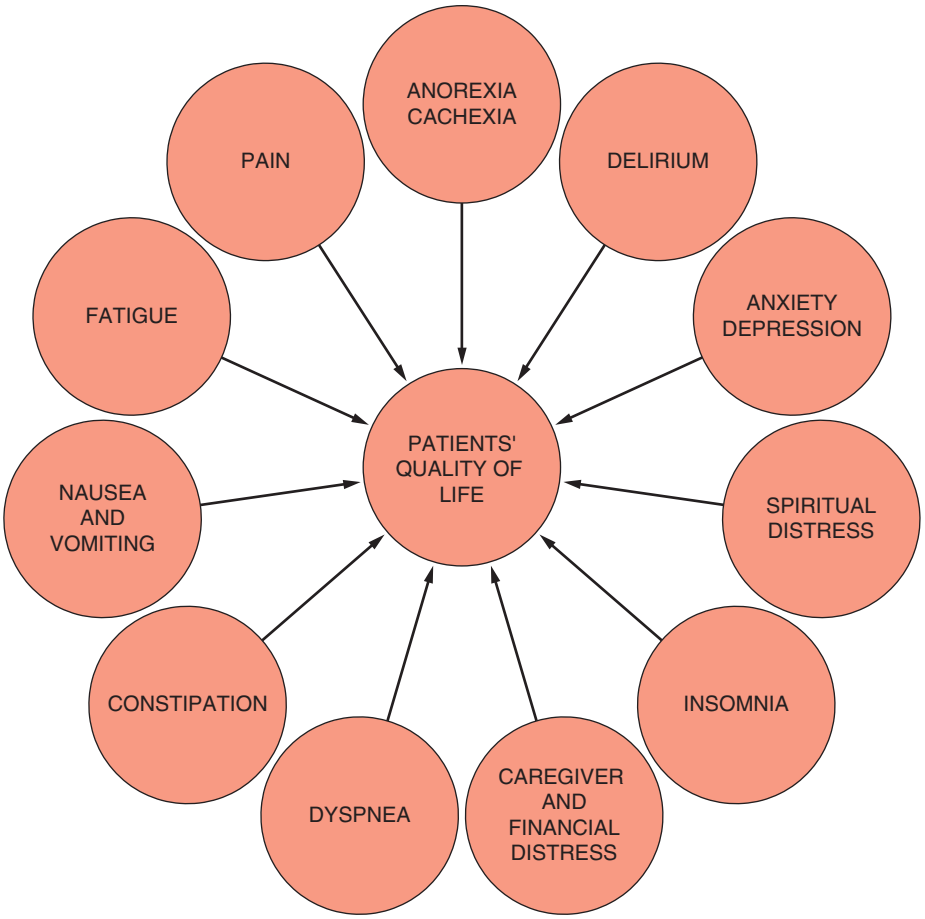

FIGURE 68–1 **Multidimensional Symptoms Impacting Quality of Life.**

categorized based on pathophysiology such as tumor related, complication of chemotherapy, radiation or surgery, or noncancer pain syndrome.

Pathophysiology

The pathophysiologic classification of pain forms the basis for therapeutic choices. Pain may be broadly divided into pain associated with ongoing tissue damage resulting in stimulation of pain receptors (nociceptive) and pain resulting from nervous system dysfunction (neuropathic) (Fig. 68–2).[6] Nociceptive pain can be classified as either somatic or visceral and results from the activation of nociceptors in cutaneous or deep tissues. Multinational data recently revealed that 72% of cancer pain is somatic, whereas 35% is described as visceral, and 40% is characterized as neuropathic.[7] Nociceptive somatic pain can be experienced as localized aching or throbbing and gnawing discomfort (eg, pain related to bony metastases). Visceral pain is the result of activation of nociceptors resulting from distention, stretching, and inflammation of internal organs, such as right upper quadrant abdominal pain due to the stretching of the liver capsule. Visceral pain is often poorly localized discomfort, described as a deep aching, cramping, and/or pressure-like sensation.

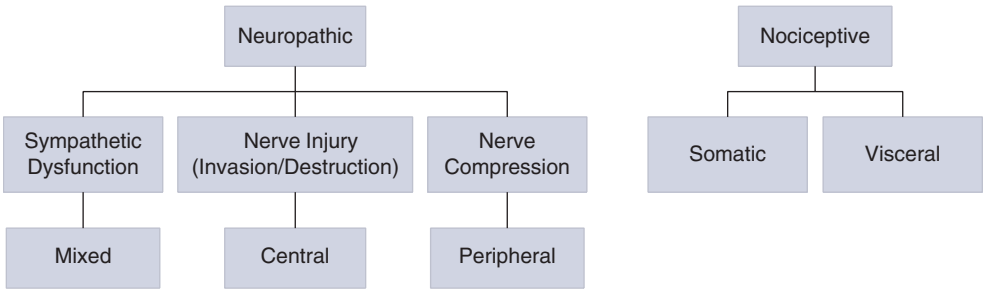

FIGURE 68–2 **Pathophysiologic Classification of Pain.**

Classification of pain can help guide selection of appropriate interventions to improve pain control. Pain mechanism, incidental occurrences, psychological distress, history of substance or opioid use disorder, and cognitive dysfunction have been indicated to be factors associated with higher ratings of pain intensity.[8] The revised Edmonton Classification System for Cancer Pain characterizing these factors has been used at our institution to guide pain management (Fig. 68–3).

1. Mechanism of pain	
No	No pain syndrome
Nc	Nociceptive pain
Ne	Neuropathic pain with or without nociceptive pain
Nx	Insufficient information to classify
2. Incident pain	
Io	No incident pain
Ii	Incident pain Present
Ix	Insufficient information to classify
3. Psychological distress	
Po	No psychological distress
Pp	Psychological distress present
Px	Insufficient information to classify
4. Addictive behavior	
Ao	No addictive behavior
Aa	Addictive behavior present
Ax	Insufficient information to classify
5. Cognitive function	
Co	No cognitive impairment
Ci	Partial cognitive impairment[1]
Cu	Total cognitive impairment[2]
Cx	Insufficient information to classify

[1]Sufficient impairment to affect patient's ability to provide accurate present and/or past pain history.
[2]Patient unresponsive, delirious, or demented to the stage of being unable to provide and present and past pain history.

FIGURE 68–3 Edmonton System of Classification of Cancer Pain. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. MD Anderson Cancer Center; 2002.)

Breakthrough pain is defined as a transitory exacerbation of discomfort that occurs on a background of stable persistent chronic pain. Causes of breakthrough pain include end-of-dose failure of an opioid or pain exacerbated by activity or spontaneous occurrence. Breakthrough pain is also characterized by a short duration, often less than 3 minutes in 43% of cases according to previous prospective surveys.[9]

Pain Assessment

Pain can be measured by using visual, analog, verbal, or numerical scales and, in the research setting, complex pain questionnaires.[10] The Edmonton Symptom Assessment Scale is a useful assessment tool that allows patients to rate average pain intensity from 0 to 10 over the past 24 hours, where 0 signifies no pain and 10 is the worst pain imaginable (Fig. 68–4). However, pain assessment needs to take into account other symptoms experienced by patients with cancer because they are often interconnected and can affect symptom expression. For example, pain expression can be influenced by psychological distress or delirium which can be misinterpreted as worsening physical pain.[11,12]

In 1984, the World Health Organization (WHO) proposed an analgesic ladder for the pharmacologic management of cancer pain[13] and recommended the simple principle of escalating from nonopioid to strong opioid analgesics (Fig. 68–5). Other guidelines have been published such as the Analgesic Quantification Algorithm and National Comprehensive Cancer Network guidelines for treating cancer pain.[14]

Principles of Management

- Assess pain syndromes and other symptoms accurately.
- Respect and accept the complaint of pain as real.
- Treat pain appropriately.
- Treat underlying disorders.
- Address psychosocial concerns.
- Multidisciplinary approach is essential.

Principles of Pharmacotherapy

- Match drug to pain syndrome.
- Low threshold to prescribe opioids.
- Sustained-release formulations for constant, chronic pain and short acting for breakthrough discomfort for pain from cancer.
- Adjunct medications for certain pain syndromes.
- Oral analgesics where possible.
- Intravenous route for acute titration.

No Pain	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Pain
No Fatigue	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Fatigue
No Nausea	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Nausea
No Depression	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Depression
No Anxiety	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Anxiety
No Drowsiness	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Drowsiness
No Shortness of Breath	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Shortness of Breath
Best Appetite	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Appetite
Best Sleep	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Sleep
Best Feeling of Well-Being	0	1	2	3	4	5	6	7	8	9	10	Worst Possible Feeling or Well-being
No Financial Distress	0	1	2	3	4	5	6	7	8	9	10	Worst Financial Distress
No Spiritual Pain	0	1	2	3	4	5	6	7	8	9	10	Worst Spiritual Pain

Completed By: Patient Family

0 = No Symptom; Best 10 = Worst Imaginable on average in the past 24 hours

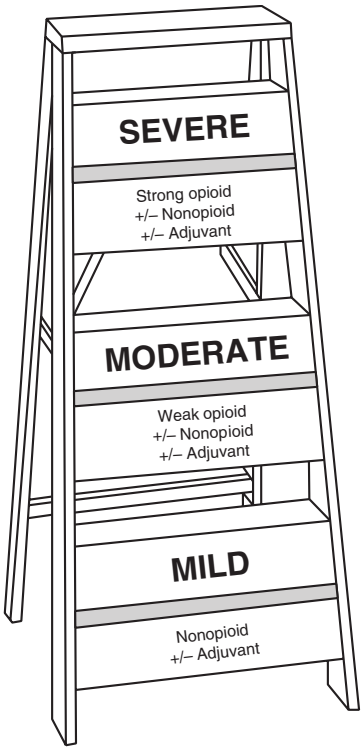
FIGURE 68–4 Edmonton Symptom Assessment Scale.

- Treat side effects before switching opioids (unless causes for rotation, see below "Opioid Rotation").
- Sequential opioid trials are often beneficial.
- Familiarize with equianalgesic dosing.
- Familiarize with the pharmacokinetics of opioids.
- Differentiate between tolerance, physical dependence, chemical coping, and opioid use disorder.
- Caution with opioid titration in the setting of renal impairment.

Constipation Prevention and Treatment

A bowel regimen should always be prescribed with an opioid prescription.

- Always include stool softeners and laxatives to prevent opioid-induced constipation.
- Preferred choices include sennosides and polyethylene glycol.
- Decreased motility (gastroparesis) is a common side effect of opioids and can be treated with metoclopramide.
- Activity and adequate hydration are important.
- Bulking agents without a pro-kinetic may worsen constipation.
- Refractory constipation may be managed with lactulose 30 mL by mouth every 6 hours until a large bowel movement occurs.
- Intractable cases may require a suppository or enema.



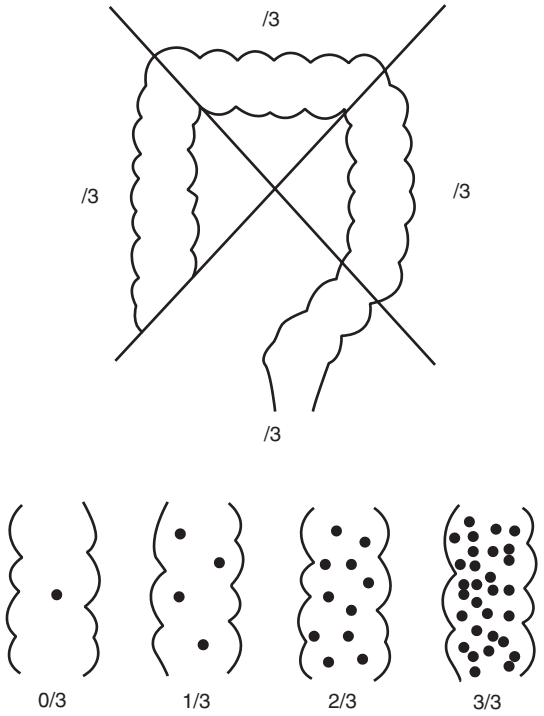


FIGURE 68–5 WHO (World Health Organization) 3-Step ladder for oral analgesic management of pain. (Reproduced with permission from World Health Organization. Cancer Pain Relief. Geneva, Switzerland: World Health Organization, 1986.)

On a flat abdominal x-ray, draw two diagonal lines intersecting at the umbilicus as shown here. This transects the abdomen into four quadrants corresponding to the ascending, transverse, descending, and rectosigmoid colons. Then, assess the amount of stool in each of the four quadrants using the following scoring system: 0 = no stool; 1 = stool occupying <50% of the lumen of colon; 2 = stool occupying >50% of the lumen; 3 = stool completely occupying the lumen. The total score will therefore range from 0 to 12. A score of 7 indicates severe constipation and requires immediate intervention.

FIGURE 68–6 Constipation score via objective assessment of fecal load on an abdominal radiograph. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

- Proximal impaction may require oral laxatives.
- Cases where hard stools are present in the vault may necessitate manual dis-impaction.
- The degree of constipation may be evaluated with imaging (Fig. 68–6).

Opioid Rotation

Defined as switching from one type of opioid to another, often in the setting of opioid neurotoxicity.

Reasons to rotate opioids:

- Uncontrolled pain despite escalating opioid doses.
- Development of tolerance or dose-limiting side effects of opioid neurotoxicity (sedation, hallucinations, confusion, myoclonus).
- Hyperalgesia as a result of the production of excitatory amino acids from the opioid itself.
- Cost necessitating alternate opioid.

Opioid rotation has been reported to not only improve pain control, resolve delirium, and alleviate myoclonus, but it may also improve other symptoms including depression and insomnia (Table 68–1).[15]

In a recent study of an outpatient population of 114 cancer patients at MDACC with a mean Eastern Cooperative Oncology Group performance status of 1, opioid rotation for side effects or uncontrolled pain achieved improved symptom control successfully in 65% of the patient population.[16]

Individual variability of opioid activation of multiple subtypes of opioid receptors accounts for the benefits of opioid rotation, which should be considered when managing uncontrolled pain.[17,18] In difficult cases, this may include rotation on two to three occasions to reduce opioid neurotoxicity and improve pain control.

General guidelines for opioid rotation:

1. Calculate total daily dose.
2. Calculate dose of new opioid using opioid conversion table (Table 68–2).
3. Reduce dose of new opioid to account for incomplete cross-tolerance.

Table 68–1 Commonly Used Opioids

Drug Usual Starting Dosages
Full opioid agonists
Morphine[a] 15–30 mg PO every 3–4 h
Morphine extended release (MScontin) 15–30 mg PO every 8–12 h
Hydromorphone (Dilaudid) 2–4 mg PO every 4–6 h
Hydromorphone extended release (Exalgo) 8–16 mg PO every 12–24 h
Fentanyl (Duragesic) 12–25 µg/h TD changed every 48–72 h
Codeine 15–30 mg PO every 3–4 h
Oxycodone (Percodan and others) 5–10 mg PO every 3–4 h
Oxycodone extended release (OxyContin) 10–20 mg PO every 3–4 h
Meperidine (Demerol hydrochloride) 75–100 mg IM q 3–4 h
Methadone hydrochloride (Dolophine)[b] 5–10 mg PO every 3–4 h
Partial agonists and mixed agonists/antagonistsc
Nalbuphine (Nubain) 10 mg IV q 3–4 h
Butorphanol (Stadol) 0.5–2 mg IV q 3–4 h
Buprenorphine 5µh/h topical patch every week or 1–2 mg SL 3×/d

[a]Morphine can be given as an immediate-release or sustained-release preparation. It is recommended that a relatively rapid onset, short-acting opioid preparation (such as immediate-release morphine) be given to patients who take sustained-release morphine to provide rescue medication for breakthrough pain.
[b]Methadone is 10 to 15 times more potent than morphine. Expertise is needed to prescribe and administer it.
[c]This class of drugs is *not* recommended for the management of chronic cancer pain because it will reverse analgesia when coadministered with full opioid agonists and precipitate withdrawal in physically-dependent individuals.
IM, intramuscular; IV, intravenous; PO, by mouth.

Table 68–2 Opioid Conversion Table

IV MO	PO MO	1:2.5
IV HM	PO HM	1:2.5
PO HM	PO MO	1:5
IV HM	IV MO	1:5
PO Oxymorphone	PO MO	1:3
PO Oxycodone	PO MO	1:1.5
PO HCD	PO MO	1:1 at ≥ 40 mg HCD/day
PO HCD	PO MO	1:1.5 at <40 mg HCD/day
Fentanyl patch	PO MO	Fentanyl Patch × 2.5 = PO MO
IV FENT	IV MO	15 µg: 1 mg

Steps for conversion: (1) take the total amount of opioid that effectively controls pain in 24 hours; (2) multiply by conversion factor in table; give 30% less of the new opioid to avoid partial cross-tolerance; (3) divide by the number of doses per day.
HCD, hydrocodone; HM, hydromorphone; MO, morphine.

Opioids

Codeine

Codeine is a prodrug used to treat mild to moderate pain, diarrhea, and intractable coughing spells. It is the second most common alkaloid in opium and is hypothesized to be 200 times less potent than morphine. Metabolism by the liver converts 90% of the drug to inactive metabolites and 10% as morphine. The cytochrome oxidase 2D6 (*CYP2D6*) gene is responsible for the conversion to morphine and, in some groups, may not be fully active, whereas others may express multiple copies of the gene and are considered ultrarapid metabolizers.[14] These ultrarapid metabolizers pose a greater risk of opioid neurotoxicity because of the codeine rapidly metabolizing into morphine, especially in the pediatric population. On the other hand, patients who have decreased metabolization may experience ineffective analgesia with the drug.

In addition, some medications are CYP2D6 inhibitors and block conversion of codeine to morphine when coadministered. These include antidepressants paroxetine, fluoxetine, bupropion, and diphenhydramine. Medications known to increase *CYP2D6*, such as dexamethasone, should also be used with caution with codeine (Fig. 68–7).

Hydrocodone

Hydrocodone has historically been considered a weak opioid on the WHO ladder. It is manufactured commonly in combination with acetaminophen or

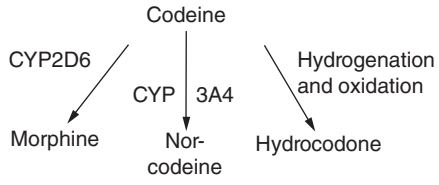

FIGURE 68–7 Codeine metabolism diagram.

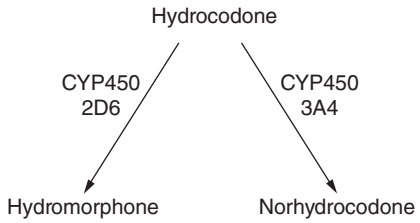

FIGURE 68–8 Hydrocodone metabolism diagram.

ibuprofen. It is a semisynthetic opioid derived from codeine and is metabolized by the liver and excreted in the urine. Hydrocodone is metabolized by cytochrome P450 2D6 to hydromorphone (Fig. 68–8). Recent studies have shown that hydrocodone, when taken at doses of less than 40 mg per day, is equivalent to twice the strength of morphine; however, the ratio of morphine to hydrocodone at doses greater than or equal to 40 mg per day have been shown to be closer to 1:1.[15]

Morphine

Morphine is commonly used as a standard prototype drug for opioid pain management. It is a naturally occurring opioid purified from opium poppy seeds and is available in short- and long-acting preparations. In the liver, it is converted to morhine-3-glucoronide and morphine-6-glucoronide (M3G and M6G, respectively) by glucuronyl transferase (Fig. 68–9). M3G is responsible for excitatory neurotoxic side effects including myoclonus, hallucinations, seizures, and confusion, and accumulates with renal insufficiency. Morphine is available as oral, rectal, intramuscular, intravenous, and sublingual preparations.

Hydromorphone

Hydromorphone is a semisynthetic opioid derived from morphine and is 6 to 7 times more potent. It is available for administration via all routes including neuroaxial. It may be an alternative to morphine when dose-limiting side effects require rotation to a more potent opioid. Long-acting formulations are available (trade name Exalgo) but are expensive.

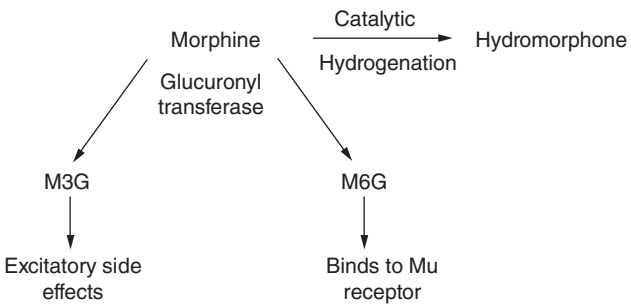

FIGURE 68–9 Morphine metabolism diagram.

Oxycodone

Oxycodone is another semisynthetic opioid derived from thebaine, a minor natural component of opium similar to morphine and codeine. Oxycodone has been known to be 1.5 times more potent than morphine. Previously its dosage was limited by its combination with acetaminophen or aspirin, but it is now commonly available in the US as oxycodone by itself as a pill. It has a higher bioavailability than morphine and exists both as extended-release and short-acting formulations.

Oxymorphone

Oxymorphone is produced after the *CYP2D6* metabolism of oxycodone. It is a semisynthetic opioid and, like oxycodone, is derived from thebaine. It has low bioavailability orally and is three times more potent than morphine. Its maximum serum concentration is reached in 30 minutes, and immediate-release tablets may last up to 6 to 8 hours. Extended-release oxymorphone lasts 12 hours and should be dosed as such because of its long half-life of 14 hours. Advantages of oxymorphone include its compatibility with either a venting gastrostomy-tube (administer by mouth and clamp tube for 30 minutes) or with a feeding tube (crush and administer immediate-release form via the tube every 8 hours as scheduled) as an option for a scheduled analgesic regimen. It should be noted that extended-release morphine, oxymorphone, and hydromorphone are all contraindicated in patients with partial or complete bowel obstruction and should be avoided in those at risk as well.

Meperidine

Meperidine (Demerol) is a weaker opioid with potency one-tenth that of morphine. Dose escalation is limited by the risk of accumulation of the metabolite normeperidine, metabolized by the liver. Both meperidine and nor-meperidine cause central nervous system toxicity including convulsions, especially in renal impairment and in the geriatric population. Because of these risks, it is becoming used less commonly.

Fentanyl

Fentanyl is a synthetic opioid that is 80 to 100 times more potent than morphine and has a rapid onset and short duration of analgesia. It is often used in the setting of acute or incidental breakthrough pain. Transdermal sustained-release formulations (fentanyl patches) are a good choice for stable pain and are changed every 72 hours. Fentanyl patches are convenient in patients

in whom oral routes are limited or unavailable. Oral transmucosal fentanyl has been used for breakthrough pain; however, fentanyl has a very rapid onset of action, which makes it difficult to calculate total dose delivered, and erratic equianalgesic dosing often raises safety concerns.

Methadone

Methadone is a synthetic opioid. Recent research[16] has characterized appropriate equianalgesic dosing,[17,18] and advantages include low cost, less active metabolites, good bioavailability, and *N*-methyl-d-aspartate antagonism, which may account for the absence of the development of tolerance associated with chronic use. Methadone potency can be 10 to 15 times that of morphine, so caution should be exercised when rotating to methadone. Close monitoring after its initiation is necessary because of its tendency to accumulate as time advances before reaching a steady state. The half-life varies with individuals between 15 to 190 hours. Clinicians prescribing methadone should be aware of potential drug interactions, because of metabolism via the cytochrome P-450 system, which include antifungals, antiretroviral medications, and selective serotonin reuptake inhibitors (SSRIs).[19] Methadone has also been associated with QTc interval prolongation,[20,21] so proper cardiac monitoring is indicated. Prospective studies at MDACC found it to be safe for use in advanced cancer.[11] It is being researched as a viable first-line treatment option for pain management[22] and is especially useful for patients with refractory cancer pain.[23]

Opioid Safety

Opioids can be a safe and effective analgesic for cancer pain treatment; however, adverse effects and unintended outcomes can still occur. It is important to conduct a thorough history that considers patient-related factors including age, renal and liver function, and drug interactions with concurrent medications that can cause altered opioid absorption, metabolism, or clearance that could potentially increase the risk of side effects.

Side effects of opioid analgesics include nausea, gastroparesis, constipation, drowsiness, cognitive impairment, hallucinations, myoclonus, allodynia, hyperalgesia, seizure disorder, QT prolongation with the use of methadone, bradycardia, hypotension, respiratory depression, urinary retention, xerostomia, sweating, pruritus, hormonal changes, and immunosuppression. Concurrent use of some medications can exacerbate these side effects, for example benzodiazepines which can increase sedation, alter mental status, or precipitate respiratory suppression.[24]

Other unintended outcomes include opioid use disorder or chemical coping. Opioid use disorder is defined as intentional use of a medication for nonmedical purposes that causes significant functional impairment or distress.[25,26] Symptoms of opioid use disorder include strong desire to use opioids, difficulty fulfilling obligations, and difficulty reducing use. Chemical coping is defined as inappropriate excessive use of opioids to cope with various stressful events including the disclosure of a cancer diagnosis and during treatment.[27–29]

Before starting prescribed opioids, it is important to screen patients with a comprehensive history covering psychosocial history and personal or family history of substance or opioid use disorder, as well as utilizing risk assessment tools. Examples include the Cut down, Annoyed, Guilty, and Eye-opener (CAGE) questionnaire; Screener and Opioid Assessment for Patients with Pain form; the Opioid Risk Tool; and Diagnosis, Intractability, Risks, and Efficacy (DIRE) inventory.

The CAGE questionnaire is clinician administered and asks about the patient's perceived:

1. Need to cut down on alcohol use.
2. Annoyance with questions about alcohol use.
3. Guilt over drinking habits.
4. Use of eye-opener drinks.[30]

For every "yes" answered, patients score 1 point with a cutoff score of 2 or greater being considered positive and with a sensitivity of 0.93 and specificity of 0.76 for identifying excessive alcohol use.[31] The CAGE-AID (adapted to include drugs) substitutes "drink" with "drink or drugs" to evaluate for the detection of substance use disorder and has a sensitivity of 0.88 and specificity of 0.55 with cut off score of 2.[32] A positive CAGE score may indicate increased risk for chemical coping and opioid use disorder. Other risk factors include being younger, male, having mental health or substance use disorders, and tobacco use. High-risk patients should have close follow-up and monitoring. Prescription drug monitoring programs that collect data from pharmacies that dispense controlled substances can also provide important information about patients' prescription history and past prescribers.

Urine drug screens (UDSs) may also provide additional means of monitoring (Table 68–3). Two main types are immunoassays and confirmatory testing. Immunoassays use antibodies to detect the presence of a specific drug or its metabolite. These are economical and have quick turnaround times but are unable to distinguish different drugs in the same class or detect synthetic opioids. Confirmatory tests use gas or liquid chromatography or mass spectrometry. These are able to detect specific drugs but are more expensive

Table 68–3 Abnormal Urine Drug Screen Results[a]

Results	Possible Indications
Absence of prescribed opioids	Diversion
Presence of unprescribed opioids	Multiple prescribers, opioids from unapproved sources
Presence of illicit drugs	Substance use disorder

[a]Data from Magnani B, Kwong T. Urine drug testing for pain management, *Clin Lab Med* 2012 Sep;32(3):379-390.

and have a slower turnaround time.[33] UDSs may still be underutilized in patients with cancer as opposed to persons with chronic pain.[24]

All patients should be given informed consent that communicates the potential risks and benefits of opioids and other controlled substances, as well as education on storage and proper disposal of opioid medications. Opioid management plans, contracts, or agreements can help outline goals, expectations, responsibilities of the clinician and patient regarding prescription, and monitoring at subsequent follow-up appointments. Safe practices include receiving opioids from one prescriber and designating one pharmacy for dispensing medication. Regular consistently scheduled appointments and random UDSs and prescription monitoring programs can assist with monitoring for adherence. Procedures if adherence is not maintained are also important to outline and convey to patients.[34]

Adjuvant Medications

Although opioids are often first-line analgesics, adjuvant medications are useful for pain control in some settings such as neuropathic pain. Because of the delay in onset and potential side effects with some drug groups, adjuvant drugs may be best reserved after optimal trials of opioids. Of the tricyclic antidepressants drug class, amitriptyline and nortriptyline are felt to be the most efficacious and have lower cardiovascular side effects. Tricyclic antidepressants are limited by anticholinergic and sedative side effects. Anticonvulsants are helpful in treating brachial and lumbosacral plexopathies, but side effects and safety limit their wide use. For the adjuvant treatment of neuropathic pain, gabapentin has been shown to be effective but does require dose adjustment in renal failure and can be associated with increased risk for sedation, altered mental status, and respiratory suppression. Pregabalin has been used as an alternative to gabapentin but is costly and has not shown greater efficacy (Table 68–4).

Table 68–4 Adjuvant Analgesics

Nonsteroidal Antiinflammatory Drugs
Acetaminophen
Aspirin
Ibuprofen
Naproxen
Celecoxib
Ketorolac
Tricyclic antidepressants
Amitriptyline
Nortriptyline
Doxepin
Doxeparin
Antiepileptic drugs
Gabapentin
Topiramate
Levetiracetam
Tiagabine
Oxcarbazepine
Lamotrigine
Felbamate

Nonpharmacologic Treatment

Adjuvant nonpharmacologic treatments include nerve blocks, neurosurgical procedures, and radiation therapy. Physical and psychological interventions to treat pain include counseling, psychotherapy, relaxation techniques, massage therapy, music therapy, and acupuncture. Addressing psychosocial and spiritual distress for both patients and family may be needed for patients experiencing complex, total pain at the end of life.

Anesthetic Procedures

- Celiac plexus/splanchnic block for abdominal visceral pain
- Subarachnoid neurolytic block for extremity and thoracic wall
- Epidural/intrathecal opioids with or without local anesthetic (eg, for neuropathic or plexopathy pain)
- Cordotomy for intractable lower extremity pain
- Vertebroplasty (injection of cement into a vertebral body) for metastatic spinal pain involving one or two vertebrae

CANCER-RELATED FATIGUE

Fatigue is among the most common and distressing symptoms encountered in approximately 60% to 90% of patients with cancer.[35] The National Comprehensive Cancer Network defines cancer-related fatigue as a persistent subjective sense of physical, emotional, and cognitive tiredness or exhaustion related to cancer or cancer treatment, that is not proportional to recent activity and is both distressing and interferes with usual function.[36] Fatigue may include a lack of interest and difficulty maintaining attention, concentration, or motivation in objects or activities. Patients may present with depressed mood, have a flat affect, and appear lethargic or somnolent. Rest or sleep does not eliminate or alleviate symptoms of cancer-related fatigue.

Fatigue may be experienced at any point in the cancer trajectory and often worsens at the end of life. Cancer-related fatigue may render patients unable to tolerate physical or mental activity, resulting in an inability to complete activities of daily living, impairment of social and occupational function, and diminishment in overall quality of life. Fatigue may also heighten other symptoms associated with cancer.

Etiologies of cancer-related fatigue are often multifactorial (Fig. 68–10) including not only the underlying cancer itself but also treatments such as chemotherapy or radiation therapy. Fatigue may be exacerbated by other underlying metabolic abnormalities such as hypothyroidism or hypogonadism and can be amplified by psychosocial distress.

Fatigue Assessment

Assessment of fatigue requires a multidimensional approach. Fatigue severity is included on the Edmonton Symptom Assessment Scale, where 0 equals no fatigue and 10 equals the worst fatigue imaginable (Fig. 68–4). Other numeric and verbal rating scales have been validated for fatigue including the Functional Assessment of Cancer Therapy-Fatigue, the Piper Fatigue Scale, Schwartz Cancer Fatigue Scale, Fatigue Symptom Inventory, and the Functional Assessment of Chronic Illness-Fatigue (FACIT-F) (Table 68–5).

Cancer-related fatigue should not be primarily a consequence of comorbid psychiatric disorders, which must be excluded, including major depression, somatization disorder, somatoform disorder, or delirium.

Table 68–5 ICD-10 Criteria for Cancer Fatigue

Symptoms present daily	Yes	No
Fatigue, decreased energy, increased need to rest[a]		
Generalized weakness/limb heaviness		
Diminished concentration or attention		
Decreased motivation/interest to engage in usual activities		
Insomnia/Hypersomnia		
Sleep unrefreshing or nonrestorative		
Struggle to overcome inactivity		
Emotional reactivity to feeling fatigue—sadness/frustration/irritability		
Difficulty completing daily tasks		
Problems with short term memory		
Postexertional fatigue lasting several hours		

[a]Significant fatigue, diminished energy, or increased need to rest, disproportionate to any recent change in activity level must be present in addition to five or more of the other symptoms present daily or nearly every day during the same two-week period in the past month (Data from National Cancer Institute).

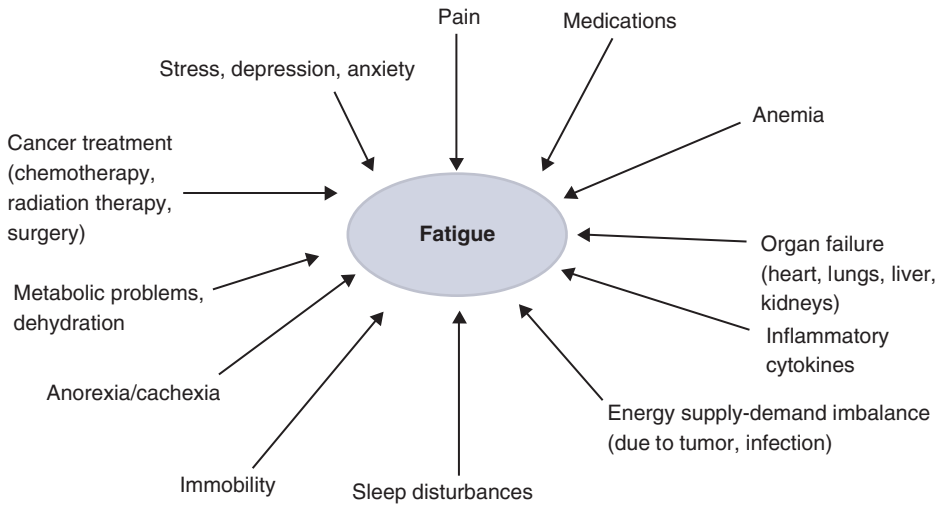

FIGURE 68–10 Multidimensional Assessment of Fatigue.

Fatigue Management

The initial assessment of fatigue should focus on contributing factors that can be corrected such as hypothyroidism, anemia, vitamin B12 deficiency, and renal insufficiency. Treatment of cancer-related fatigue should be considered only after correction of underlying etiologies.[37,38] Treatment of pain, depression, anxiety, sleep disturbances, dehydration, and cancer anorexia–cachexia syndrome are critical to improving symptoms of fatigue. Medications that exacerbate fatigue should be reviewed and discontinued if indicated, underlying infections should be aggressively treated, and patients with symptomatic anemia should receive blood transfusions when appropriate.[39]

Corticosteroids

Low-dose steroids may alleviate some symptoms of fatigue. Recent studies have confirmed their short-term benefit; however, more studies are required to determine the optimal dose.[40]

Methylphenidate

Psychostimulants such as methylphenidate may be useful if the patient is experiencing concomitant problems such as depression or drowsiness related to opioids. However, a recent randomized trial examining methylphenidate reported no significant difference in median FACIT-F scores in cancer-related fatigue when compared with a placebo.[41–44]

Antidepressants

SSRIs may improve fatigue; however, their benefit has not been proven and may be indirectly related to the treatment of underlying mood disorder. A Cochrane review that included two double-blind, placebo-controlled studies (n = 645) using paroxetine in a meta-analysis, did not show any significant improvement in fatigue in patients with cancer.[45]

Testosterone Replacement

Recently there has been evidence that cancer patients with hypogonadism on chronic opioid therapy may benefit from replacement with testosterone.[46] A pilot study of testosterone replacement at 4 weeks in hypogonadal males with advanced cancer did not have significant improvement of fatigue as measured with FACIT-F, although there was a trend for improvement with longer duration of treatment.[47]

Homeopathic Dietary Supplements

Studies have evaluated dietary supplements for treatment of fatigue. Ginseng has been used medicinally in the Far East for several millennia and is a widely used supplement to treat fatigue in the US. The composition of the active ingredients of ginseng root (ginsenosides and saponins) varies and standardization can be problematic. Moreover, a recent randomized, double-bind, placebo-controlled trial of Panax ginseng extract given twice daily versus matched placebo for 28 days did not produce significantly different fatigue scores.[48] Other potentially possible homeopathic supplements include guarana extract and l-carnitine.

Integrative Nonpharmacologic Interventions

Exercise therapy such as brisk walking, may help with fatigue. A recent meta-analysis of randomized trials examining supervised exercise therapy supports exercise improving cancer-related fatigue. These findings suggest that combined aerobic and resistance exercise regimens, with or without stretching, should be included as part of rehabilitation programs for patients with cancer.[49] Yoga has also been studied for the treatment of cancer-related fatigue with some positive results, although level of bias and inconsistent methods in previous randomized studies may have influenced the results.[50] Indirect natural light[51] and massage therapy may also help to reduce fatigue.

In addition, treatment of fatigue should also address underlying psychosocial factors such as depression, anxiety, and other symptoms including pain, cachexia, or dyspnea to be effective. Cognitive behavioral therapy in treating psychosocial distress or insomnia may indirectly improve symptoms of fatigue. In the future, multimodality treatment of cancer-related fatigue should be personalized for each individual patient, and more research is needed to develop successful interventions.

NAUSEA

Physiology

Neuronal impulses from the chemoreceptor trigger zone (CTZ), gastrointestinal tract, higher cortical areas, and vestibular apparatus are responsible for sensations of nausea and emesis when neurons in the vomiting center of the medulla oblongata are activated (Fig. 68–11). This can be either through direct activation from the gastrointestinal tract, or indirectly from visceral vagal afferent signals to the CTZ. The CTZ is located in the fourth ventricle floor outside the blood-brain barrier, which is accessible to emetogenic substances. Neurotransmitters involved in impulses to the CTZ and vomiting center include serotonin, dopamine, and substance P, which acts on natural killer–1 receptors. In addition, histamine and acetylcholine, which act on histaminic and muscarinic receptors, respectively, are involved in motion sickness–related vomiting.

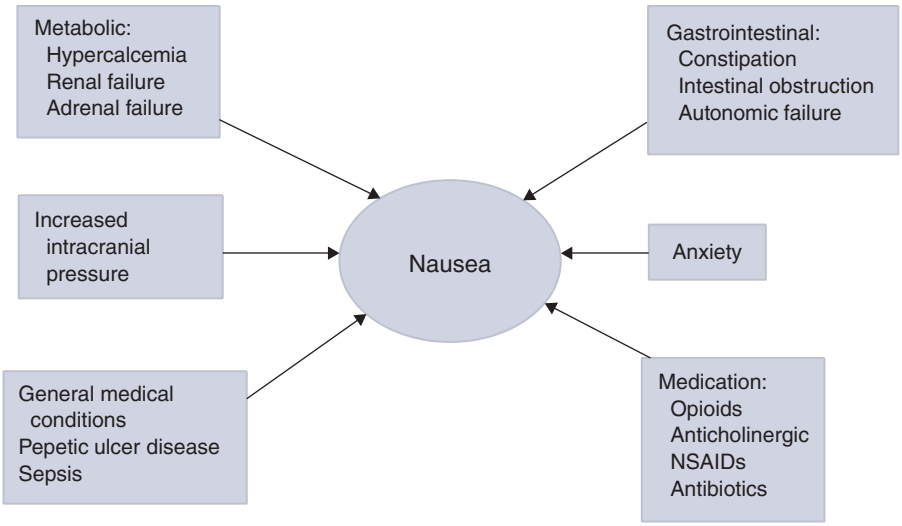

FIGURE 68–11 **Multidimensional Assessment of Nausea. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)**

Assessment

Evaluation of nausea can be approached in a stepwise fashion beginning with determining the intensity, onset, duration, frequency, and temporal factors of episodes of nausea and emesis. It is important to review a patient's history with regards to tumor site and involvement, history of past and current therapies such as chemotherapy and radiation, and a thorough review of medications that can potentially exacerbate nausea such as the use of opioids. Additional examination of the patient should assess hydration status, assessment of bowel function to rule out constipation, and other etiologies that could potential contribute to sensations of nausea and emesis including central nervous system involvement, autonomic failure, and other mechanisms (Fig. 68–11, Table 68–6).

Anorexia-Cachexia

The anorexia-cachexia syndrome is characterized by a loss of appetite coinciding with significant weight loss, loss in lean body mass including muscle wasting, loss of fat, fatigue, immune dysfunction, and metabolic derangements. Cancer cachexia has been defined as a multifactorial syndrome of ongoing skeletal muscle mass atrophy with or without the loss of fat mass that cannot be fully reversed by conventional nutritional support and leads to progressive functional impairment. Diagnosis of cachexia has been agreed upon by a panel of experts as a weight loss greater than 5%, or weight loss greater than 2% in individuals already with body-mass index less than 20.[52] Studies have shown that even a loss of 5% or more of premorbid weight before chemotherapy is associated with a shorter survival.[53]

Cachexia is found in the majority of patients with advanced cancer and is a major contributing factor to death in about 50% of these patients.[52] Complex interactions between tumor and host lead to an aberrant immune response, neuro-hormonal dysfunction, and endocrine dysregulation (Fig. 68–12). Both cachexia and fatigue are associated with increased pro-inflammatory cytokines (IL-1, IL-6, tumor necrosis factor–α), low testosterone levels, abnormal cortisol secretion, and resistance to insulin and ghrelin.[54] These cellular derangements are associated with increased production of acute-phase proteins in the liver and loss of muscle protein caused by proteolysis and lipolysis and results in elevated triglycerides and decreased high-density lipoproteins.

Unfortunately, neither nutritional supplementation nor artificial feeding reverses cancer anorexia-cachexia syndrome.[54] Multiple studies have examined the role of total parenteral and enteral nutrition in patients with cancer and have reported limited benefits. Artificial feeding of cancer patients with cachexia was found to increase acute-phase protein production without influencing the rate of albumin synthesis.[55] Other contributory factors resulting in weight loss, including depression, nausea, dysphagia, bowel obstruction, or constipation, should be treated aggressively.

Treating patients in the early stages of weight loss may be important to maintain or increase lean body mass because it is difficult to reverse cachexia in late stages.[54] A comprehensive history including recent changes in weight and diet patterns is important. Simple and inexpensive tests are available to assess body composition, such as anthropometric measurements, skinfold thickness, arm muscle circumference

Table 68–6 Common Nausea Treatments

Druga	Main Receptor	Main Indication	Starling PO Dose/Route	Equivalent Priceb	Side Effects
Metoclopramide	D2	Opioid-induced, gastric stasis	10 mg q4h PO, SC, IV	1	EPS (akathisia, dystonia, dyskinesia)
Prochlorperazine	D2	Opioid-induced	10 mg qbh PO, IV	3	Sedation, hypotension
Cyclizine	HI	Vestibular causes, intestinal obstruction	25–50 mg q8h PO, SC, PR		Sedation, dry mouth, blurred vision
Promethazine	HI	Vestibular, motion sickness, obstruction	12.5 mg q4h PO, PR, IV	2	Sedation
Haloperidol	D2	Opioid, chemical, metabolic	1–2 mg bid PO, IV, SC	1	Rarely EPS
Ondansetron	5 HT^3	Chemotherapy	4–8 mg q8h PO, IV	84	Headache, constipation
Diphenhydramine	HI, Ach	Intestinal obstruction, vestibular ICP	15 mg q4h PO, IV, SC	0.2	Sedation, dry mouth, blurred vision
Hyoscine	Ach	Intestinal obstruction, colic, secretions	0.2–0.4 mg q4h SL, SC, TD	0.4	Dry mouth, blurred vision, urine retention, agitation

[a]Corticosteroids are not included because they vary in dosage and have limited indications (see text).
[b]Prices are compared with metoclopramide 10-mg tablets orally for 10 days based on the formulary prices at MD Anderson Cancer Center. November 2001.
Ach, acetylcholine; D2, dopamine; EPS, extrapyramidal symptoms; HI, histamine; ICP, intracranial pressure; PR, per rectum; SL, sublingual; TD, transdermal.

and area, and weight and body mass index. Laboratory markers such as electrolytes, serum albumin, transferrin, and pre-albumin may also be useful.

Management

Identify etiology and treat the underlying cause.

- Treat nausea/early satiety: metoclopramide 5–10 mg every 4 to 6 hours (renal adjustment required) (Table 68–6)
- Progestational agents
- Megestrol acetate: 40–120 mg orally four times daily (risk of thromboembolism, hypogonadism, and adrenal suppression)
- Corticosteroids
- Dexamethasone: 4 mg orally twice daily (lower mineralocorticoid effect than other steroids[54])
- For cancer patients with depression: antidepressants (tricyclic and SSRI, eg, mirtazapine 15 mg orally nightly)
- Nutritionist consultation

Counseling and psychosocial support for cachectic patients and their family/caregivers is critical at the end of life and will decrease patient-family conflict. Counseling should emphasize the pleasure of eating as well as promote social participation of patients in family

meals as opposed to monitoring caloric intake. Emphasis should highlight the normal loss of appetite as patients approach end of life (and are often not hungry), and family/caregivers should not pressure patients to eat, which could result in nausea and psychological distress.

DYSPNEA

Dyspnea is a subjective symptom defined as an "uncomfortable awareness of breathing."[56] It is often described as a sensation of air hunger, suffocation, choking, or heavy breathing. Dyspnea may be related to underlying tumor progression, altered by psychosocial factors including anxiety, and exacerbated by preexisting pulmonary comorbidities. Shortness of breath can develop in response to pain or a mismatch between perceived ventilation rate and respiratory drive. Dyspnea is considered refractory when it persists at rest or with minimal activity and is distressful despite optimal medical therapy.[57]

Dyspnea in patients with advanced cancer is an indicator of poor prognosis.[58,59] The etiology of dyspnea is often multifactorial. It is postulated that in the brain, the cortical-limbic network is responsible for dyspnea perception. Recent research reports that the anterior cingulate cortex and the dorsolateral prefrontal cortex are involved in sensing dyspnea.[60] In addition, the insular cortex is modulated by sensations of dyspnea, and studies of asthmatic patients have shown that it is downregulated in patients experiencing dyspnea and pain.[61]

Treatment of Dyspnea

The aim of treatment for dyspnea is to improve the patient's perception of shortness of breath and involves not only treating the underlying cause but also palliating symptoms of air hunger. Treating the underlying etiologies can vary from thoracentesis for a pleural effusion, blood transfusions for anemic patients, corticosteroids for systemic inflammation or lymphangitic carcinomatosis, or antibiotics for pneumonia.

Symptomatic relief may include oxygen therapy, bilevel positive airway pressure or high-flow oxygen therapy.[62] In patients with chronic obstructive pulmonary disease, long-term oxygen therapy has shown mortality reduction but does not necessarily improve dyspnea. Palliative oxygenation is often prescribed irrespective of oxygen saturation levels. Oxygen delivery by nasal cannula compared with room air does not always equate to relief of dyspnea in nonhypoxemic patients with advanced illness.

Pharmacologic interventions for dyspnea include opioids, benzodiazepines, and corticosteroids and are often utilized when medical therapy fails to improve the perception of dyspnea. Opioids, when titrated carefully, will often improve dyspnea without reducing oxygenation or causing respiratory depression.[60] Immediate-release, short-acting, and sustained-release morphine have been used in clinical trials of dyspnea management. The American Thoracic Society and the Canadian Thoracic Society advocate opioid dose titration to achieve the lowest effective dose based on patient ratings of shortness of breath.[60]

Corticosteroids are most useful in situations of lymphangitic spread or inflammation causing obstruction of airways.[63] Bronchodilators may also play a role when dyspnea is related to bronchospasm and reduce airway smooth muscle tone, thereby improving airflow and deflating an overinflated lung.[60] Tachycardia is a common side effect of bronchodilators.

Integrative approaches may also be effective such as relaxation techniques or guided imagery for patients with anticipatory or anxiety-driven dyspnea. Low-dose benzodiazepines in conjunction with opioids may have a role in the treatment of dyspnea complicated by severe anxiety, but they have the potential to cause delirium and decrease respiratory drive.[64] Acupuncture has also been researched for the treatment of dyspnea. In a study by Jones and colleagues,[65] one 45-minute session of transcutaneous electrical nerve stimulation at acupuncture sites resulted in improvement of dyspnea, increased forced expiratory volume in 1 second, and blood levels of β-endorphin compared with placebo. Suzuki and colleagues reported exertional dyspnea was reduced in patients with chronic obstructive pulmonary disease after receiving acupuncture once per week for 12 weeks compared with placebo.[66] Assistive devices can be used to minimize muscular effort, and postural drainage, a fan with airflow directed to the face,[67] and incentive spirometry can help in certain settings.

DELIRIUM

Delirium, an acute state of encephalopathy, results from diffuse organic brain dysfunction. The prevalence of delirium is approximately 10% in hospitalized medical and surgical patients and is noted in 26% to 44% of patients with advanced cancer at the time of hospital admission. Roughly half of these cases may be reversible. In advanced cancer, delirium will develop in more than 80% of patients at the end of life.[68] Delirium is often misdiagnosed and associated with increased morbidity and mortality.[69] It complicates assessment of pain and other symptoms and results in distress for patients, family/caregivers, and health care providers.

Clinical Presentation

Delirium is characterized by a waxing and waning mentation. The main diagnostic criteria, according to

the *Diagnostic and Statistical Manual of Mental Disorders Fourth Edition-Text Revision* (DSM-IV-TR), includes a disturbance of consciousness with a reduced ability to focus, sustain, or shift attention; a change in cognition (disorientation/language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting dementia; and the disturbance develops over a short period of time (hours to days) and fluctuates during the course of the day. Three clinical variants of delirium have been designated based on type of arousal disorder: hypoactive, hyperactive, and mixed.

Assessment

Delirium is often misdiagnosed as anxiety, insomnia, worsening pain, or mood disturbance, resulting in inappropriate treatment with anxiolytics, hypnotics, inappropriate increase in opioids, or antidepressants, which can worsen symptoms. Maintaining a high index of suspicion can help to avoid misdiagnosis of delirium and routine use of screening tools such as the Memorial Delirium Assessment Scale or Mini Mental Status Exam is recommended. Clinicians should pay attention to metabolic derangements, which may precipitate delirium such as liver or renal failure (Fig. 68–13). Medications may also be the cause, including use of opioids (responsible for almost 60% of cases[70]), benzodiazepines, some antiemetics, and corticosteroids.

Management

1. Provide patients a safe environment including fall precautions, minimize noise and excessive light, and place patients in a familiar setting with a visible clock and calendar as well as family at the bedside to help reorient patients.
2. Treat underlying causes such as hypercalcemia or pneumonia Treatment of agitation:
3. To treat severe agitation secondary to delirium, it may be necessary to give haloperidol more frequently initially (Table 68–7). In agitated cancer patients with terminal delirium who are refractory to haloperidol, a combination of haloperidol and a benzodiazepine may be necessary. However, in a study by Breitbart et al,[71] lorazepam alone was ineffective in the treatment of delirium and actually contributed to the worsening of delirium and increased cognitive impairment in terminal patients with HIV. Newer atypical antipsychotics may be just as effective as typical antipsychotics but are more expensive. Olanzapine may be more sedating. Sometimes acute dystonia and extrapyramidal side effects are seen with haloperidol, in which case benztropine can be administered. Once symptoms are under control, reducing haloperidol to the minimal effective dose is recommended.[72,73]

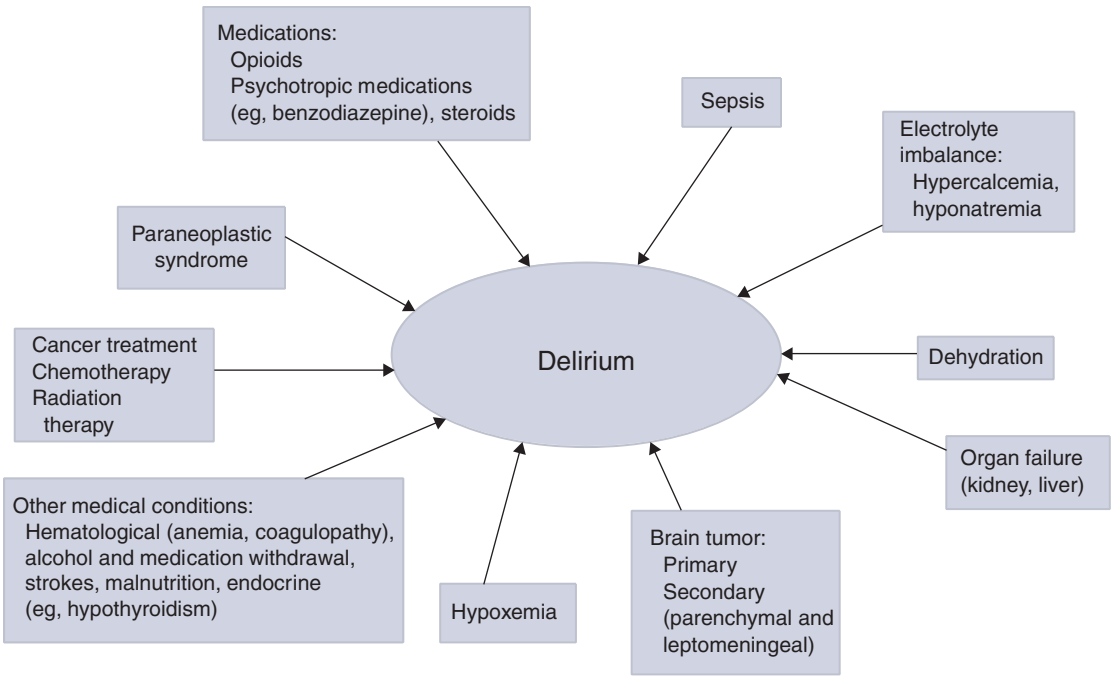

FIGURE 68–13 **Multidimensional Assessment of Delirium. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)**

Table 68–7 Common Pharmacologic Management for Delirium

Haloperidol[a]	IV/PO/IM	Start 1–2 mg q6h and 1–2 mg q2h PRN
Olanzapine	PO/ODT/IM	2.5–5 mg daily, titrated to 5.5–10 mg daily
Risperidone	PO/ODT/IM	0.25–0.5 mg q12h titrated to 1.5 mg q12h
Quetiapine	PO/IM	12.5–25 mg PO q12h titrated to 100 mg q12h
Chlorpromazine	IV/PO/IM	Start 10–25 mg/h and 10–25 mg q2h PRN
Lorazepam	IV/PO/IM	0.5–1 mg q1h until calm; recommend against use as single agent

[a]The oral bioavailability is approximately 60% to 70% when converting from oral to parenteral.

4. Counseling patient's family caregivers and healthcare providers regarding patient expression of previously well-controlled physical symptoms by grimacing or moaning may be inhibition of emotions due to delirium. In such cases, treatment should be directed at controlling delirium and not inappropriately increasing opioids (Fig. 68–14).

Palliative Sedation

Instances of refractory delirium, as well as other uncontrolled symptoms at the end of life, may require palliative sedation. Palliative sedation is defined as "the monitored use of sedative medication to reduce patients' awareness of intractable and refractory symptoms near the end of life when other interventions have failed to control them."[74] It is important to ensure all available symptomatic measures including palliative medicine consultation have been tried before deeming symptoms as refractory. The goal of palliative sedation is to control symptoms, not hasten death, which is differentiated from physician-assisted euthanasia. Therefore, it is imperative to discuss this with the patient and family/caregivers to avoid misunderstanding. Midazolam, titrated to control symptoms, is often used for palliative sedation.

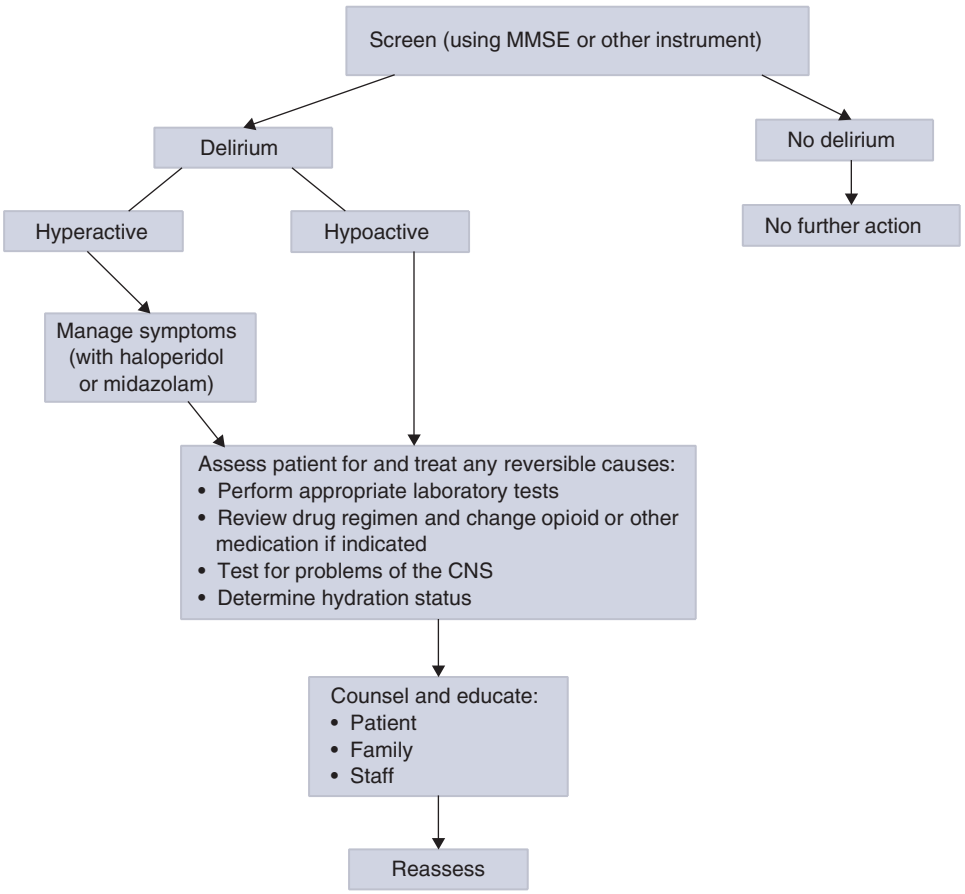

FIGURE 68–14 Algorithm of Delirium Screening and Management. (Reproduced with permission from Elsayem A, Driver LC, Bruera E. *The MD Anderson Palliative Care Handbook*. Houston, TX: MD Anderson Cancer Center; 2002.)

Patients need regular assessments, including the Richmond Agitation Sedation Scale, to monitor for excessive sedation. If underlying symptoms have improved, sedatives may be decreased and even discontinued.

DEPRESSION

Clinical depression is a common mood disorder encountered in patients with cancer and can affect from 25% to 35% of the patient population.[75] Clinical depression increases in frequency in advanced disease,[76] and diagnosis can be challenging in these patients. For instance, symptoms often strongly associated with clinical depression in healthy individuals are often commonly encountered in patients with advanced disease including fatigue, impaired decision-making ability, insomnia, and poor appetite. Per DSM-IV-TR criteria,[77] the cardinal features of clinical depression include anhedonia; feelings of guilt, hopelessness or worthlessness; and suicidal ideation. A thorough patient history directed at assessment for these symptoms is needed.

In addition, the diagnosis of clinical depression can be difficult to differentiate from adjustment disorder, anticipatory grief, or delirium. Validated measures of assessing depression in the primary care setting include the WHO-5 well-being index,[78] the PHQ-9 screening test,[79] Hamilton Rating Scale for Depression (HAM-D),[80] and the Montgomery Asberg Depression Rating Scale[81] (MADRS). Other factors that increase the risk of depression include a history of substance abuse, family history of depression and suicide, concurrent life stressors, and poor social support.

Common Antidepressants

Common initial doses for some antidepressants are:

- Nortriptyline 25 mg/day (at bedtime)
- Amitriptyline 25 mg/day (at bedtime)
- Fluoxetine 10–20 mg/day
- Paroxetine 10 mg/day
- Sertraline 20 mg/day
- Citalopram 20 mg/day
- Venlafaxine 37.5 mg/day
- Mirtazapine 15 mg/day (at bedtime)
- Methylphenidate 5–10 mg in the morning and 5 mg at noon[82]

Escitalopram has a lower side-effect profile and works slightly faster than other first-generation SSRIs. Side effects include reduced appetite, nausea, and anxiety. Antidepressants should be given for a trial of 6 weeks for beneficial effects, and if there is no significant improvement, the dose may need adjustment or an alternate medication prescribed. In patients with cancer who have unclear criteria for clinical depression or suicidal ideation, consultation with a psychiatrist is indicated.

COMMUNICATION

The majority of patients with advanced cancer desire as much information as possible about their diagnosis and treatment.[83] A majority of patients also feel it is important to know about their prognosis[84] and prefer either shared or active decision making with their physician or family/caregivers.[85] Healthcare providers' ability to accurately prognosticate life expectancy of patients with cancer is still very limited. In addition, a patient's acceptance of information regarding prognosis and end-of-life issues is heavily influenced by the manner in which this information is conveyed. It is common that healthcare professionals feel uncomfortable with discussing poor prognosis and other end-of-life issues. Reasons include lack of training, stress, feeling rushed and not having enough time to address the emotional needs of patients, fear of upsetting the patient or family/caregivers, or reluctance to diminish hope about the unavailability of further curative treatment. Avoidance of end-of-life discussions can lead to patient dissatisfaction and further psychological distress.[86]

There are very few trials testing the effectiveness of different strategies in delivering bad news.[87] Most recommendations on discussing bad news agree on the following key features: preparation, content of message, dealing with the patient's responses, and ending the encounter (Table 68–8).[87]

Important guidelines regarding end-of-life discussions have emphasized the following: identify the reason for the discussion and the patient's expectations, elicit their knowledge of their current situation, consider cultural awareness and preferences in regards to disclosure of information, validate feelings and take an empathetic approach, explain information by using language without medical jargon, use terms and phrases that are easy to understand, explain the limitations of prognostication, and avoid exact timelines.[86]

Family meetings initiated by healthcare professionals as a tool to improve communication can be helpful to inform, deliberate, clarify goals, and mediate difficult end-of-life discussions. They can help to formulate acceptable care plans between patient, family/caregivers, and healthcare providers[86] and clarify goals of care so everyone is "on the same page" (Table 68–8).[88,89]

Table 68–8 SPIKES Protocol: Setting Up, Patient's Perception, Invitation, Knowledge, Emotions, and Support[a]

Step 1: Setting Up the Interview	
Goals	**Process**
Prepare for the interview	Have a plan in mind before seeing the patient
Establish rapport	Arrange for uninterrupted time and decide who should be present and whether the patient is ready
Facilitate information exchange	Sit down, try to remain calm, and speak slowly with eye contact; have facial tissues ready
Step 2: Find out the Patient's Perception	
Goals	**Process**
Determine what the patient understands	Ask open-ended questions
Promote rapport with listening	Correct misinformation and misunderstanding
Assess denial	Address denial ("I can see that it is hard to hear this") and unrealistic expectations ("I wish")
Understand expectations and concerns	Define your role
Step 3: Get An Invitation to Give Information	
Goal	**Process**
Determine how much information the patient wants and when they are ready to hear it	Ask "Are you the type of person who wants information in detail or…"
Resolve conflicts with families regarding information disclosure	Explore family concern
Step 4: Giving the Patient Knowledge and Information	
Goal	**Process**
Prepare the patient for bad news	Forecast the arrival of bad news
Ensure understanding	Give information in small parcels and check periodically for understanding
	Avoid medical jargon
	Address questions
Step 5: Responding to Emotions	
Goal	**Process**
Address emotional responses	Anticipate emotional reactions
Facilitate emotional recovery	Have facial tissues ready
Acknowledge our own emotions	Do not speak from you own limbic lobe; resist the temptation to make bad news better than it really is
	Avoid "fix it" responses ("It is not as bad as you think")
	Support with empathic responses to expressions of emotion (ie, crying)
	Clarify emotions you are not sure about ("Tell me more")
	Validate feelings
Step 6: Communicating Strategy and Summary	
Goal	**Process**
Ensure a clear negotiated plan for the future	Treatment recommendations
	Ensure patient understanding about the plan
	Provide options
	Understand barriers and concerns patients may have
	Communicate your role; patients will be comforted knowing you will follow them

ADVANCED CARE PLANNING

Advanced directives are routinely comprised of the patient's specific preferences regarding medical care, often in the form of a living will, which details a person's desires for when they are no longer able to express informed consent as well as indicating a medical power of attorney, the patient's surrogate decision maker. The goals of advanced directives are to decrease anxiety and suffering of patients and families and ensure autonomy for the patient if they are unable to express informed consent. Inverse associations between end-of-life discussions before the last 30 days of life and aggressive treatment measures have been observed.[90]

Ideally, goals-of-care discussions are conducted in an outpatient setting during a stable clinical period and initiated by a physician that includes a patient's healthcare proxies and family. It is helpful then to periodically review and edit advanced directives as a patient's condition and prognosis change. Guidelines for developing advanced care plans with patients include the following:

1. Inform the patient of a desire to discuss health preferences related to their medical condition. Transparency on topics to be discussed is important.
2. Arrange for a convenient time and a comfortable setting (without interruptions) to have the discussion. It is important to include surrogate decision makers in addition to loved ones and family who are important to decision making for the patient.
3. Assess, understand, and reflect on the patient's state of health and care options in the context of his or her values and goals.
4. Formulate and document a care plan.
5. Communicate a treatment plan to the surrogate decision maker/family/caregivers/loved ones and the medical team.
6. Review the plan periodically whenever new events or changes to a patient's condition arise.
7. Implement the plan as needed with corresponding circumstances.[91]

Advanced care plans may be forms of medical orders such as the Physician Orders for Life-Sustaining Treatment (POLST) or Medical Orders for Life-Sustaining Treatment (some state programs may vary by name) scanned into the patient's electronic health record. These portable medical orders are an approach to documenting treatment preferences in advance and have been associated with less in-hospital death, hospitalization, and unwanted cardiopulmonary resuscitation.[92]

However, there is still a portion of patients, sometimes more than one-third who receive treatment discordant with their preferences as outlined in their POLST. This was seen with patients with less predictable prognostic trajectories, as opposed to patients with more predictable illness.[92] Advanced care planning documents are one piece of information that are used at the time of decision making, and they depend on prognosticating at a single point in time, which may change. Other challenges to advanced care planning can include additional substantial logistic, financial, and caregiver burdens that arise.

Patients and surrogates may not want to think about issues related to illness and death. Patients may often have a difficult time envisioning disability and forgo aggressive treatments in more stable states, but after experiencing and adjusting to declines in health, they may be willing to accept more invasive treatments. However, some patients may also shift focus from life-prolonging measures to one of comfort after experiencing a decline in their function and health.[93]

These challenges highlight the importance of advanced care planning discussion as an ongoing process, best when started early, revisited periodically to clarify and articulate patients' values over time, and incorporating room to adapt for unforeseen changes in clinical condition, as well as honoring the values of patients and their family/caregivers.

CONCLUSION

Patients with cancer will encounter distressing symptoms that can diminish their quality of life and interfere with the ability to receive cancer therapy. Physical and emotional symptoms are encountered at any point during the illness trajectory from diagnosis, treatment, survivorship, or end of life. An oncologist may be overwhelmed with the challenges of cancer treatment when patients have uncontrolled symptoms. In collaboration with an interdisciplinary palliative care team, healthcare providers may simultaneously treat cancer aggressively while maintaining the integrity of human life and diminishing unnecessary suffering.

There is an urgent need to incorporate assessment and treatment of physical and emotional symptoms facing patients with cancer and integrating palliative medicine teams into the delivery of cancer care. For patients with complex symptoms, early adoption of interdisciplinary palliative care is often indicated to prevent the sequelae of physical and emotional pain. In addition, an open dialogue with patients and family/caregivers regarding issues of treatment options, prognosis, and end-of-life care, including a transition from focus on curing cancer to care directed at controlling symptoms, is needed within the continuum of cancer treatment.

MD ANDERSON PRACTICE TIPS

- The routine use of validated tools in a consistent manner (Edmonton Symptom Assessment Scale, Memorial Delirium Assessment Scale, CAGE-AID) can assist in completing a thorough symptom assessment.
- It is important to consider total pain when prescribing analgesics. Laxatives are essential to consider when prescribing opioid analgesics. Benzodiazepines may cause unintended oversedation, altered mental status, or respiratory suppression. Morphine Equivalent Daily Dose can be a useful baseline calculation for opioid dosing. The process of prescribing opioid analgesics includes discussing potential risks and benefits and is useful for other controlled substances, education on storage and proper disposal of opioid medications, and careful monitoring with prescription monitoring programs.
- For symptomatic relief of fatigue, a short course of corticosteroids, methylphenidate for patients with drowsiness or depression, exercise, and cognitive behavioral therapy may be effective in mitigating fatigue. Physical activity has shown the best evidence-based treatment to date.
- Systemic opioids can help to relieve dyspnea.
- Anorexia-cachexia in patients with cancer can benefit from nutritional counseling, exercise, symptom control, and multiple specific pharmacologic agents directed at the mechanism of cachexia.
- A majority of patients with advanced cancer feel it is important to know about their prognosis. Prognostication is a longitudinal process in which survival estimates may change over time. There is always uncertainty in prognostication, and clinicians can acknowledge this while facilitating decision making over multiple dialogues throughout the disease course.

KEY CONCEPTS

- Dose selection by a phase I/II trial should be based on efficacy rather than the maximum tolerated dose (MTD), among dose levels with acceptable toxicities.
- A response-adaptive randomization (RAR) schema must control covariate imbalance between the treatment arms to guarantee valid comparison results between them.
- A personalized RAR is used to assign each individual to the treatment arm that fits them best based on their biomarkers.
- An efficient RAR accounts for both tumor response and survival.
- An innovative statistical design for target therapies is proposed to consider both the overall effects and effects for an unknown sensitive subset whose signature is to be identified from the ongoing trial.
- A new enrichment design selectively enrolls sensitive patients during the trial while keeping updating the selection criteria for sensitive patients as the trial proceeds.

A BRIEF INTRODUCTION OF THE DRUG DEVELOPMENT PROCESS

Public Significance of Efficient Statistical Design for Clinical Trials

Based on the analysis of National Institutes of Health (NIH), the medical cost associated with cancer was $124.6 billion in the United States in 2010, and it was expected that the expense would reach $158 billion by 2020 as the prevalence of cancer increases.[1] The skyrocketing cost of drug development is one of the top contributing factors for the high-cost healthcare system in the United States. One generally accepted estimate for preapproval cost of new drug development is about $0.8 billion.[2] Studies have shown that for every 5000 to 10,000 compounds that enter the research and development pipeline, ultimately only one can reach the market.[3] When considering all failed development programs, the cost per successful new drug will be even more expensive. Because all the costs in drug development will eventually be passed down to patients and healthcare system payers, a cost reduction in the drug development process can lower the financial burden on the US health care system.

To effectively reduce the cost and speed up the drug development process, collaborative efforts from all relevant parties are necessary. The role of biostatisticians in a clinical study team is to design a sound clinical trial that can generate high-quality data and analyze data appropriately so the intended scientific questions can be answered correctly with minimum bias and adequate quantification of uncertainty. Therefore, biostatisticians can help to reduce the cost of drug development by implementing innovative statistical methods that can help shorten the duration of a clinical trial and enable physicians to make better informed decisions through more efficient use of existing data.

The Process of Drug Development

The first step in the drug development process is "Discovery," which often begins with the identification of a suitable target. The target normally is a molecule or a protein receptor or a gene that is specifically associated with a disease condition or pathology. For this purpose, researchers are required to have thorough knowledge about the disease mechanism at the molecular, cellular, and genetic levels. Once a target is identified, it needs to be validated in living cells and

in animal models to confirm its role in disease. After the validation, researchers need to search for a molecule or "lead compound" to act on the disease target. Initially, a large number of lead compounds are identified, but most of them are too toxic for the human body. Therefore, early safety tests for drug absorption, distribution, metabolism, and excretion are used to choose a handful of the most promising candidates for further lead optimization. At the lead optimization step, the structures of lead compounds that survive the initial safety screening are altered to enhance safety and effectiveness. Next, additional preclinical laboratory and animal tests are conducted to determine whether the drug is safe for human testing. To identify a potential new drug candidate, this discovery process includes all of the early research explorations and lab testing. During this process, up to 5000 to 10,000 compounds are subject to rigorous screening, which takes approximately 3 to 6 years.[4]

After selecting the drug candidates and establishing their nonclinical safety and efficacy, researchers must file an Investigational New Drug application with the regulatory agencies (such as the Food and Drug Administration (FDA)) and obtain approval to start testing in humans. The FDA reviews the application, which includes information on the chemical structure, manufacturing, safety profile, study results from preclinical studies, and detailed clinical development plan, to make sure trial participants will not be exposed to unreasonable risks. In addition to the FDA approval, all studies must be reviewed and approved by the Institutional Review Boards at study sites.

Once appropriate approvals have been acquired from the FDA and Institutional Review Board, clinical trials can be conducted. According to the NIH, clinical trials are research studies that explore whether a medical strategy, treatment, or device is safe and effective for humans. Based on research questions under study, clinical trials can be classified as treatment trials, prevention trials, screening trials, diagnostic trials, supportive and palliative care trials, or quality-of-life trials. Most cancer clinical trials are treatment trials in which the effectiveness of new treatments or new ways of using current treatments are tested in cancer patients. Based on the phases in the clinical development plan, a clinical trial can be classified into phase 1, 2, or 3.

In phase 1 cancer trials, the candidate drug is tested in humans for the first time in a small group of patients to assess its safety, tolerability, pharmacokinetics, and pharmacodynamics. Most of the cancer drugs are cytotoxic agents, in which higher doses are associated with both greater therapeutic benefits but an increased probability of severe toxicities. Thus, the goal of a phase 1 cancer trial is to establish the maximum tolerated dose (MTD), which is the highest dose associated with an acceptable level of toxicity,[5] and to establish the recommended dose and/or schedule of a drug or drug combination for efficacy testing in subsequent phase 2 trial.[6] Phase 1 trials may not focus on a single tumor type, but rather a broad sample of patients with cancer are recruited and the sample size ranges from roughly 15 to 30 patients.

Once the safety of a new drug or drug combination has been confirmed in the phase 1 trial, a phase 2 cancer trial will be conducted to assess whether the drug has sufficient efficacy to warrant further investigation in a specific patient population.[7] The sample size of phase 2 trials is usually from 30 to 100 patients. If a new drug shows promise in phase 2 trials, a phase 3 cancer trial will be conducted to definitively demonstrate the drug's efficacy and safety. Phase 3 trials are usually large-scale, confirmatory, randomized trials in which the new drug will be compared with the current standard treatment. The primary end point for phase 3 cancer trials is usually related to survival, such as the rate of overall survival (OS) or disease-free survival. Interim tests are commonly performed during phase 3 trials.[8] The sample sizes involved in phase 3 trials may range from 100 to several thousand patients. Because of the longer duration and larger sample size, a phase 3 is the most expensive phase in the drug development. Once all three phases of the clinical trials are completed successfully, a New Drug Application will be filed to FDA requesting the approval to market the drug. Only after the efficacy and safety have been established in all three phases of the clinical trials can a new treatment be considered for marketing approval by the FDA. This whole drug development process is costly and may take more than 10 years.[2]

After a new drug has been approved for marketing, phase 4 trials may be required by regulatory authorities to evaluate the long-term safety and efficacy of the drug. Because they are conducted after the new treatments have been approved for marketing, phase 4 trials are often referred to as "Post Marketing Surveillance Trials." Phase 4 trials usually involve much larger sample sizes and a longer time period compared with phase 2 or 3 trials.

OVERVIEW OF CLINICAL TRIAL DESIGNS

In this section, we introduce statistical designs for phase 1, 2, and 3 trials. The phase 2 trials can be further classified as phase 2a and phase 2b. Phase 2a trials usually involve a single arm compared with historical data, whereas phase 2b trials are usually randomized with two or more arms.

Phase 1 Clinical Trials

For clinical trials evaluating new drugs, phase 1 focuses on the clinical pharmacology and toxicity. In this

phase, humans are administered a new drug, a new dosing schedule, or a new drug combination for the first time. According to Piantodosi,[9] the four main elements of a phase 1 trial design are (1) choosing the initial treatment dose; (2) choosing the dose increments and size of the patient cohorts; (3) defining the dose-limiting toxicity (DLT) level; and (4) setting guidelines to increase or decrease the dose given to subsequent patients. The final goal is to define the MTD in the study. Usually there are several dosage levels or schedules to be tested in an ascending order in terms of dose intensity. Because patient safety is the major concern for a phase 1 trial, in most cases, the lowest dose identified in animal studies of the drug is used as the starting dosage level. Taking a cancer clinical trial as an example, the starting dose may be set at one-tenth the lethal dose in mice or one-third the lowest toxic dose in dogs.[10] Because it is usually assumed in oncology that a more toxic treatment leads to a more efficient treatment effect, the MTD is defined as the highest dose level at which some target percentage of patients (eg, 30%) experience DLT.

Typically, there are two types of phase 1 designs: algorithm-based designs and model-based designs. Algorithm-based designs have prespecified rules for dose escalation or de-escalation. Because of their easy implementation, algorithm-based designs are by far the most frequently used. For example, the "3+3" design is the most popular algorithm-based design.[11,12] In this design, patients are enrolled in the trial in a cohort of three. Based on how many of them experience DLT, specific rules determine whether the dose level should escalate, de-escalate, or stay the same, with the addition of three more patients. Similar decision rules are also specified for action based on data from six patients. The MTD is the highest dose level with 0 or 1 DLTs observed in six patients.

Some alternative algorithm-based designs similar to the traditional "3+3" design include the "2+4," "3+1+1," and "3+3+3" designs.[12] Although these designs are easy to be implemented, they only use the data at the current dose to arrive at the decision and may enroll many patients to receive the ineffective low dose levels and expose some patients to the unsafe toxic dose levels.[13,14] Some publications also show that the performance of the "3+3" design has a low probability of selecting the true MTD[15] and it is highly variable in estimating MTD.[14]

In contrast, model-based designs use all available patient toxicity information to fit a parametric dose-toxicity model, which is a monotonically nondecreasing function. The most well-known model-based design is the continual reassessment method (CRM) proposed by O'Quigley, Pepe, and Fisher.[16] The CRM uses all the accumulated data to select the next dose level for new patients. In contrast, the "3+3" design uses only the data from the most recently enrolled cohort of 3 or 6 patients.

Additional model-based designs based on CRM include dose escalation with overdose control,[5] Bayesian model averaging CRM,[17] time-to-event CRM,[18] Bayesian logistic regression model,[19] and others. Although CRM has shown more desirable operating characteristics than the rule-based designs, such as having a higher probability to more accurately determine the true MTD, its application is still limited because of its conceptual and operational complexities.[6]

Recently, another type of adaptive dose-finding design, termed *model-assisted design*, combines key elements of the rule-based and model-based designs. Similar to rule-based designs, its dose escalation/de-escalation rules are determined before the start of the trial. It also borrows the strength from model-based designs by using a statistical model to aid decision making. Some examples include the modified toxicity probability interval (mTPI) design,[20] its variation mTPI-2,[21] and the Bayesian optimal interval design.[22]

For multiple-agent combination or biological agents, the dose-response function is not a one-dimensional monotone increasing curve. In this case, the rule of "higher dose, higher efficacy" does not apply either (biological agents), or it may not be clear which dose is higher (combination agents: Drug A 3 mg + Drug B 10 mg vs Drug A 10 mg + Drug B 3 mg), so the dose selection should not be purely based on MTD. Both efficacy and toxicity need to be considered for the dose selection. Huang et al[23] provide a parallel phase 1/2 design for dose selection based on efficacy but that is subject to toxicity constraints.

In the parallel phase 1/2 design, toxicity and efficacy of all doses are assessed simultaneously, whereas dose escalation can be done using a traditional "3+3" algorithm,[11] the CRM,[16] or other Bayesian interval designs.[6,22] Adaptive randomization based on efficacy data start after the initial dose escalation, among those safe dose levels. The dose levels with lower efficacy or intolerable toxicity are eliminated. Patients are assigned to the remaining doses with unequal probabilities, where patients have higher probabilities to be assigned to the doses with higher efficacy. Instead of considering each dose level separately, logistic regression models for toxicity and efficacy data from all dose levels can be used to obtain more stable estimation and thus make more reliable decisions for dose selection. Compared with separate phase 1 and phase 2 trials, the integrated phase 1/2 design is more efficient.

Phase 2 Clinical Trials

The MTD or recommended dose found in phase 1 is then applied in a phase 2 study to examine the treatment efficacy and refine the toxicity profile of the agent. In many phase 2 cancer trials, the antitumor activity of a new drug is usually quantified by

tumor response, and the treatment is considered to be successful for an individual patient if his or her tumor burden is reduced by at least 50%.[24] As of this writing, various techniques have been developed for monitoring tumor response to the treatment. However, the most common way is to measure the tumor shrinkage or tumor lesions on computed tomography or magnetic resonance imaging after the therapy, and the Response Evaluation Criteria in Solid Tumors (RECIST 1.1)[25] is the most widely accepted standard method to assess tumor shrinkage. Under RECIST, tumor response can be categorized as complete response (CR), partial response (PR), stable disease (SD), and progressive disease. The proportion of patients who have achieved CR or PR among the total number of evaluable patients is defined as the objective tumor response rate. The objective tumor response rate has been the most widely used primary end point for phase 2 clinical trials because a tumor response can be considered as a clear sign of treatment activity, and tumors rarely shrink by themselves. In addition, tumor response can be obtained quickly after treatment (most often within 4–6 weeks), which results in a shorter duration of clinical trials.

Single-Stage Design

The most common designs of phase 2 oncology trials are single-arm designs. Fleming[26] proposed a single-stage procedure to test a hypothesis against a clinically meaningful efficacy target. Fleming used a normal approximation to estimate the sample size. A'Hern[27] created a sample size table for Fleming's single-stage procedure based on that exact method.

Two-Stage Design

In a single-arm design, all patients are enrolled before the tumor response rate is estimated and a decision is made. If the final response rate turns out to be very low, then all patients have been exposed to the ineffective regimen. For this reason, a two-stage design is proposed to enroll patients in two stages. The data are examined after the first stage and the trial can be terminated if the drug is ineffective. Gehan[28] proposed a two-stage design when the response rate of standard of care is very low. In that case, a new drug with the small response rate is clinically significant and warrants further study. In the first stage, n_1 patients are enrolled and r_1 responses are observed. If $r_1 = 0$, the trial is stopped. If one or more patients have tumor response, they continue to the second stage. In the second stage, n_2 additional patients are accrued and r_2 responses are observed. In Gehan's design, the first-stage sample size n_1 is chosen to give a small probability of the trial ending early (eg, 5%) at a fixed target response rate pa that is considered to be the minimum response rate of interest. The first-stage sample size n_1 is found by solving $\Pr(\text{Stop Early} \mid pa) = \Pr(r_1 = 0) = (1 - p_a)^{n_1} = 0.05$. The second-stage sample size n_2 is chosen to give sufficient precision for estimating the response rate p after all patients are observed.

Simon[7] proposed two types of two-stage designs (Optimal design and Minimax design). The design procedures produce optimal sample sizes for both stages while controlling the type I and II error rates under the null and alternative hypotheses. Using the same notation for Fleming's and Gehan's designs, the Simon Two-Stage Design is as follows. First enroll n_1 patients in Stage 1, reject the alternative hypothesis and terminate the trial for futility if the number of responses $r_1 \leq s_1$, where s_1 is a parameter to be specified. Otherwise, continue to n_2 patients in Stage 2. At the end of Stage 2, reject null hypothesis if the sum of the responses in the two stages $r_1 + r_2 \geq s_2$; otherwise, reject the alternative hypothesis. Simon's two-stage designs are to choose appropriate values for n_1, s_1, n_2, and s_2 to meet specific type I error and power constraints. They are also chosen to meet specific optimality criteria such as minimize the expected total sample size by Simon's Optimal design or minimize the maximum sample size by Simon's Minimax design.

Multistage Design

Fleming[26] also proposed a multistage design to allow an early termination of the trial when intermediate results are extreme, either in favor of the efficacy or the inefficacy of the treatment. Fleming's multistage design can be reduced to a two-stage design when K=2. The difference between a Simon Two-Stage Design and a Fleming Two-Stage Design is that the Simon design does not permit early acceptance of a drug based on a positive Stage I result. Usually, when the drug shows promising activity with a limited number of patients, it is of clinical interest to keep the study ongoing to benefit patients and at the same time to gather more safety information. For this reason, the Simon design is much more commonly used than the Fleming design in oncology phase 2 trials.

Randomized Clinical Trials

In a single-arm design, the tumor response rate of a new drug is typically compared against a fixed rate based on historical data. The variability of historical data is not taken into consideration. Furthermore, the entry criteria of a single-arm trial may not be similar to those of the historical trials on which the fixed response rate is based. The effects from single-arm designs are greatly influenced by entry criteria, supportive care, the definition of response, dose

modification procedures, and compliance patterns or some unknown latent variables.[29]

It is widely acknowledged that randomization is a way to eliminate systematic patients' selection bias and provide a basis for unbiased comparisons of treatment effects.[30] Recently, the use of randomization in phase 2 trials has dramatically increased, especially when the primary end point is progression-free survival (PFS).[31,32] Randomized designs are considered when the aim of a phase 2 trial is to evaluate two or more new agents or new regimens concurrently, or if adequate historical control data are not available.

The randomized selection design was first proposed by Simon.[33] In such a design, patients are randomly assigned to one or more competing regimens or treatments with the same entry criteria. Generally, no control arm is included in the design. The trials are conducted as several independent phase 2 trials simultaneously. Each arm is designed to be evaluated separately, and often there is no adequate power for comparison between arms.[34] At the end of the trial, the results from all arms are considered jointly,[35] and the arm with the highest treatment effect is selected for phase 3. The advantage of this type of design is less selection bias owing to the uniform enrollment and evaluation criteria in each arm. However, when there are multiple arms with similar treatment effects, the probability of selecting the best arm is diminished.

Usually a single-arm phase 2 trial for initially assessing the efficacy of a new treatment is called phase 2a, and the subsequent randomized, multiarm phase 2 trial is called phase 2b. In the current postgenomic and high-throughput era, we have seen a dramatic increase in the number of treatment regimens or agents to be evaluated. Hence, phase 2b serves as a prescreening stage before the large phase 3 trial. The large number of treatment options increases the importance of phase 2b as an intermediate step for the goal of identifying the most efficient treatment options before selecting the candidates to be evaluated in a time-consuming and costly phase 3 study.

Once promising results are found in phase 2 (with or without a phase 2b), a full-scale phase 3 trial is then begun. The phase 3 trials compare the new treatment with the standard treatment in a rigorous manner. The most popular phase 3 trial design is to randomize the patients into different treatment groups. The goal is then to define the best treatment, which has an implication of changing the current practice for that patient population. Randomization, in either a phase 2b or phase 3 setting, has been established as the hallmark for obtaining scientifically valid treatment comparisons in clinical trials. The use of randomization eliminates systematic treatment assignment bias in the trial. It increases the likelihood that the known, and especially the unknown, risk factors are balanced across the treatment groups under study and that the responses observed among the patients result from the treatment and not from confounding factors.

Researchers use clinical trials to assess the effects of specific treatments or other interventions in a target population based on their resulting outcomes. Randomized controlled trials provide the most decisive means for examining clinical interventions and for comparing the characteristics of the competing treatment options, including the associated cost, short-term and long-term effectiveness, and side effects—thus, the overall value. This information is vital to guide health care decisions regarding quality and cost of treatment.

Generally, there are two types of randomization: fixed allocation randomization and adaptive randomization. Because adaptive randomization is relatively complicated, we discuss it in the next section. Fixed randomization means the assignment probability remains fixed throughout the whole process of enrollment of participants to the study. In contrast, adaptive randomization refers to the assignment probability changing during the enrollment period as a function of the treatment assignment, baseline information, and outcomes of previously enrolled subjects.

The most commonly used fixed allocation randomization designs include simple randomization, blocked randomization, and stratified randomization. Simple randomization is similar to conducting a coin flip to determine each patient's treatment assignment in a trial. Conducting a trial with this type of randomization design is straightforward, and therefore easy, but it does not guarantee that the number of patients assigned to each treatment group are equal. For example, with a total of 100 patients, the trial may end up with 47 patients in one treatment arm and 53 patients in the other. Even if the numbers of patients are balanced at the end of trial (eg, 50 per arm), the first 20 patients may be imbalanced as 15 in one arm and five in the other. Especially if patient characteristics change over time (eg, early patients have worse prognosis than later patients), then the early imbalances may introduce bias. Block randomization is often used to avoid this problem. For example, a block randomization with a block size of four may assign the first four patients to ABAB, and the second block of four patients to BBAA, where A and B are the two treatments. Equal sample size is guaranteed within each block, whereas the sequence within each block is a random draw from all possible sequences of equal sizes between A and B. When there are prognostic factors that may affect the treatment response, stratified randomization is often used. For example, if age (≥65 vs <65 years) and a genetic mutation status (yes vs no) are prognostic factors, then four strata are defined by these factors, and the patients are randomly assigned within each stratum.

INNOVATIONS FOR CLINICAL TRIAL DESIGNS

In this section, we first describe different types of adaptive designs, and then introduce our recent publications on innovative clinical trial designs.

An Overview of Adaptive Designs for Randomized Clinical Trials

Traditional randomized clinical trials use a fixed ratio to assign patients to each treatment arm and analyze the treatment effect at the end of the study. In recent years, adaptive designs have become increasingly popular because of their flexibility as an alternative to traditional randomized clinical trials. Adaptive designs allow modifications of the ongoing clinical trials according to the information collected during the trial without undermining its integrity and validity. The use of adaptive design is attractive to investigators, sponsors, and even patients because it may reduce the trial duration, limit the number of patients exposed to the ineffective/inferior treatments, modify the design based on updated information, and increase the probability of success in later-phase drug development. Here we focus on some common types of adaptive designs including (1) response-adaptive randomization (RAR), (2) adaptive group sequential, (3) biomarker-adaptive designs, and (3) seamless phase 2/3 designs. Details of each design are described below.

Response-Adaptive Randomization Design

Equal randomization is commonly used in clinical trial settings to generate reliable data for making inferences about the difference when two treatments are compared. However, when the treatment difference is large and the end point of the study is survival time, it does not seem appropriate to assign a large number of study patients to the inferior treatment arm.[36] A RAR is a data-dependent treatment allocation rule that the probability of assigning the next patient to treatment arms depends on the outcomes of the previously randomly assigned and treated patients.[37–40]

In recent years, increased interest in the RAR design has resulted in more frequent applications of RAR designs in oncology phase 2 studies.[41] This type of randomization is based on the relative success of patients treated, and it tends to put more study patients on the better treatment, which is more likely to be acceptable by patients and their physicians than equal assignment. Examples of RAR designs include play-the-winner,[37,38] urn model,[39] drop-the-loser design,[42] doubly adaptive biased coin design,[43] and Bayesian RAR design.[40,44]

In the play-the-winner design, a success on one treatment arm results in the next patient's assignment to the same treatment, with changes to the alternative treatment only in the event of a failure. The urn model design changes the allocation probabilities during the course of the trial by adding balls of an appropriate color to the urn based on previous patients' outcomes. In the drop-the-loser design, an inferior treatment arm (loser) can be completely dropped from further randomization during the trial to improve the trial efficiency. It may also allow adding additional arms during the trial. For two-arm trials with binary response measurements, Wei and Durham[45] proposed a generalized Friedman urn model for a RAR procedure.

Another approach named doubly adaptive biased coin design was first proposed by Eisele and Woodroofea[46] and further modified by Hu and Zhang[47]. This design depends on the current proportion of patients from each treatment arm and the current estimate of the desired allocation proportion. The advantages of this design include flexibilities to target any given allocation and allowance of multiple types of responses while attaining the lower bound of variance.

A doubly adaptive biased coin design consists of three steps: (1) assign a small proportion of patients using equal randomization as a burn-in period; (2) calculate the optimal allocation probability based on current patient responses; and (3) apply the allocation function to calculate the assignment probability for the next new patient, which targets the optimal allocation probability in step 2.

Several methods of calculating the optimal allocation probability have been proposed. The Neyman allocation[48] minimized the variance of the testing statistic and is a popular choice. The method proposed by Rosenberger et al[49] minimizes the number of failures while keeping the conditional variance of the Wald test statistic at a fixed level. Generalization of this approach has been discussed by Hu et al.[50]

Although adaptive randomization was initiated from the frequentist point of view, it was quickly utilized within the Bayesian framework. Bayesian methods incorporate the prior and historical information with the currently available data to make future assignment decisions. Based on likelihoods, Bayesian inference provides the investigators with greater flexibility and naturally updates the posterior assignment distribution based on the most updated information. For the Bayesian RAR, the allocation probabilities are based on the posterior probabilities of the treatment arm being the best. In such designs, initially, patients are equally randomly assigned to the treatment arms. As efficacy data accrue, patients' assignments are unbalanced in favor of the arm that has the higher treatment effect (higher objective tumor response rate or longer PFS

time). It has the ability to use accumulating data in real time to alter the course of the trial, therefore enabling dynamic allocation of patients to experimental arms and early dropping of ineffective arms.

Berry and Eick[51] provided a thorough comparison of the Bayesian adaptive assignment scheme with balanced randomization. Zhou et al[52] introduced an adaptive randomization design in a trial, namely, biomarker-integrated approaches of targeted therapy of lung cancer elimination (BATTLE), using the hierarchical Bayes model. The method used historical information to define the prior information and "borrowed strength" across patients with different covariate profiles.

Also under the Bayesian framework, Ning and Huang[53] proposed a new RAR schema that controls covariate imbalance between the treatment arms to guarantee valid comparisons between them. A measure of covariate imbalance is provided. As opposed to equal randomization, this design is more likely to assign new patients to the treatment arms that would minimize this covariate imbalance measure. Yuan, Huang, and Liu[54] developed a different method to balance the covariate, either continuous or categorical, by using the Kolmogorov-Smirnov statistic to measure the imbalance across different arms. All these efforts have aimed to incorporate the complex patient heterogeneity and assign future patients to the more promising treatment arm. These new designs achieve scientifically valid results by ensuring patients in different treatment arms are comparable, and also help assign more patients to the better treatment arms.

Adaptive Group Sequential Design

Classical group sequential designs repetitively apply significance testing at prespecified stages. At each stage, they offer a possibility of stopping early without the need of setting a fixed number of sample size. At each interim stage, a decision may be made to support or reject the null hypothesis based on a stopping criterion. A classical group sequential design is required to prespecify the total number and the timing of the analyses. The trial will be stopped until the maximum information is obtained or when a stopping boundary is crossed.

Examples of the stopping boundaries include those by O'Brien and Fleming,[55] Wang and Tsiatis,[56] and Lan and DeMets.[57] O'Brien and Fleming used increasing boundaries. Wang and Tsiatis' boundaries depended on a shape parameter and the prespecified information fraction. Lan and DeMets proposed a flexible alpha-spending function without requiring a prespecified number of interim analyses and the timing of those stops. The alpha-spending function can also approximate the O'Brien and Fleming group sequential boundaries.

Adaptive group sequential design allows adaptations or modifications at interim analyses.[58] Those adaptations may include but are not limited to sample size re-estimation, adding/dropping treatment arms, randomization scheme modification, etc. Although the classical group sequential design is well understood and the Type I error rates can be well controlled under spending functions, adding changes at interim analysis may inflate the Type I error rate. Statistical procedures are still needed to control the study-wise Type I error rate.[59]

Biomarker-Adaptive Design

A biomarker is a biological molecule that is objectively measured and evaluated as an indicator of normal biological, pathogenic processes, or pharmacologic responses to a treatment.[60] The emergence of biomarker development can guide treatment selection for patients according to their biological characteristics or genomic profiles. Based on the type of usage, biomarkers can be classified into prognostic or predictive biomarkers. Prognostic biomarkers assess patient responses independent of treatment, whereas predictive biomarkers provide information regarding the most likely response to a given treatment. Prognostic biomarkers can separate potential patients into good or poor prognosis at diagnosis, whereas predictive biomarkers can separate patients into sensitive or insensitive for a given treatment.[61] Based on the characteristic of predictive biomarkers, they can be used to guide treatment selection to allow a better fit between patients and treatment options.

Many molecular cancer treatments only benefit a subset of patients. A biomarker-adaptive design identifies a subgroup of patients who are most likely to respond to the investigated treatment based on their biomarker profiles. It can allow more patients to benefit from the trial compared with the traditional all-comers design, which may increase the trial efficiency and limit insensitive patients to experience the toxicity of the investigated treatment.

Xu et al proposed a subgroup-based adaptive design for multiarm biomarker trials.[62] This design simultaneously searches for prognostic subgroups using a random partition model and assigns patients to the best subgroup-specific treatment based on posterior predictive probabilities.

If a biomarker is known at patient screening, this trial should only enroll sensitive patients. If the biomarker information is unknown, the adaptive signature design[63] may be used. The adaptive signature design tests the overall treatment effect at a significance level of δ (eg, $\delta = 0.04$). If the overall treatment effect is statistically significant, then it can be concluded that the experimental treatment may benefit all treated patients. Otherwise, the treatment effect is tested in a sensitive patient

subset at a significance level of θ (eg, $\theta = 0.01$). This controls the overall type I error rate at $\alpha = \delta + \theta = 0.05$.

Gu et al proposed a Bayesian two-stage biomarker-based adaptive randomization design (BATTLE-2).[64] This design has three main goals: (1) to test the treatment effect, (2) to identify prognostic and predictive biomarkers for targeted agents, and (3) to provide a better treatment for patients enrolled in the trial. The Bayesian adaptive randomization approach applies to both the biomarker development (stage I) and validation stages (stage II). In stage I, adaptive randomization is applied based on a known biomarker. At the end of the first stage, a Go or No-Go decision is made from testing the overall treatment effect. If a Go decision is made at the end of stage I, a two-step Bayesian Lasso strategy is used to select additional prognostic or predictive biomarkers based on the accumulated data: group lasso is used to select important biomarkers, and adaptive lasso is used to refine the selection and estimation. Patients enrolled in the second stage receive treatment based on the refined adaptive randomization scheme.

Seamless Phase 2/3 Design

During traditional drug development, phase 2 trials select a promising treatment/dose, and phase 3 trials further confirm the treatment efficacy. The seamless phase 2/3 design (also called pick-a-winner design, drop-the-loser design, and adaptive seamless design) is a multistage design that combines phases 2 and 3 into a single trial. It consists of two stages: a selection stage (phase 2b) and a confirmation stage (phase 3).[65] For the selection stage, the objective is to select the best dose/treatment by employing a parallel design with multiple treatment arms and a control arm. The inclusion of a control arm at the selection stage allows the data to be easily combined with those from the confirmation stage for final analysis. The confirmation stage evaluates the efficacy of the selected treatments versus the control treatment.

The general framework for a seamless phase 2/3 design is as follows: patients entering the trial are randomly assigned between the experimental arms and the control arm. At the end of the first stage, the selected dose/treatment moves to the confirmation stage. Newly enrolled patients are randomly assigned to receive the selected dose/treatment or the control treatment. If multiple arms are selected at the end of the first stage, or only the inferior treatments are dropped, each selected arm is compared with the control arm at the confirmation stage.

Thall, Simon, and Ellenberg proposed a two-stage design with binary end points to avoid continuous monitoring.[66] Schaid, Wieand, and Therneau extended their design to the time-to-event end point and allowed early stopping for efficacy after the selection stage.[67] Stallard and Todd generalized their designs to allow more than two stages using the error spending function and it is suitable for all types of end points by using an efficient score for test statistics.[68] Huang, Liu, and Hsiao presented a seamless design that allows prespecifying the probabilities of rejecting an arm at each stage.[69] Bischoff and Miller proposed a two-stage adaptive design based on the means of the normal distribution for treatment selection.[70] Their design requires a minimal number of patients to reach the desired power while controlling the type I error rate and limiting the probability of selecting an inferior treatment after the first stage. Todd and Stallard presented a group sequential design that allows a change of end point for the confirmation stage.[71] Chow and Tu derived formulas for sample size calculation, assuming the same study objectives at different stages.[72] Posch, Maurer, and Bretz presented two methods to control the type I error rate when applying sample size reassessment and/or treatment selection: one uses simulation to adjust the critical value, and the other uses an adaptive Bonferroni-Holm procedure.[73] Stallard described a method to control the type I error rate by adjusting the usual group sequential boundaries when using a short-term end point for the treatment selection at the first interim analysis for a confirmatory seamless phase 2/3 trial.[74]

Instead of running multiple experimental arms versus a control arm in phase 2 and 3 designs, the seamless phase 2/3 design requires a smaller sample size by using data from both stages and can expedite the drug development process.[67,77] Because the results of a seamless 2/3 trial are sensitive to the timing of the analysis for the selection stage, simulations should be done to find an optimal time for the interim analysis.[67]

Recently Proposed Innovative Clinical Trial Designs

In this subsection, we introduce our own work on clinical trial designs with innovations specifically motivated by the need for oncology clinical trials. We describe a new design that can help assign the best individualized treatments to individual participants in the trial.[76] We also provide an innovative design that accounts for both tumor response and survival.[77] Further, we consider biomarker signatures for patients with cancer, selectively enroll patients through an enrichment process, and adaptively assign patients to the treatment that would best fit them based on their biomarker signatures.[78]

A Response-Adaptive Clinical Trial Design Accounting for Patient Heterogeneity

One important ethical question is: In an ongoing trial, what is the best way to assign patients to treatment arms so they are more likely to benefit from the

treatment? To answer this question, we need a flexible design that continuously draws inferences and an ethical design that guides each patient toward the best available regimen during the trial. To meet these needs, Qiao et al[76] provided an adaptive randomization design accounting for patients' characteristics (covariates) under a Bayesian framework.

To present the real situation in which the treatment effect varies in different subgroups, the terms of predictive and prognostic factors in oncology research are introduced here. Italiano[79] provided the following definitions: a prognostic factor is a clinical or biologic characteristic that is objectively measurable and that provides information on the likely outcome of the cancer disease in an untreated individual. Patients with good performance status are likely to do better than those with poor performance status, and performance status would be considered as "prognostic." In contrast, a predictive factor is a clinical or biologic characteristic that provides information on the likely benefit from treatment (either in terms of tumor shrinkage or survival). Such predictive factors can be used to identify subpopulations of patients who are most likely to benefit from a given therapy. A good example of predictive biomarkers used in oncology research is estrogen and progesterone receptors to predict sensitivity to endocrine therapy in patients with breast cancer. Statistically, a prognostic factor can be considered as the main effect and its effect can be concluded in a single-arm trial because the effect does not vary with different treatments. On the contrary, the predictive factor can be considered as the "interaction" term and can be evaluated in a multiarm trial because the effect differs across subgroups.

In our current research environment, we are interested in finding sensitive subgroups of patients for whom the treatments are more effective. Therefore, we focus on studying the predictive factor, that is, the interaction terms of treatment and other covariates. The treatment assignment probability is based on a stable algorithm that accounts for the confidence level of treatment comparisons based on all the observed data.[76] By using RAR, this design results in a greater total number of responders. It also tries to detect the treatment effect difference in subgroups and assign patients to the most beneficial treatment according to their biomarkers. This results in a higher proportion of individuals receiving their best individualized treatment compared with equal randomization. This adaptive design is a step toward precision medicine. It aims to benefit each patient enrolled in a prospective clinical trial.

An Efficient Design Accounting for Both Tumor Response and Survival Outcomes

The survival outcomes in clinical trials take a long time to collect, but early tumor response data are available in a short time after treatment initiation. Huang et al[77] provided an efficient design accounting for both tumor response and survival outcomes. We illustrate the advantages of this new statistical design through an example of consideration for patients with advanced non–small-cell lung cancer (NSCLC) as follows.

NSCLC accounts for approximately 75% to 80% of all lung cancers. NSCLC originates from the "non–small cell" within the lung. Advanced NSCLC is a late stage of the disease characterized by the spread of cancer from the lung to lymph nodes or distant sites in the body. Although OS is the gold standard for clinical benefits of cancer treatments, periodical measurements of the size and locations of tumors are often used as early indicators to determine whether the cancer is responding to treatment. Generally speaking, partial responses (often defined as at least a 50% reduction in tumor) and CRs (often defined as nondetectable cancer) are considered to be successful responses to cancer treatments and are often associated with better long-term survival. However, more patients have disease stabilized through treatments rather than PR or CR. According to an article published in the *Journal of Clinical Oncology*,[80] the addition of disease stabilization to CR and PR at 8 weeks (defined as 8-week disease control rate) can predict long-term outcomes more accurately than the standard measurement of responses for patients with advanced NSCLC. A more recent publication shows that the prediction of survival benefits by 8-week disease control rate is consistent across different ethnicities (Western vs Chinese patients).[81]

Despite developments in the designs of phase 2 trials, there are still many limitations in current phase 2 oncology trial designs. Some of these limitations are caused by the inherent trade-off of the decision-making process in exploratory studies. For example, a short-term outcome such as tumor response rate, which can be obtained in a relatively short time period after treatment (eg, 2–3 months), is often used in phase 2 oncology trials to reduce drug development time and expedite the screening process for drug candidates. However, prolonged survival is still the ultimate goal of cancer treatments, and OS, PFS, or other similar survival outcomes are still the standard end points of phase 3 trials for FDA approval. Efficacy seen in tumor response outcomes may not be readily translated into efficacy in the survival end point. On the other hand, if OS time is used as the primary end point, the final data may require months or years to complete, and the design and the conduct of the trials may be more complex and difficult, especially for RAR designs.[77] Therefore, PFS has been used as an alternative primary end point in many cancer phase 2 trials because it is more relevant to OS compared with tumor response and requires less follow-up time compared with OS.

Although short-term response status can be obtained quickly and can potentially be used to speed up the adaptation of randomization, tumor response status is not incorporated in the decision making in most of the phase 2 RAR oncology trials with PFS as the primary end points.

As mentioned above, the primary goal of phase 2 trials is to screen for promising drug candidates to be studied in phase 3 trials. Because of the limitations in traditional phase 2 oncology trials, the attrition rate in cancer drug development remains high. Only 5% of agents that have anticancer activity in preclinical development demonstrated sufficient efficacy in phase 3 testing.[82] For drug candidates already evaluated in phase 1 trials, data from 1975 to 1994 show that only 10% were approved for clinical use.[83] As of this writing, more than 400 new compounds are available for testing.[84] At the same time, the percentage of patients enrolled in clinical trials remains at a rate of 3% to 5% among the potentially eligible patient populations.[85] These statistics indicate that the phase 2 trials are historically not very successful in screening out "weak" drug candidates. Many "weak" drug candidates are competing with "strong" drug candidates for patients in phase 3 trials, and patients being treated with "weak" drug candidates lose the opportunities to receive clinical benefits. Therefore, current designs for phase 2 oncology trials are far from optimal. Innovative methods should be used to enable more efficient use of scarce resources and achieve more effective elimination of inefficacious agents.

In the traditional phase 2 oncology clinical trials with survival as the primary end point, the interim analysis is usually based on the observed survival information. Patients without events are treated as censored observations. In this subsection, a joint modeling approach between short-term tumor response and long-term survival time is introduced to enable early interim decision making during a clinical trial. In particular, the joint modeling is used to impute censored event time based on baseline covariates and expected tumor response, and the interim decision is made based on results from multiple imputed complete data sets. To be able to impute the censored event time, a Bayesian method with explicit modeling of baseline hazard rate is used. The goal of joint modeling is to improve interim analysis by taking advantage of the correlation between short-term and long-term outcomes. This can enable early decision making while leveraging additional information about long-term outcomes provided by early short-term outcomes.[77]

In addition to NSCLC, the joint modeling approach is potentially applicable to other oncology indications, where early tumor response to treatment in patients with advanced disease could be indicative of longer survival time. The joint modeling approach is also applicable to increase the clinical development process of some rare diseases when the patient population is small or the enrollment rate is slow, as long as early tumor response information is available.

To do a joint modeling, first, a logistic regression model with baseline covariates was assumed for the short-term categorical tumor response with two levels of response status. The long-term PFS outcome was assumed to follow an exponential distribution conditional on the tumor response status. In the adaptation stage, before each new patient was enrolled, the posterior probabilities of different tumor response status conditional on treatment and baseline covariates were calculated first, and then the average posterior mean of PFS was calculated for each treatment arm using posterior tumor response probabilities as the weighting factors. The randomization probability was based on the conditional posterior PFS probability that one arm is superior to the other. A multinomial probit model was used to model the three categories of tumor response. Two binary and one continuous covariate were added to the joint modeling. As a priori, it was assumed that the two binary covariates were interacted with treatment and had effects on tumor response. The continuous covariate had an effect on PFS. The proportional hazards model was assumed for PFS and the randomization probability was based on the posterior probability of the hazard ratio comparing the two treatments.

Two major extensions were made to expand the original joint modeling strategy to more complicated settings: (1) one additional baseline continuous covariate was included in the joint model; and (2) tumor response statuses were expanded to multiple categories (3 categories): disease progression, SD, and response (PR or CR). It was assumed that the baseline continuous covariate was a prognostic biomarker for PFS and was included in the model for PFS. In addition, two baseline binary biomarkers were assumed to be predictive biomarkers for tumor responses, where one biomarker was predictive of a worse treatment effect in the experimental treatment and the other biomarker was predictive of a better treatment effect in the experimental treatment. The choice of biomarkers was to demonstrate that the joint modeling approach is capable of allocating patients more effectively to the better treatment. In principle, the joint modeling approach can accommodate any type of covariate in either the model for tumor response or the model for PFS.

A Signature Enrichment Design with Bayesian Adaptive Randomization

The development in the field of genomics and a better understanding of disease-causing mechanisms have

resulted in a shift toward molecularly targeted treatments. In cancer research, because most human tumors are heterogeneous with regard to molecular pathogenesis, genomic signatures, and phenotypic properties, a target agent is likely to benefit only a subset of patients. For example, trastuzumab works well in a subset of patients with breast cancer whose tumors have high expression levels of HER-2. In this case, reliable assays help to target patients whose tumors will be sensitive to the treatment. However, in most cases, we often do not know an assay or genomic signature that can identify the patients who have a favorable response to a given treatment. Consequently, the conduct of a traditional equally randomized clinical trial with broad eligibility criteria often fails to identify the effective agents and the sensitive patient population. Therefore, for clinical trial practitioners, the following questions arise: Does the treatment work for all patients with the specific diagnosis or for only a subset of patients with certain biomarker profiles? How can these biomarkers be identified in the trial? The assessment of drug efficacy using population statistics at the final look has shown its obvious limitations. Promising new molecular therapies may be discarded because of the absence of statistical criteria to efficiently detect them.

When the group of patients who are likely to benefit from the test treatment is known, the clinical trial should focus on that sensitive subpopulation. The use of biomarkers in adaptive clinical trials can guide the assignment of individually optimal treatments to patients. To address this objective, we proposed a cross-validated signature enrichment design combined with Bayesian RAR.[78] We evaluated the performance of this design using four criteria based on the benefits and losses for individuals inside and outside of the clinical trial. The proposed design allows more patients to receive optimal personalized treatments, thus yielding a higher response rate. This design can identify therapies that are globally beneficial as well as treatments that are effective only in a sensitive subset.

Freidlin and Simon[63] proposed to identify the sensitive patients in the middle of the trial and to test the treatment effect among the subset of sensitive patients selected among the remaining patients. Their approach provides a second chance to assess a treatment effect among the sensitive patients. As a result, it may increase the chance of detecting the treatment effect and enrich our understanding of the treatment-sensitive subpopulation.

The above signature-identification procedure can be implemented in the Bayesian RAR design described above. An adaptive signature component is implemented to identify treatment-sensitive patients and then test the treatment effect among them.[78] To distinguish the sensitive patients from the insensitive patients, we can use different statistical methods, such as the predicted odds ratio for treatment effect, among others. When there is an enormous number of covariates, we need to use variable selection to identify the treatment-sensitive subpopulation or use the covariate adaptive randomization. We conduct an initial exploration for variable selection and implement the machine learning voting methods used by Freidlin and Simon.[63] We can also use the least absolute shrinkage and selection operator method and the smoothly clipped absolute deviation method to identify the most effective variable selection method.[86,87]

The rapid advancement of cancer biomarker development allows for a better fit between patients and treatment options.[88,89] If a treatment targets a particular biomarker, such information can be used to categorize patients into either "sensitive" or "insensitive" patient subgroups to further assess the patients' responses. When the group of "sensitive" patients who are likely to benefit from the experimental treatment is known, the clinical trial should focus on that sensitive subpopulation. Some predictive cancer biomarkers that have been used to guide patient screening include HER-2 for breast cancer,[90,91] BRAF for colorectal cancer and melanoma,[92] estimated glomerular filtration rate for non–small-cell lung cancer and colorectal cancer.[87,93] Furthermore, in 2017, the FDA approved pembrolizumab for any solid tumor with the microsatellite instability-high or mismatch repair–deficient biomarker, which marked the agency's first approval based on biomarkers rather than tumor location.[94]

To use patients' biomarker information for treatment selection, during patient enrollment we apply an enrichment strategy that oversamples the sensitive patient cohort and undersamples the insensitive patients.[78] We also apply Bayesian RAR, adaptively adjusting future allocation probabilities based on the accumulated data. As a result, our design has the advantages of Bayesian adaptive randomization as well as an enrichment strategy, yielding a higher overall response rate on the trial. At the end of the trial, we test the treatment effects in the overall patient group and in the sensitive patient subgroup and control the sum of the type I error rates from these two tests.

The emergence of translating biomarker information into clinical use calls for more efficient and accelerated drug development. A master protocol is an overarching protocol that concurrently operates multiple substudies to simultaneously evaluate one or more interventions in one or more disease types, where each substudy may be conducted based on tumor type or biomarker.[95–97] Based on the characteristics of the study, master protocols are classified into basket, umbrella, and platform trials. The basket trial evaluates one treatment for multiple diseases with a common biomarker; the umbrella trial evaluates

multiple treatments, with each substudy targeting one biomarker for one disease type. The platform trials perpetually assess several treatments for one disease and permit flexible addition and/or exclusion of new treatments during the trial. If basket and umbrella trials allow the addition of new therapies and exclusion of inferior treatments during the trial, they can also be considered as platform trials.[97]

In contrast to the traditional two-arm trial, an umbrella trial is a master protocol that studies multiple drugs within a single indication, which can result in more accurate and efficient drug development. The above Signature Enrichment Design with Bayesian Adaptive Randomization (SEDAR) can be extended to a SEDAR-U design that is suitable for umbrella trials. The SEDAR-U design incorporates multiple arms and early termination rules and allows more enrolled patients to benefit from the promising treatment and achieve favorable operating characteristics.

CONCLUSION

In general, a good clinical trial design should be flexible, adaptive to the data accumulated during the trial. Compared with trials in many therapeutic areas, these features are particularly important for oncology trials. First, most cancer trials are relatively small. When many candidate drugs (trials) competing for eligible patients (recourses in this sense), a trial with small sample size is more feasible. If a trial requires too many patients, it may take a long time to recruit the requisite number of patients and thus the drug under testing may become obsolete owing to the fast advances in medicine. To help save sample sizes, a Bayesian clinical trial design could be used by considering historical information as prior statistical parameters. Second, a large proportion of cancer patients seek treatments through participating in clinical trials. This proportion might be the largest when compared with patients with other diseases. Based on this consideration, it is crucial to maximize the trial participants' benefit from the trial. That is to say, the purposes of an oncology trial include not only scientific research, but also treating patients. This is true for all trials, but because of the large number of patients with cancer participating in clinical trials, this consideration becomes especially important for oncology trial designs. This is why RAR, which assigns more patients to the better treatment arms than equal randomization would, is especially appealing for oncology trials. Because of the complications and regulation considerations, RAR has not been commonly used in phase 3 trials yet. However, for early-phase trials, which have more flexibility, RAR should have broad application.

MD ANDERSON PRACTICE TIPS

- For phase 1/2 trials, dose selection should be based on efficacy among those dose levels with acceptable toxicities. Statistical designs for these trials should reflect this consideration.
- For randomized oncology trials with relatively small sample sizes, we may still consider RAR but need to control covariate imbalance between the treatment arms to guarantee valid comparison results between them. This control can be implemented through continuously monitoring covariate imbalance during the trial and adjusting the randomization ratio for newly enrolled patients to minimize it.
- Each type of cancer is heterogeneous. Each patient with cancer has his/her unique genetic profile. We use personalized RAR aiming to assign each individual to the treatment arm that fits him/her best based on his/her biomarkers.
- Phase 2 trials usually use short-term response as the primary end point, whereas phase 3 trials are usually required to use survival (disease-free survival, PFS, or OS) as the primary end point. To better select successful candidates for phase 3 trials, we use an efficient RAR in phase 2 trials to account for both tumor response and survival.
- Targeted therapies may have "off-target" effects and thus not work as anticipated. We use statistical designs that consider both the overall effects and effects for an unknown sensitive subset whose signature is to be identified from an ongoing trial.
- Patients may be sensitive or insensitive to a targeted therapy. It lowers a trial's chance to succeed if a substantial proportion of enrolled patients are insensitive to the investigational therapy. This also hurts those insensitive patients because they may suffer from the toxicities but do not receive the benefits, and they lose time and opportunities to participate in other trials that may better benefit them. We use enrichment designs to selectively enroll sensitive patients while constantly using the data accumulated during the trial to find out which patients are sensitive.

Big Data and Machine Learning in Oncology

Peng Wei
Hai Shu

KEY CONCEPTS

- Machine learning is aimed at developing computer algorithms and statistical models to discover patterns underlying complex and large datasets (unsupervised learning) or to predict an outcome based a set of predictors and a decision rule (supervised learning).
- Deep learning (DL) is a family of machine learning methods based on multilayered artificial neural networks and has been shown to outperform classical supervised learning methods in many applications; however, it requires a large training dataset (at least thousands of samples) because of its model complexity.
- Big data in oncology mainly arise from cancer genomics (such as The Cancer Genome Atlas project), medical imaging (such as magnetic resonance imaging and positron emission tomography–computed tomography), as well as the electronic health record.
- Integrative genomic analysis is a powerful tool to study the biological mechanisms underlying a complex disease, such as cancer, across multiplatform high-dimensional data, such as DNA methylation, copy number variation, and gene expression.
- Radiomics, an emerging field in imaging analysis for diagnosis, prognosis, or treatment response prediction, refers to the extraction of a large number of quantitative features, including shape features, first-order histogram features, and second-order texture features that capture spatial arrangement of the voxel intensities.
- Assessment of prediction model performance should be based on the test error, that is, the prediction error over an independent test sample. On the other hand, minimizing the training error, that is, the prediction error over the sample used to train a model, will lead to overfitting and over-optimism about the model performance. Test error can be objectively evaluated by proper training/test data split or cross-validation.

The term *artificial intelligence* (AI) was first coined by John McCarthy for the famous workshop Dartmouth Summer Research Project on Artificial Intelligence held in 1956,[1] defined as "the science and engineering of making intelligent machines."[2] As a subfield of AI, machine learning is the study of mathematical and statistical approaches that automatically improve the performance of computers through experience.[3] Deep learning (DL), a revolutionary family of machine learning methods based on multilayered artificial neural networks (ANN),[4] has caused a third boom of AI and is integrated into our daily lives in ways such as face recognition,[5] self-driving cars,[6] personal electronic assistants (Siri, Alexa, and Google Assistant), and intelligent medical diagnostics.[7,8]

MACHINE LEARNING

Machine learning, also referred to as statistical learning in the field of statistics, is aimed at developing computer algorithms and statistical models to discover patterns underlying complex and large data sets (unsupervised learning) or to predict an outcome based a set of predictors and a decision rule (supervised learning).[9] The development of machine learning has been bolstered by the big data and emerging analytics challenges in medicine, in particular, oncology, because of the breakthroughs in high-throughput technologies, such as microarray profiling technologies in the late 1990s and early 2000s,[10,11] next-generation sequencing technologies in the mid- to late 2000s,[12,13] and single-cell

sequencing technologies[14,15] in the 2010s. For example, a typical gene expression microarray or RNA-sequencing experiment can interrogate the expression levels of genome-wide messenger RNAs (>20,000 mRNAs) in dozens to hundreds of samples. The Cancer Genome Atlas (TCGA) project, begun in 2005, exemplifies the big data in oncology. It uses a variety of high-throughput platforms to molecularly characterize more than 20,000 primary cancer and matched normal samples spanning 33 cancer types, generating more than 2.5 petabytes of genomic, epigenomic, transcriptomic, and proteomic data.[16,17]

To address the need to uncover cancer subtypes based on high-throughput genomics data, a number of unsupervised machine learning methods have been developed and refined, such as hierarchical clustering, clustering based on multiple types of genomic data (iCluster[18]), and model-based clustering methods.[19] On the other hand, supervised machine learning has also had unprecedented breakthroughs in the past couple of decades, motivated by the need to build prediction models based on high-dimensional predictors (tens of thousands) and relatively small sample sizes (dozens to hundreds), that is, the so called "large p, small n" problem. Major breakthroughs in supervised machine learning include penalized regression methods (lasso,[20] elastic net,[21] and sure independent screening,[22] to name a few); support vector machine,[23] and ensemble-based methods (random forests[24] and boosting[25]); see Hastie et al for a comprehensive introduction.[9]

DEEP LEARNING

DL was notably brought to the public's attention by AlphaGo versus Lee Sedol in 2016, where the DL-trained computer program vanquished the world's Go champion.[26] In the AI community, the spectacular success of DL can be dated 4 years earlier to the well-known ImageNet Large Scale Visual Recognition Challenge 2012 in which the AlexNet, a deep convolutional neural network, achieved a top-5 error rate of 15.3%, more than 10.8% lower than that of the runner up (a non-DL approach).[27] Since then, DL has been successfully applied in various areas of academia and industry,[5–8] which is ascribed to the availability of large datasets (ImageNet,[28] COCO,[29] BraTS[30]), the exponential growth in computing power (graphics processing unit and tensor processing unit), and the well-optimized open-source software libraries (Pytorch, Tensorflow, and Keras).

As the base of DL, an ANN is a nonlinear mathematical model that builds a complex relationship between the input data and the output.[4] In an ANN, the input data are provided to an input layer and then transmitted through one or multiple hidden layers that are linked to an output layer (Fig. 70–1). A layer is a collection of

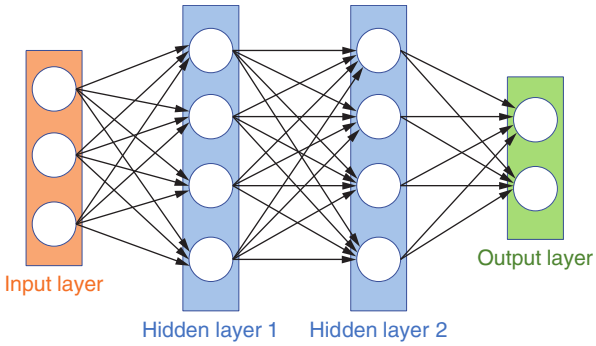

FIGURE 70–1 Architecture of an artificial neural network.

nodes, called neurons, imitating the ones in the human brain, which are connected through edges to the previous and the next layers. Edges are assigned with trainable weights to sum the output values of neurons in the previous layer as the input to each neuron in the next layer. Each neuron nonlinearly transforms the data by applying an activation function. A deep neural network is an ANN with many hidden layers, commonly 10+ and even 100+ layers. A convolutional neural network is a specialized type of ANN designed for image data, which performs a linear operation called a "convolution" that is capable of capturing the spatial dependency in an image.

AI, especially DL, has been recently gaining popularity in medicine, to improve time efficiency, reduce human errors and variability, as well as lower the medical cost.[7,8] The widest application is the field of medical image analysis, mainly because of the remarkable progress in computer vision. For instance, McKinney et al[31] developed a DL model for identifying breast cancer in screening mammograms, which had the area under the receiver operating characteristic curve (AUC) greater than that for the average of six radiologists by an absolute margin of 11.5%. More examples include the BraTS Challenge 2019 for brain tumor magnetic resonance imaging (MRI) segmentation,[32] IDRiD Challenge 2018 for diabetic retinopathy segmentation and grading,[33] and Data Science Bowl 2017 for lung cancer detection in computed tomography,[34] where automated DL algorithms won championships and dominated the challenges. Beyond the medical imaging field, DL is also successfully used on electronic health records for personalized risk predictions and health trajectories and applied in genomic research for predictions of genomic features and functions.[35]

To advance the development and applications of DL and AI in medicine and healthcare, many impressive platforms have been established. Grand Challenge (https://grand-challenge.org/) and Dream Challenges (http://dreamchallenges.org/) post medical and public health competitions in which novel AI algorithms can be devised, for example, the famous U-Net[36] invented for a segmentation challenge. The journals *Artificial Intelligence in Medicine* and *Radiology: Artificial Intelligence*

publish high-quality articles concerning the theory or practice of AI in medicine, and the JAMA Network archives the relevant articles published in its journals (https://sites.jamanetwork.com/machine-learning/).

TRAINING ERROR VERSUS TEST ERROR IN MACHINE LEARNING

Assessment of prediction model performance should be based on the test error, that is, the prediction error over an independent test sample. However, a common mistake in machine learning modeling is the attempt to minimize the training error, that is, the prediction error over the sample used to train a model. Unfortunately, this will lead to overfitting of the model and over-optimism about the model performance. In fact, the training error typically keeps decreasing with increasing number of predictors included in the model, regardless of whether true or noise predictors are included. For example, the training error misclassification rate in a binary outcome prediction problem can be as small as zero with many purely noise predictors. On the other hand, the test error for the same model can be very large.

To objectively estimate the test error, a given data set for prediction modeling should be split into training and test samples (3:1 to 5:1 ratio) with the former being used for model building and the latter for prediction accuracy evaluation. Should the sample size be limited, a K-fold cross-validation can be used to estimate the test error, where commonly used K include 3, 5, 10, or *n* (the sample size, that is, the leave-one-out cross-validation). For example, a five-fold cross-validation entails randomly and equally splitting the entire samples into five groups. Each of the five folds is then held out in turn as the test set and the remaining four folds comprise the training data; the overall prediction accuracy is calculated as the averaged accuracy across all five folds. In the case studies to be detailed later, we used a three-fold cross-validation with a sample size of 74 in Case Study II and a 5:1 training/test data split in Case Study III with a total sample size of 3713. See Chapter 7 of Hastie et al[9] for a comprehensive treatment on this topic.

CASE STUDIES OF MACHINE LEARNING APPLICATION AT MD ANDERSON

In this section we present three case studies to showcase the machine learning research and applications at MDACC, including (1) integrative analysis of cancer genomics data, (2) predictive modeling using MRI radiomics features for treatment response, and (3) DL modeling for mammography.

Case Study I: Integrative Analysis of Cancer Genomics Data

Genomic profiling studies have demonstrated that bladder cancer can be divided into two molecular subtypes, referred to as luminal and basal, with distinct clinical behaviors and sensitivities to frontline chemotherapy.[37,38] Twenty-three mRNA gene expression markers have been reported to play a major role in these molecular subtypes[38]; however, it is not yet known (1) whether those gene expression markers also demonstrate difference at the DNA methylation and copy number variation (CNV) levels, and (2) whether there are other genes associated with the molecular subtyping through any of the three data types (ie, mRNA expression, DNA methylation, and CNV). Although it is common to perform large-scale genome-wide association analysis of an outcome for each data type separately and combine the results ad hoc, it can result in loss of statistical power and uncontrolled overall false discovery rate (FDR).[39] To this end, we proposed a novel multivariate mixture model (IMIX) framework that integrates multiple types of genomic data and allows modeling of interdata-type correlations.[40] IMIX features across-data-type FDR control, computational efficiency, and a user-friendly software package "IMIX" in R (https://github.com/ziqiaow/IMIX). In addition, IMIX only requires summary statistics as its inputs, not individual patient-level data.

We applied IMIX to analyze the TCGA bladder cancer patient cohort, which was profiled by three genomic platforms: DNA methylation (M), mRNA gene expression (GE), and CNV. Our objective was to classify each of the genome-wide genes into one of eight possible classes based on association patterns of the three data types: (M–, GE–, CNV–), (M+, GE–, CNV–), (M–, GE+, CNV–), (M–, GE–, CNV+), (M+, GE+, CNV–), (M+, GE–, CNV+), (M–, GE+, CNV+), and (M+, GE+, CNV+). For example, genes in class (M–, GE–, CNV–) were not associated with the basal/luminal subtype through any of the three data types, whereas those in class (M+, GE+, CNV+) were associated through all three. After quality control, we separately analyzed 373 DNA methylation samples, 391 RNA-sequencing samples, and 387 CNV samples with 15,672 genes with respect to the molecular subtypes, adjusting for the clinical covariates, including age, sex, race, smoking status, and pathologic stage. We applied IMIX to the final *P* values obtained from the association tests of individual-level data. At an FDR of 1%, we identified 61 significant genes in class (M+, GE+, CNV+), ie, genes that were associated with all three data types. We show the DNA methylation, gene expression, and CNV levels of the 61 genes in Fig. 70–2A, where the differential gene expression between luminal and basal subtypes appeared to be positively correlated with CNV levels and negatively correlated with DNA methylation

levels. We further conducted Ingenuity Pathway Analysis (Ingenuity Systems; www.ingenuity.com) on the 61 significant genes. The results showed strong peroxisome proliferator activator receptor (PPAR) pathway activation in luminal samples. This pathway was previously reported by Choi et al,[38] who first proposed the molecular subtypes of muscle-invasive bladder cancer and showed that PPARα and PPARγ activation played essential roles in regulating gene expression signature for the luminal subtype. Specifically, they exposed the PPARγ-selective agonist rosiglitazone in two bladder cancer cell lines and further confirmed that rosiglitazone activated the PPAR pathway and enriched gene signatures in primary luminal samples.

We also present the levels of the luminal and basal markers for DNA methylation, gene expression, and CNV in Fig. 70–2B. Among the 23 markers, we found that 6, 15, and 1 gene belonged to class (M–, E+, CNV–), (M+, E+, CNV–), and (M+, E+, CNV+), respectively. In particular, PPARG belonged to class (M+, E+, CNV+), ie, associated with the subtypes via all three molecular mechanisms. This gene was reported to be one of the driver genes for basal and luminal differentiation. As expected, the luminal samples showed a higher PPARγ gene expression level than did the basal samples; furthermore, we discovered a concordant significant differential pattern in the methylation and CNV levels that has not been previously reported.

In summary, our integrative genomic data analysis revealed that the luminal and basal markers demonstrated substantial differences in at least two data types (Fig. 70–2B). By applying the IMIX framework, we

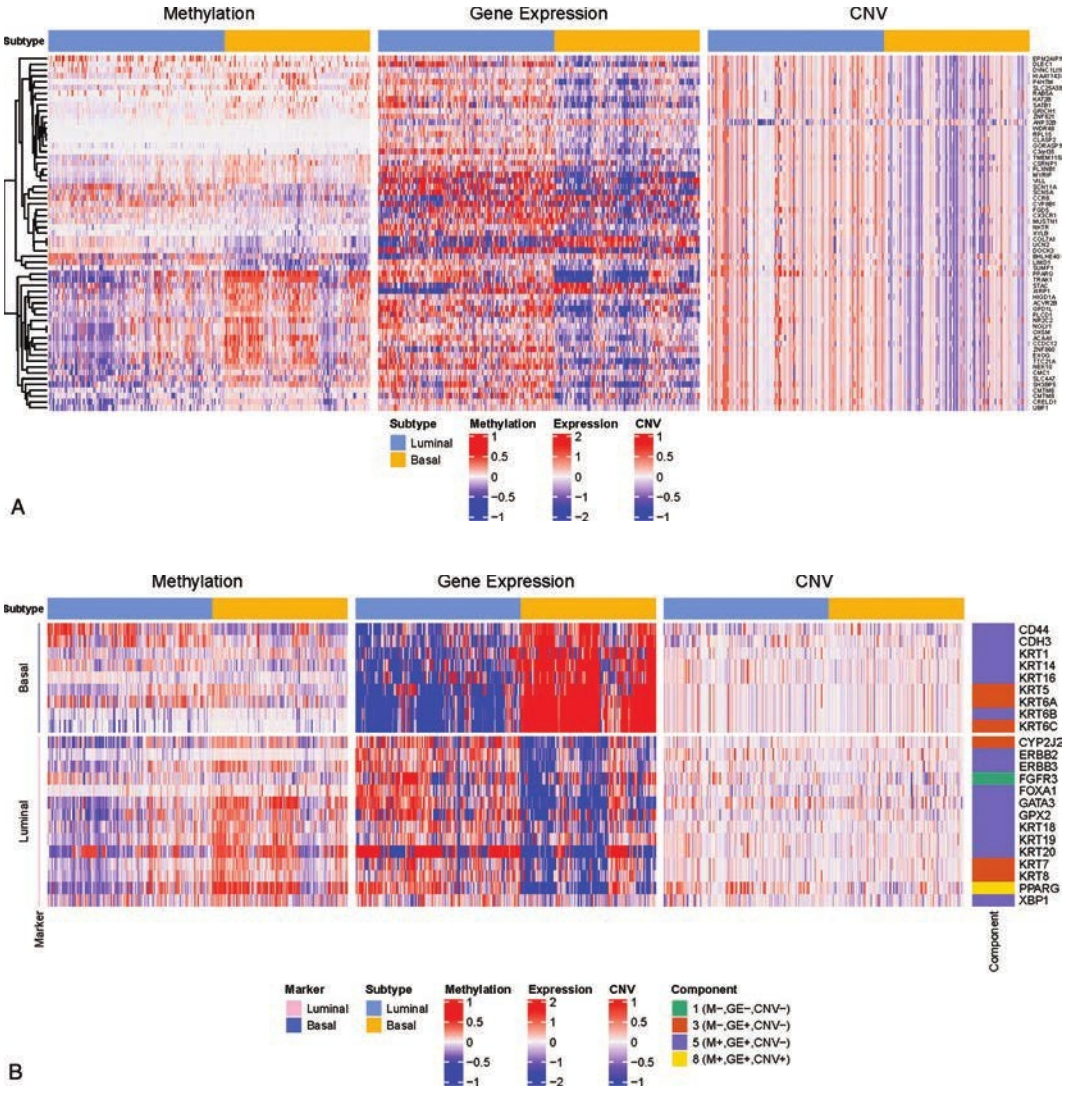

FIGURE 70–2 **A. Heatmaps of genes in IMIX analysis for bladder cancer molecular subtypes in The Cancer Genome Atlas (TCGA). (a) Methylation, gene expression, and copy number variation (CNV) patterns of top significant genes associated with the three data types (M+, GE+, CNV+) identified by IMIX in molecular subtypes of TCGA muscle-invasive bladder cancer patients, with FDR at 1%. B. Expression patterns of luminal and basal markers of TCGA bladder cancer cohort.**

successfully discovered novel genes that were associated with the molecular subtypes across all three data types (Fig. 70–2B) and confirmed the PPAR/RXR activation canonical pathway that was previously reported to play a central role in luminal and basal differentiation.[38]

In addition to being key contributors to the TCGA project,[16,41,42] MDACC investigators have also utilized the TCGA data as a reference to molecularly characterize rare, yet clinically aggressive, cancer subtypes, such as sarcomatoid,[43] small cell carcinoma,[44] and micropapillary[45] variants of bladder cancer, using a multiple-omics approach. A basal to luminal transition score has also been recently developed by applying the lasso regression model[20] to the TCGA bladder cancer cohort (n = 408) as the training data and subsequently validating it in two MDACC cohorts (fresh frozen samples n = 132 and formalin-fixed paraffin-embedded samples n = 89).[37]

Case Study II: MRI Imaging in a Triple-Negative Breast Cancer Clinical Trial

Triple-negative breast cancer (TNBC) accounts for approximately 20% of all breast cancers and is a subtype of breast cancer that lacks estrogen receptor, progesterone receptor, and HER2 expression.[46] Compared with other breast cancer subtypes, TNBC is more aggressive and is associated with a higher rate of relapse and a lower rate of overall survival. Patients with TNBC usually undergo neoadjuvant systemic therapy (NAST) for downstaging of disease to facilitate less invasive surgery. The extent of downstaging is used as a surrogate prognostic marker. Pathologic complete response (pCR) to NAST is seen in about half of the patients with TNBC undergoing the treatment but is weak or absent in the others. The ongoing "A Robust TNBC Evaluation FraMework to Improve Survival" (ARTEMIS) clinical trial (NCT02276443), a part of the MDACC Breast Cancer Moon Shot Program®, is aimed at using longitudinal genomic and imaging signatures to identify patients with TNBC who are sensitive/insensitive to standard NAST chemotherapy. TNBC patients of stage I–III in the study undergo biopsy before treatment, and then immediately begin NAST. Genomic profiling by RNA sequencing and whole-exome sequencing, as well as ultrasound and multiple sequences of MRI imaging (T1, T2, ultrafast dynamic contrast enhanced [DCE]-MRI, and chemical exchange saturation transfer–MRI), are performed at baseline, after two cycles, and at completion of four cycles of NAST. pCR is then ascertained by pathologists after appropriate surgery according to the size of the residual tumor.

Here we introduce a pilot radiomics study that is aimed at using radiomic features of MRI imaging to predict pCR in TNBC patients receiving NAST.[47] Radiomics, an emerging field in imaging analysis, refers to the extraction of a large number of quantitative features, including shape features (eg, volume and maximum diameter), first-order histogram features (eg, mean, median, minimum, maximum, skewness, and kurtosis of intensity distribution), and second-order texture features that capture spatial arrangement of the voxel intensities.[48] To investigate whether radiomic phenotypes can predict pCR, we extracted 390 radiomic features (first-order histogram features and second-order grey-level-cooccurrence matrix) from each of 74 patients with stage I–III TNBC who underwent ultrafast DCE-MRI (temporal-resolution: 9–12 s) at baseline in the ARTEMIS trial using an in-house MATLAB library. AUC was used to determine how well radiomic features could predict pCR. Given the relatively small sample size and large number of radiomic features, we used three-fold cross-validation and a penalized logistic regression model with the elastic net penalty to build a prediction model. The elastic net penalty is appealing because it enables feature selection while accommodating potentially correlated features as is the case for radiomics.[21,49,50] The resulting radiomic model consisting of 24 features had an AUC of 0.80 for predicting pCR. This model is being validated in an independent set of ARTEMIS patients. Other ongoing research efforts include integrating molecular, genomic, and imaging biomarkers to tailor personalized treatment for patients with TNBC and developing DL models for longitudinal MRI imaging to predict pCR.

Case Study III: Deep Learning Approach to Mammography

MERIT (Mammography, Early detection biomarkers, Risk assessment and Imaging Technologies) is a multidisciplinary MDACC initiative designed for discovery, evaluation, and validation of biomarkers for early detection of breast cancer. In this section, we describe a MERIT project that proposed a DL approach to recover for-processing full-field digital mammograms for breast density and texture feature analysis. Interested readers are referred to the article by Shu et al for details.[51]

Full-field digital mammography generates two types of imaging data[52]: the raw "for-processing" images in which the greyscale is proportional to the x-ray attenuation through the breast, and the processed "for-presentation" images that are optimized for visual cancer detection. For-processing images are more appropriate for quantitative analyses (eg, breast density evaluation and texture feature analysis) than for-presentation images because they reflect the original physical properties of the breast. The literature has reported significant differences in breast density and texture measures between the two image types.[53,54] However, in clinical settings, for-processing images are rarely archived because of cost and storage constraints; only for-presentation images are routinely stored. Moreover,

mammography equipment manufacturers do not disclose raw-to-processed-image conversion steps, and inversion algorithms are not available. Hence, retrospective calculations of breast density and texture features using preferred for-processing image-based algorithms and software[55,56] are not applicable to most historical images stored only in the for-presentation format.

This motivated our research to recover for-processing images from for-presentation images. We developed an image recovery approach by utilizing the powerful DL technique, the U-Net.[36] The U-Net and its variants[57,58] have exhibited state-of-the-art performance in various medical image segmentation tasks.[32,33,59] We extended the use of U-Net to image estimation, in which the recovered image can be viewed as a continuous-valued segmentation map. We mathematically used U-Net as a nonlinear regression function to fit for-processing images based on for-presentation images. Specifically, in the original U-Net we changed the loss function to the mean square error from the cross-entropy of classification and the final activation function to the continuous ReLU function from the categorical softmax function.

All for-processing and for-presentation mammograms were generated using the Selenia Dimensions Mammography System (Hologic). The for-presentation images were retrieved from the Picture Archiving and Communication System, and the for-processing images were stored on a Picture Archiving and Communication System–based research server. The data set contained 3713 pairs of for-processing and for-presentation mammograms from 884 women (age range, 28–80 years; mean ± standard deviation [SD] age, 56.7 ± 9.9 years), including 1891 pairs in the mediolateral oblique view and 1822 pairs in the craniocaudal view. The dataset was randomly split into disjoint training and testing sets, consisting of images from 737 and 147 women (737:147»5:1) with 1569 and 322 pairs in the mediolateral oblique view and 1519 and 303 pairs in the craniocaudal view. Both for-processing and for-presentation images were used in model training. In testing, the for-presentation images were input into the trained model to generate the estimated for-processing images, and the original for-processing images were used only to evaluate image recovery performance.

In the testing data set, the estimated for-processing images had acceptable mean absolute percentage error (mean ± SD = 0.115 ± 0.059) and high structural similarity index (0.986 ± 0.007) for the breast portion. The estimated and original images had a strong correlation in breast density percentage (Pearson r = 0.946; 95% CI 0.926, 0.966) and a strong agreement in breast density grade (Cohen κ = 0.875; 95% CI 0.845, 0.905). The breast density percentage and grade were evaluated by Volpara software (version 1.5.4.0; Volpara Solutions). We also considered the widely used 28 mammographic texture features listed in Gastounioti et al.[53] The estimated images had satisfactory correlations with the originals in 22 texture features (Pearson $r \in$ [0.762, 0.986] and [0.503, 0.668] for 18 and two features, respectively; Spearman ρ ³ 0.705 for another two) and were well complemented by for-presentation images for the other six features ($r \in$ [0.832, 0.846] and = 0.650 for four and one features, respectively; Spearman's ρ = 0.553 for the other one). We obtained comparable results for the training dataset. Hence, our DL approach performed well in recovering for-processing mammograms with strong consistency in image error and similarity metrics, breast density, and the majority of 28 widely used texture features. Figure 70–3 illustrates examples of our recovered for-processing images.

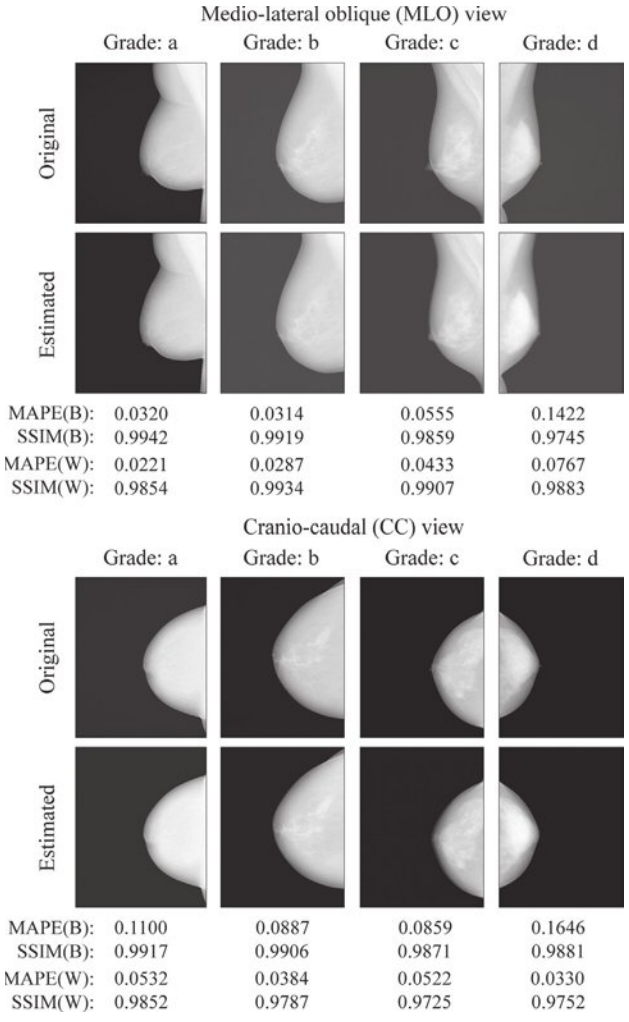

FIGURE 70–3 **Comparison of original and estimated for-processing images for four randomly selected patients with different true Volpara breast density grades. The images were negative log–transformed to improve readability. (B), (breast portion); MAPE, mean absolute percentage error; SSIM, structural similarity index measure; (W), (whole image).**

CONCLUSION AND FUTURE DIRECTIONS

Big data in oncology arise from cancer genomics, medical imaging, and the electronic health record. Recent advances in machine learning methods, particularly, DL, have revolutionized precision oncology and, more broadly, precision medicine.[60] A promising direction is to integrate genomics and medical imaging data to build prediction models for diagnosis, prognosis, or treatment response.[61]

Two emerging directions in AI are the deep reinforcement learning[62] and deep causal inference,[63] which are the combination of DL with reinforcement learning and causal inference, respectively. DL enables them scale to problems that were previously intractable. Reinforcement learning is to learn a strategy for an agent to take actions in an environment to maximize expected cumulative rewards. A prominent application of deep reinforcement learning in medicine is robotic surgery, which is expected to improve precision, increase safety, and reduce time and expenses.[64,65] In contrast with the relatively acceptable robot-assisted surgery, that is, under a human surgeon's supervision, the autonomous robotic surgery may face ethical issues.[66] Causal inference studies the causal relationships among different components of a system. Deep causal inference is useful to address complex medical problems, such as the causal effect estimation in the presence of high-dimensional covariates and high cardinality treatments.[67]

MD ANDERSON PRACTICE TIPS

- Machine learning research in oncology requires a team-science approach by investigators from multiple disciplines including medical oncologists, radiologists, pathologists, medical physicists, biostatisticians, bioinformaticians, and computer scientists.
- Team-science research at MDACC is facilitated by the National Cancer Institute Cancer Center Support Grant, Specialized Programs of Research Excellence grants, and MDACC's Breast Cancer Moon Shot Program®.
- Machine learning, in particular DL research, needs strong computational infrastructure, including high-performance computing (HPC) with a large number of central processing unit and graphics processing unit computing nodes, large memory, and storage space. MDACC investigators have access to institutional HPC with dedicated IT support, as well as world-class HPC resources at the Texas Advanced Computing Center as afforded by the University of Texas Research Cyberinfrastructure Initiative.
- Public data sets such as those form TCGA, the database of Genotypes and Phenotypes (dbGaP), and the Gene Expression Omnibus, which can be effectively leveraged to compare and combine with data generated from local patient samples.
- Given a data set for prediction modeling, it should be split into training and test samples (3:1 to 5:1 ratio) with the former being used for model building and the latter for prediction accuracy evaluation. Should the sample size be limited, cross-validation can be employed to estimate the test error. Ideally, an independent data set from a different source, for example, institution, should be further used to validate the prediction model.
- DL has been shown to outperform classical machine learning methods in imaging and other applications; however, because of the model complexity, it requires a large training data set (at least thousands of samples). For prediction modeling with moderate sample sizes, traditional machine learning methods, such as penalized regression, random forests, and boosting, can still be good options.

71 Value-Based Oncology

Casey J. Allen
Aileen Chen
Ryan W. Huey
Ya-Chen Tina Shih

KEY CONCEPTS

- As the demand to curb costs and improve the quality of cancer care increases, cancer care delivery should align with patients' value and preference.
- Value assessment is of paramount importance to the delivery of value-based cancer care effectively and efficiently.
- There are evolving value-based practices specific to the fields of medical, radiation, and surgical oncology.
- To serve the need for value assessment in today's health care environment, there is ongoing development of various value frameworks.
- Management science and health economics and outcomes research both contribute to value assessment frameworks.
- Our ability to effectively communicate value will facilitate shared decision making among all stakeholders involved in value-based health care.

OVERVIEW OF VALUE-BASED HEALTHCARE

As projections indicate that healthcare spending will account for nearly one-fifth of the Gross Domestic Product in the United States in 2021, the rate at which healthcare costs are growing will limit our country's growth and possibly even bankrupt the nation.[1] Cancer care in particular is of great concern because of its relatively high costs to deliver treatment. Furthermore, cancer care costs are expected to grow 40% from 2010 to a projected $175 billion in 2020.[2]

The rising cost of cancer care impacts many stakeholders including patients and their families, providers, payers, and manufacturers. If the costs of cancer care continue to rise unchecked, it will be become unaffordable for many Americans—a concern raised by an Institute of Medicine (now National Academies of Sciences, Engineering, and Medicine) consensus study in 2013.[3] Financial hardship, or financial toxicity, describes the impact of direct and indirect healthcare costs that lead to significant financial burden for patients and their caregivers, resulting in increased psychosocial distress, worse outcomes, and poorer quality of life (QOL).[4,5] In addition, as specialized cancer care continues to become more centralized, one well-recognized disadvantage is the limited access to high-quality care in patients with low socioeconomic status.[6–8] Barriers to access treatment may impact patient-centric outcomes.

Moreover, there is now widespread recognition that high-cost care does not necessarily translate into high-quality care or improved outcomes. The per capita healthcare spending in the United States far exceeds that in other developed countries, yet when juxtaposed against life expectancies, it is clear there is a great deal of wasted expense in our healthcare system.[9]

As the demand to curb costs and improve quality increases, there is a societal consensus that healthcare should be more greatly assessed on value. Thus, the United States healthcare system is now in the midst of transitioning to a value-incentivized system.[10] As policymakers and those covering the costs (insurers and patients) seek ways to assure the best use of limited resources, they are turning to business leaders, physicians, and health economists for a better understanding—and definition—of value. There is a growing understanding that true healthcare reform will require major strategic and organizational changes in the way healthcare is actually measured, delivered, and reimbursed.[11,12] Also, because the federal government and individual states are beginning to mandate insurers

and providers to improve price transparency by offering patients information about their healthcare costs,[13] patients will likely want to be more actively engaged in their interactions with clinicians to ensure that the treatment choice aligns with their value and preference.

CONCEPTUAL FRAMEWORK OF VALUE ASSESSMENT

Value Assessment from Management Science Approach

The value-based healthcare movement is based on the work of leading authorities on competitive business strategy Michael E. Porter and Elizabeth O. Teisberg. Their landmark book, *Redefining Health Care Creating Value-Based Competition on Results*,[14] was published after more than a decade of research into why the healthcare industry failed to conform to the standard economic principles of competition. They described how healthcare had fallen into dysfunction as providers competed for the wrong things. Value-based healthcare's central tenet is that value for patients must be the overarching principle in the organization and management of healthcare delivery systems.

The Value Equation

As originally proposed by Porter and Teisberg, "value" for patients is determined by assessing the relationship between the outcomes that matter to them and the cost incurred to deliver those outcomes across the full cycle of care.[14] To capture the multiple dimensions of a patient's health, they proposed the concept of a three-tiered outcome measures hierarchy.[14,15] This hierarchy highlights the importance of survival but also accounts for degree of recovery, time to recovery, harm caused during treatment, recurrences, and long-term consequences of care.

The Expanded Value Equation

Adhering to Porter's principles, MDACC has favored a definition that integrates the outcomes component of the value framework with traditional quality, safety, and patient experience measures.[16] Our detailed equation incorporates the dimension of time by including short-term complications with long-term disability, and both early and late survival with functional recovery. It also expands the definition of cost to include the costs to both payers and patients. As depicted in Equation (1), our value equation includes components specified to metrics of quality (survival, functional recovery, experiences); harm/safety (complications, pain, disability); and/or cost (patient-borne, third-party payer, institutional).

$$VALUE = \frac{QUALITY\ (survival,\ functional\ recovery,\ experience) - HARM/SAFETY\ (complications,\ pain,\ disability)}{COSTS\ (institutional,\ patient,\ payer)} \quad EQ(1)$$

Value Assessment from Health Economics and Outcomes Research Approach

Recognizing the urgent need for better understanding and assessing value in today's healthcare environment, the International Society for Pharmacoeconomics and Outcomes Research (ISPOR), a leading organization in health economics and outcomes research (HEOR), formed a Special Task Force on Value Assessment in 2016.[17] A series of reports from this ISPOR Special Task Force, alone with other articles covering the conceptual, theoretical, empirical, and practical aspects of value assessment, were published in a themed issue in *Value in Health* in 2018.[18] In this section, we provide a broad overview of value assessment from the HEOR approach. Readers who are interested in deeper learning on this topic are encouraged to read this themed issue.

Elements of Value

The biggest challenge in value assessment is to define "value" because the word is inherently subjective and multifaceted. HEOR experts acknowledged 12 elements of value: (1) quality-adjusted life-years (QALYs); (2) net costs; (3) productivity; (4) adherence-improving factors; (5) reduction in uncertainty; (6) fear of contagion; (7) insurance value; (8) severity of disease; (9) value of hope; (10) real option value; (11) equity; and (12) scientific spillovers.[19] QALY is a measure that weighs life-years (LYs) gained from interventions with health utility associated with various health states in that duration, with weight 1.0 giving to perfect health and 0 to death. Net costs refer to the additional (or incremental) cost associated with a new intervention compared with alternative(s)—often the current standard of care. QALYs and net costs are the two value elements most commonly found in value assessment in HEOR because they form the basic components of cost-effectiveness analysis (CEA). Productivity captures health-related work impairment and consists of two components: absenteeism and presenteeism. The former quantifies time absent from work because of illness, whereas the latter measured reduction in the quality of work performed when coming to work while sick.[20] Adherence-improving factors reflect value through improving health outcomes as a result of better adherence to treatment, which can be achieved with certain product features (eg, switch medications from twice daily to once daily) or technologies (eg, MEMS® Cap device). In the context of oncology value assessment, all four value elements discussed above are important to consider.

The remaining eight elements of value are relatively underexplored in the HEOR literature; several are especially relevant in the discussions of value-based oncology. For example, the value of an intervention can be enhanced by reducing uncertainty in outcomes (element #5) with the use of tests or algorithms to identify subgroups most likely to benefit from an intervention (eg, pharmacogenomic tests to better differentiate responders and nonresponders of certain chemotherapy regimens or risk-stratified screening strategies). Severity of disease (element #8) debates whether the value of an intervention differs by the severity of disease intended for the intervention, raising the question of whether higher values should be placed on end-of-life care or treatment of late-stage cancers. Value of hope (element #9) is especially relevant when comparing values between two oncology products: a high-risk treatment with a small chance of achieving large survival benefit versus a lower-risk treatment with moderate survival benefit. Real option value (element #10) refers to the situation in which life extended from a treatment creates an opportunity for patients to benefit from treatment advances in the future. With a large pipeline of oncology products, this value element is particularly meaningful. Indeed, research has found that the inclusion of option value increases the value of treatment for chronic myeloid leukemia by 10%.[21] The other elements are equally applicable to oncology as well as other diseases. Interestingly, fear of contagion (element #6) is traditionally thought to be more relevant to infectious diseases and less relevant to oncology. However, current experience with a highly contagious virus like Covid-19 sounded the alarm that value assessment of oncology may need to consider the overall public health environment and how cancer care interacts with other diseases in such an environment.

Methods to Quantify Value

The ultimate goal of value assessment is to assist stakeholders in making informed decisions. The transition from "value framework" to "decision making" requires methods that synthesize and quantify information into a metric useful to decision makers. Two commonly used approaches to generate such metric is CEA and multicriteria decision analysis (MCDA).

Cost-Effectiveness Analysis

CEA summarizes study findings in terms of the incremental cost-effectiveness ratio (ICER).[22,23] The ICER, as shown in Equation (2) below, estimates the additional resource consumption needed to achieve an increase in an additional unit of effectiveness, often measured by LYs saved or QALYs gained.

$$ICER = \frac{E(COST_{NEW}) - E(COST_{OLD})}{E(EFFECTIVENESS_{NEW}) - E(EFFECTIVENESS_{OLD})} \quad EQ(2)$$

Incremental cost, the numerator of ICER, calculated the difference in the mean cost of the new treatment and that of the old (existing) treatment. Incremental effectiveness, the denominator of ICER, is the difference in the mean effectiveness of the new treatment and that of the old treatment. The ICER is then compared with a threshold value; an intervention is considered cost-effective if the ICER is below the threshold value. Although many countries have explicitly specified the threshold value acceptable for the new treatment,[24] there is no threshold value published by the US government. A survey of medical oncologists in the US and Canada indicated that the majority of oncologists considered $100,000/QALY an acceptable threshold value.[25] A review of economic evaluation methods in the context of oncology can be found in an article published in *CA: A Cancer Journal for Clinicians* in 2008.[26] More recently, researchers have extended the conventional CEA to incorporate broader topics of interest to health policymakers, such as equity, distributional benefits, and financial protections.[27,28]

The value equation proposed by Porter and Teisberg[14] resembles the concept of average cost-effectiveness ratio (ACER) in the HEOR literature. The ACER quantifies the average cost per effect for an intervention, whereas ICER emphasizes the concept of incremental efficiency that captures the additional costs consumed to gain an additional unit of effectiveness. It is generally agreed in the HEOR literature that ICER is supported by economic theories and better reflects the nature of decision making in that decision makers often determine the value of a new treatment by comparing its improvement in outcomes as well as the additional costs with the existing treatment. It has been documented that ACER can lead to the wrong choice in healthcare decision making.[29]

Multicriteria Decision Analysis

One of the key requirements in CEA is to explicitly specify the study perspective, with societal perspective being the preferred choice.[30] However, this single-metric approach creates a challenge for decision makers to incorporate the viewpoints from multiple stakeholders simultaneously. MCDA is an emerging approach in HEOR that offers an analytical framework to explicitly incorporate the subjective and multidimensional features of value into decision making.[31] MCDA involves four key steps to prepare the data for decision makers. First, researchers need to determine the elements of value to be considered. For example, the value elements for oncology care may include median survival,

progress-free survival, toxicity profile (eg, nausea/vomiting, anemia, febrile neutropenia), pain, anxiety, total cost of treatment, and out-of-pocket cost for patients, among others. The next step is to define the boundary values for each of these value elements or "attributes." For some attributes, it is obvious that the boundary values would have to be confined within a range that meets the statistical property of that attribute, such as probabilities are bound between [0,1] range. For other attributes, such as costs, the boundary values are less obvious and will rely on additional research to determine these values. Next, scores need to be assigned to each attribute based on each patient's preference through some forms of value function. The last step is to solicit weights for each attribute. One approach is to simply ask stakeholders to rank order the attributes and convert the ranking into weights using methods such as the rank order centroid method.[31] For ease of illustration, assume that there are three treatments (X, Y, and Z), three patients (A, B, and C), and three attributes: probability of 5-year survival, probability of severe side effects, and costs. Using the rank order centroid method and in the case of three attributes, the weight for each attribute, ranked by the order of importance, is calculated as (1+1/2+1/3)/3 (~0.61), (1/2+1/3)/3 (~0.28), and (1/3)/3 (~0.11), respectively.

After completing the first two steps described above, results can be summarized in the input table for MCDA (Table 71–1A), followed by soliciting preference scores for each patients (Table 71–1B). A patient's value for each treatment can then be calculated by taking the weighted average across attribute values (Table 71–1C). As an emerging method, many methodological details of MCDA are still under development, such as the scoring algorithm for the attributes and the weighting methods. The most critical issue is the decision rule to determine which treatment/intervention yields highest "value" at the population level. As shown in Table 71–1C, although the treatment choice of each patient is clear, the best choice for the society as a whole may not be obvious. Readers who are interested in learning more about MCDA are recommended to read the task force reports by ISPOR MCDA Emerging Good Practices Task Force.[32,33]

Value Assessment in Oncology

Cancer care is an opportune context in which to target value-based healthcare delivery. As clearly stated by the President of the American Society of Clinical Oncology (ASCO) in 2014, Dr Clifford A. Hudis: "*In oncology, we face the fascinating challenge of determining the value of today's cancer treatments….What is the worth … of three or four more weeks of time … relative to the cost and side effects of the treatment? … The answers to these kinds of questions may vary widely among different patients, families, healthcare providers, and communities, but we must confront these difficult issues with courage, compassion, and integrity.*"[34]

Value assessment is of paramount importance to the delivery of value-based cancer care effectively and efficiently. Despite the desire to transition into a value-driven system, our capability of quantifying value is in flux and there had been no objective way to quantify and communicate the many outcomes and cost components of value to patients, stakeholders, or healthcare providers. For these reasons, frameworks have been developed to provide a comprehensive measure of healthcare value.

Value frameworks have gained broader use in the field of oncology. The benefits of new and promising therapies might not necessarily be uniformly distributed. When considering a cancer treatment—especially one that could financially imperil a patient—a value framework has become critically important. This environment of increasing costs of drugs and healthcare services (and increased patient cost sharing) versus inconsistent benefits propelled the development of various cancer-focused value frameworks. Herein we detail some existing value frameworks in oncology, and propose the advantages of new, theoretical models.

The American Society of Clinical Oncology Value Framework

ASCO has proposed assigning a numeric score, Net Health Benefit (NHB), to cancer treatments based on an assessment of their clinical benefit, side effects, associated symptoms, effect on QOL, and costs.[35] The framework determination, on the basis of consensus among framework developers, is weighted most heavily by clinical benefit, with overall survival being the most important, progression-free survival less important, and response rate the least important. The framework also includes bonus points for extended survival to reflect "tail of the curve" survival for those therapies that benefit only a meaningful minority, but that help those few patients tremendously. Toxicity is included as a liability and detracts from the clinical benefit. Finally, the patient's out-of-pocket costs (a major source of financial toxicity) are also included in the value framework.

The National Comprehensive Cancer Network Evidence Blocks

The National Comprehensive Cancer Network Evidence Blocks (NEB) proposed by the National Comprehensive Cancer Network (NCCN) presents assessments of treatments as a visual matrix.[36] Guided by staff from the NCCN, in consultation with the group's members, their approach uses a standardized scale to provide consensus-based scoring of efficacy, safety, quality of evidence, and costs of a particular treatment. Each of the five measures in the NCCN's approach is displayed as a solid block using a scale from 1 to 5, where 1 is

Table 71–1 Example of Multicriteria Decision Analysis

A: Inputs of MCDA

		Attributes		
		5-year survival prob (0–1)	Prob. of side effect (0–1)	Cost ($5000–$300,000)
Treatment option	Treatment attribute values			
	X	0.8	0.7	$30,000
	Y	0.6	0.4	$10,000
	Z	0.2	0.1	$5,000
Patient	Patient rankings (weights) of attribute			
	A	1 (0.61)	2 (0.28)	3 (0.11)
	B	2 (0.28)	3 (0.11)	1 (0.61)
	C	3 (0.11)	1 (0.61)	2 (0.28)

B: Preference score for Patient A–C

	Attributes		
Treatment Option	5-year survival prob (0–1)	Prob. of side effect (0–1)	Cost ($5,000–$300,000)
Patient A			
X	80	20	30
Y	40	30	20
Z	20	40	10
Patient B			
X	40	10	10
Y	30	20	50
Z	20	30	80
Patient C			
X	60	10	30
Y	55	65	48
Z	10	70	50

C: Patient Value by Treatment Option

	Treatment X	Treatment Y	Treatment Z
Patient A	**57.7**	35	24.5
Patient B	18.4	41.1	**57.7**
Patient C	21.1	**59.14**	57.8

Note: For each patient, the bold entry marks the treatment option that yields the highest value for the patient.

considered least favorable and 5 is most favorable. An example of the NEB is depicted in Fig. 71–1. Here we provide a theoretical comparison of "Drug A" versus "Drug B." "Drug A" scores better on efficacy and quality of evidence; however, "Drug B" scores better on safety and affordability. The total "score" for "Drug A" is 15 and the total "score" for "Drug B" is 16, thus inferring "Drug B" is the superior choice. However, if a patient or provider seeks the more efficacious drug (over safety and affordability), "Drug A" may be the preferred treatment. Therefore, although the NEB creates a robust comparison, the preference of the stakeholder is not incorporated into the comparative capabilities of the framework.

Here we reference other existing value frameworks in oncology including Memorial Sloan Kettering Cancer Center's DrugAbacus tool,[37] the Institute for Clinical and Economic Review's Value Assessment Framework,[38] and the European Society for Medical Oncology (ESMO)'s Magnitude of Clinical Benefit Scale.[39]

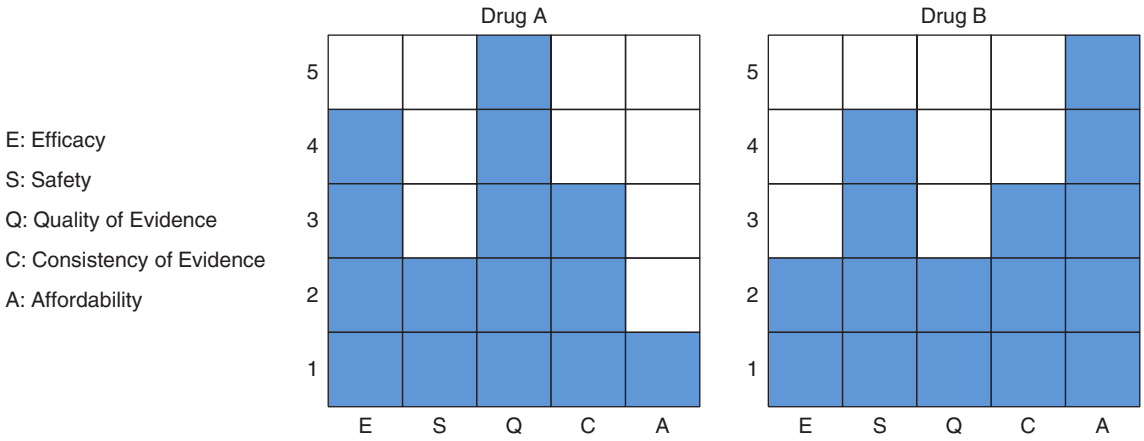

FIGURE 71–1 **Example of NCCN Evidence Blocks (NEB), comparison of "Drug A" versus "Drug B".**

Novel Framework with Use of Radar Charts

To address limitations of existing value frameworks, and to promote adoption through a more robust tool, a group of investigators at MDACC have developed a novel, alternative framework to visualize and communicate value. With so many individual components in the value equation, we found that data visualization is absolutely crucial to all stakeholders. A radar chart is a graphic method of displaying data in which quantitative variables are represented on multiple axes. The simple radar chart is a practical tool with which to improve shared decision making between stakeholders because it provides clinicians, patients, administrators, and policymakers with a readily understandable snapshot that can facilitate value assessment. At MDACC, we have embraced the utility of radar charts as a novel framework to effectively measure and communicate value,[40] most recently reporting how the implementation of clinical care pathways for patients undergoing pancreatectomy provides an overall value advantage by improving several metrics (Fig. 71–2).[41]

Although each of the value frameworks discussed above has targeted patients, physicians, and/or payers using a unique interpretation of value, the relevance of each of the frameworks to stakeholders will depend on their adoption. Factors that may drive framework adoption include appreciation for real-world evidence, the relation of cost to affordability, ability to accurately estimate costs, transparency regarding the quantification process, and the framework's applicability to individual decision making.

Limitations of How We Currently Assess Value

Despite the major advancement in value assessment, there remain multiple limitations to how we effectively assess total value. The ASCO NHB score is useful, but the extent to which value can be summarized by a single number using data generated across multiple dimensions is unclear. Furthermore, there is currently no reason to believe that total value would be accurately represented by the linear sum of such metrics. The NEB from the NCCN attempts to address these limitations by quantifying consensus-based scores of various value elements, but it does not provide a final summation directly from data that reflect stakeholders' differential preferences across value elements. Neither the NCCN's nor the ASCO's framework is optimized to allow visualization of value from the perspective of different stakeholders. The radar chart may be different in that it facilitates intuitive understanding of value differences through robust graphic depiction of actual data across multiple metrics and can compare alternate processes within a single figure. Still, future research is needed to guide not only the selection of metrics used by different stakeholders, but also how stakeholders' preferences may be reflected into more aggregate indexes of value.

There are also important limitations to our current abilities to quantify many domains considered in value assessment, although several domains can be measured using data readily available in electronic health records, registries, hospital billing records, and/or insurance claims. However, other metrics—especially patient-reported outcomes (PROs) such as pain measures, functional outcomes, QOL, and measures of financial toxicity—are not routinely available. Also challenging is the ability to accurately estimate out-of-pocket expenses given the sophistication of insurance benefit designs and the complexity of cancer care.[42]

For practical reasons, many value assessments are assessing process measures, and the assessment often takes place at a snapshot in time, often at the beginning of treatment. For many cancers, it can take many years to observe outcomes such as survival and long-term

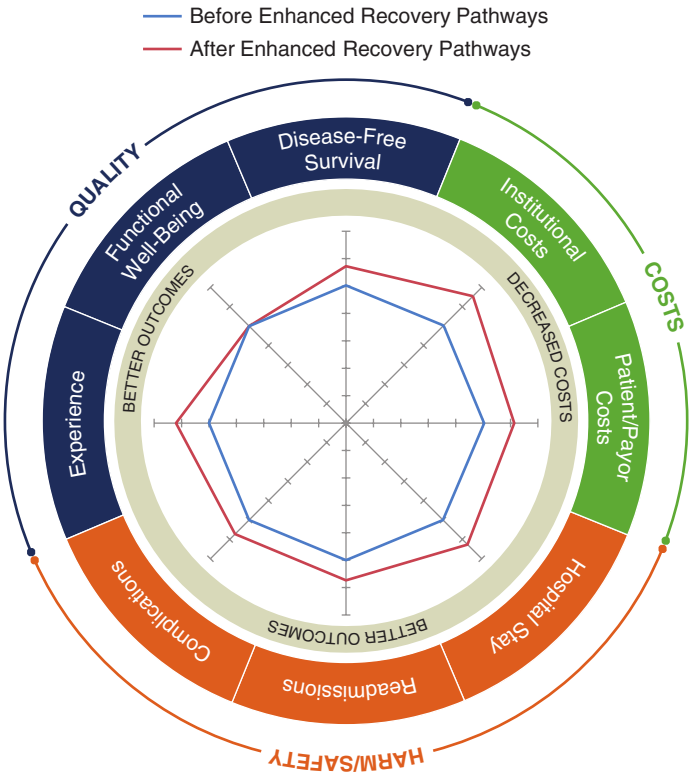

FIGURE 71–2 **Radar chart comparing value before and after implementation of risk-stratified clinical care pathways for patients undergoing pancreatectomy for pancreatic adenocarcinoma. Post-implementation metrics are displayed using relative change from an index value. Blue depicts quality metrics, green depicts cost metrics, and orange depicts harm/safety metrics. (Reproduced with permission from Allen CJ, Thaker NG, Prakash L, et al: Communicating Value: Use of a Novel Framework in the Assessment of an Enhanced Recovery Initiative, *Ann Surg* 2021 Jan 1;273(1):e7-e9.)**

treatment-related toxicities, and by that time treatment has been administered and paid by payers and patients. This suggests the need to incorporate long-term outcomes data as one of the metrics in value assessment. Finally, many factors beyond the control of providers can contribute to outcomes such as survival and financial toxicity; these factors introduce uncertainties in value assessment. How to address uncertainties is an underexplored area in value assessment and value communication.

Opportunities and Challenges of Using Administrative Claims Data to Aid Value Assessment

With the rising importance of data-driven decision making, administrative claims data are emerging as valuable tools in assessing value in hopes of improving healthcare delivery. These data sets provide the information from which companies including *US News & World Report*[43] and The Leapfrog Group[44] rank and compare hospitals across the country. In addition to private groups, the Center for Medicare and Medicaid Services (CMS) is working in collaboration with consumers, hospitals, doctors, employers, accrediting organizations, and other federal agencies to develop Hospital Compare, a publicly available data source informing the quality of care of more than 4000 Medicare-certified hospitals across the country.[45] Multiple stakeholders can utilize Hospital Compare to identify and compare the value of their own care delivery.

These administrative data sets are available from a myriad of sources including hospitals, payers, data organizations, departments of health, and federal agencies, and can act as tools to identify areas in which to improve healthcare delivery. Many quality measures are created using hospital administrative discharge data. Administrative claims data make it possible to identify individuals or cohorts who meet specific inclusion/exclusion criteria, define episodes of care, estimate costs, measure outcomes,[46] and present advantages over other data sources (eg, single-institution data, trials or surveys) because of its larger sample size, completeness, and availability. For inpatient care, these data provide patient demographics, diagnoses, procedures, discharge status, length of hospital stay, as well as estimated hospital costs, charges, and patient out-of-pocket payments; and they have been shown to be more accurate than data collected through

qualitative means.[47] This can help providers access complete, accurate, and longitudinal clinical data along the care continuum. Quality experts regard claims data as a reliable and usable source for the purpose of assessing hospital quality.[37] For cancer care overall, the linked Surveillance, Epidemiology, and End Results Program (SEER)-Medicare data offer unique opportunities to examine treatment patterns, costs, and outcomes for Medicare beneficiaries diagnosed with cancer.[48]

Despite the reliability and widespread uses of claims data, they also have important limitations. Administrative data are primarily used to support the billing process and often do not contain detailed clinical information, thus lacking important value measures. Long-term survival is not available in some administrative claims data, especially those from private insurance companies. PROs including pain measures, functional outcomes, and QOL are not available, regardless of the source of claims. There is also no formal system to accurately report costs of care to all stakeholders. Although we have a partial surrogate for payer and patient costs through variables of charges and/or payments, the majority of the financial burden (financial toxicity) of treatment is not currently measured. Some major organizations are already making these realizations. For example, the Oncology Care First Model, as recently proposed by CMS, mandates hospitals to collect PROs along with all other outcome and cost metrics.[40]

As we continue to use administrative claims data in our assessment of value-based healthcare, we need to emphasize the importance of collecting and reporting more long-term and patient-centric outcomes.

Future Endeavors

The ultimate goal of these efforts is to engage patients, caregivers and providers with data to make informed decisions regarding their care. Cancer treatment can often be physically taxing, emotionally draining, and financially toxic to patients. Bringing the patient into the conversation about their care allows treatment to be reframed from the patient's perspective based on their value, preference, and priorities in life. To the extent that patients are increasingly engaged in their healthcare,[41] it is critical that the patient perspective is accurately reflected by any value measurement. By also communicating value in a manner that is accessible to all stakeholders, better decision making will aid in the continual effort to deliver better value to patients.

Thus, in order to enhance the value of care, interventions should aim at improving end points that matter to patients. Gathering reliable and valid QOL data, designing patient preference studies that use reliable and generalizable methods, and using the results to develop decision aids for shared decision-making strategies are recommended going forward.

Until we have access to multiple disparate outcomes, each measured routinely and reliably, it will be difficult to assess the total value of any care process. As we develop better data, our ability to effectively communicate value will facilitate shared decision making among all stakeholders involved in value-based healthcare.

VALUE-BASED ONCOLOGY IN PRACTICE

Value-Based Practice in Medical Oncology

As the cost of oncology drugs continues to increase, the notion of value-based care has become increasingly important. Historically, data on survival and QOL have been the most important factors in the choice of systemic therapies. However, financial toxicity has been increasingly recognized as an important factor for patients.[49]

Efforts to promote value-based care in medical oncology have centered on physician-patient conversations about cost, drug pricing and reimbursement models, standardization of practice patterns, and the elimination of low-value care.

Price Transparency/Conversations About Cost

Attitudes surrounding discussing the cost of cancer care differ among patients and oncologists. The majority of patients are interested in discussing costs of cancer care, but oncologists are less comfortable with these conversations.[50] Although cost communication is recognized by the ASCO Cost of Cancer Care Guidance Statement[51] and the Institute of Medicine Committee on Improving the Quality of Cancer Care[3] as an essential component for high-quality cancer care, a recent review article showed low prevalence of cost communication reported by patients and physicians (27% and 47%, respectively).[52] In addition, some oncologists consider the value of a treatment only if it poses a significant financial burden to the patient.[53] However, these conversations remain important, because financial toxicity has important implications not only for a patient's QOL, but data suggest some patients skip doses of oral chemotherapy to reduce the burden of prescription refills or copayments, which could ultimately compromise the efficacy of a treatment.[54] Furthermore, the lack of price transparency both to patients and providers remains a substantial barrier, because this information is crucial for informing patient-provider discussions.[42,55] Recent public policy has focused on making the prices of cancer treatment services available to patients, but a lack of standardization has made it difficult to interpret such data, and more work is needed to provide value to patients.[56]

Drug Pricing

Although one may expect the introduction of competitor drugs or generic drugs to result in lower prices, in oncology this is not necessarily the case, and the opposite is often true.[57] In fact, studies exploring the drug prices of targeted oral anticancer medications have reported a trend toward not only higher prices at launch over time but also a sustained increase in prices post-launch.[58–60] Health policy plays a role in drug pricing, because Medicare is required to cover drugs approved by the Food and Drug Administration but is not allowed to negotiate drug prices. Reimbursement structures are also important for drug pricing, and the notion of value-based drug pricing has gained momentum in recent years. Value-based drug pricing is a concept that centers around tying the price of a drug to its efficacy or outcomes for a specific indication.[61] For instance, some have suggested that if a drug has multiple indications for use (eg, in multiple cancers), then its price should be tied to the clinical benefit it provides to a specific set of patients. Another proposed payment model is outcomes-based, in which a pharmaceutical company only receives reimbursement for a drug if the patient has a favorable outcome. CMS explored using outcomes-based pricing for the chimeric antigen receptor T-cell therapy Kymriah, but ultimately suspended the payment deal before launch.[62] Future efforts by policymakers and payers will continue to focus on innovative payment and drug reimbursement models.

Value Pathways and Drug Formularies

Standardization of physician practice patterns has emerged as an important method to improve quality and reduce cost. In oncology, providers and payers are increasingly using clinical pathways.[63] These clinical pathways use a variety of tools to promote guideline-concordant, evidenced-based care. One component typically involves a committee of experts in a field who review clinical benefit, toxicities, and cost of drugs to develop recommendations and/or algorithms. A common second component is a decision-support tool with electronic health record integration that assists providers in making clinical decisions, providing education and recommendations at the point of care. Clinical pathways have been demonstrated to reduce costs while maintaining or improving outcomes.[64,65]

Drug formularies can also play an important role in the utilization of drugs and in some instances can affect pricing as well. A notable example was highlighted in an op-ed in *The New York Times* by a group of physicians at Memorial Sloan Kettering Cancer Center who detailed a new cancer drug that had similar efficacy and mechanism of action to other drugs but was more than twice the cost.[66] This gained significant attention and criticism directed at the pharmaceutical company, which subsequently announced a price reduction for the drug.[67] Drug formularies are important for helping to determine the utilization of a drug, but price reductions based on well-publicized articles in the media are the exception rather than the norm.

Choosing Wisely

In 2012, the Choosing Wisely initiative was launched by the American Board of Internal Medicine Foundation in partnership with several specialty societies, with the goal of helping reduce waste in the US healthcare system.[68] ASCO was one of the specialty societies to join this initiative, and over the next 2 years created a Top 10 List of "Things Physicians and Patients Should Question," identifying and discouraging the use of low-value tests and interventions for patients with cancer.[69,70] Of these 10 items, four relate to the use of imaging, three address indications for chemotherapy, two focus on supportive care medicines such as antinausea drugs or hematopoietic growth factors, and one discusses cancer screening. The goal of the Choosing Wisely initiative is not to restrict necessary and appropriate care, but rather to highlight evidence and educate physicians and patients regarding the use of low-utility tests and interventions.

Value-Based Practice in Radiation Oncology

Radiation oncology represents approximately 4% of overall cancer spending and, similar to overall cancer spending, increased by 62% from 2004 to 2014.[71] The primary drivers of radiation cost from the payer's perspective include: (1) costs associated with radiation technologies used, and (2) number of radiation treatments delivered. Furthermore, there can be downstream costs associated with radiation, including management of toxicities from treatment. In addition to direct costs of care, patients may also incur substantial costs from daily radiation treatments, such as travel costs and time lost from work for patients and their family or friends who accompany patients to their radiation treatment. The most commonly measured treatment outcomes, as with other treatment modalities, include cancer-specific outcomes, such as overall survival, as well as treatment toxicity and QOL. Though there have been efforts to define standard sets of cancer outcomes for the purpose of measuring value, these have not yet been widely adopted.[72]

Radiation Technologies

Although value-based practice in radiation oncology shares many features with both medical and surgical

oncology, the adoption of high-cost technologies is of particular importance. The delivery of radiation therapy is a multistep process involving simulation, treatment planning, and radiation delivery, each with a variety of technological options associated with different costs. Unlike for most chemotherapy and drugs, the introduction of many new technologies in radiation oncology have not been subject to the same rigorous approval process. In the past, Medicare has covered new technologies, such as intensity-modulated radiation therapy (IMRT), based on promising dosimetric and clinical studies, but before large, randomized studies comparing its effectiveness with that of conventional radiation therapy.[73]

In many cases, comparative effectiveness studies may not be feasible without incurring high upfront fixed costs, often largely borne by providers. An example of this was the adoption of proton therapy, which required the construction of proton therapy centers, with costs that exceeded $100 million. However, it was not until a critical mass of proton therapy centers were built that large-scale multi-institutional trials could be performed, leading to a conflict between the need for evidence before coverage versus the need for coverage to support evidence development.[74]

The multistep process of radiation therapy can also make clean comparisons of new technologies challenging, and technologies may become outdated by the time randomized studies are completed. For example, a randomized study comparing proton therapy with photon therapy for lung cancers failed to show a difference in toxicity or local failure,[75] which was a surprise to many proponents of proton therapy. However, on closer examination, the trial was not a straightforward comparison of protons versus photons, because at the time, more advanced treatment planning and imaging technologies were available to patients undergoing photon IMRT versus patients receiving proton IMRT. Additional trials are now underway evaluating more modern proton techniques.

Number of Radiation Treatments

Though most curative intent radiation regimens have a fairly standard number of treatments, there has been recent interest in decreasing the number of treatments delivered, or hypofractionation, in a number of cancer types, with most studies supporting the efficacy and safety of this approach.[76–78] This has the potential benefit of reducing costs to both payers and patients. For palliative intent treatments, there is considerable provider discretion in the number of treatments delivered. Reducing the use of extended fractionation for the treatment of bone metastases has long been a target of value-based efforts in radiation oncology, with multiple guidelines, including a National Quality Foundation (NQF 1822) measure, all supporting shorter regimens than what is commonly being done.[79–82] The NQF measure has been adopted by the CMS programs that provide financial incentives for reporting data on care quality.

Value-Based Payments Models in Radiation Oncology

The traditional fee-for-service payment model incentivizes both the use of high-cost technologies and a greater number of radiation treatments. Value-based payment models seek to increase physician accountability and risk for cancer spending. Though there have been a variety of models proposed in radiation oncology, the most common are described below:

Guidelines, Clinical Pathways, and Quality Measures

The primary goal of most guidelines, clinical pathways, and quality measures is to improve physician accountability and reduce variation in care. Examples of such efforts in radiation oncology include clinical guidelines issued by NCCN, the Choosing Wisely initiative, and the American Society for Radiation Oncology (ASTRO). Increasingly, payers are using these guidelines and pathways to determine coverage of care and to provide financial incentives to providers.[83,84] However, a frequent challenge is that use of pathways and guidelines may result in burdensome reporting requirements and lag new developments in clinical practice.

Episode-Based Payment Models

Episode-based payment models in radiation oncology aim to increase the proportion of financial risk providers bear for costs of care and to incentivize lower-cost care while maintaining quality standards.

Radiation oncology has been incorporated both into broader condition-based models, as well as radiation modality–specific models. One example of a cancer condition–based model is the United Healthcare and MDACC bundled payment pilot in patients with head and neck cancer, which included multidisciplinary oncology care over a one-year period.[85] Another example is the Oncology Care Model, a voluntary episode-based payment program sponsored by the CMS, which is centered on 6-month chemotherapy episodes and incorporates total costs of care during the episode, including radiation therapy.[86] One challenge of this model is that benchmarks are based on total costs of care, which oncologists may not be able to fully control. Furthermore, the model could potentially introduce disincentive to care that is not well-captured by quality measures, such as palliative radiation. More recently, the Oncology Care First Model has been proposed as a successor to the Oncology Care Model, with a target start date in 2021.[84]

Radiation modality–specific episode-based models have previously been developed between individual payers and radiation therapy practices.[87] Nationally, a Radiation Oncology Model has been announced by the CMS to test a prospective episode-based payment model, with a target start date in 2022. Participation in the model would be mandatory for radiation oncology providers in selected Core-Based Statistical Areas for 17 different cancer types. Provider payments would be based on 90-day episodes of care and linked to reporting and performance on quality measures. The goal would be to test whether episode-based payments lead to shorter courses of treatment and higher-value care delivery in radiation oncology, while allowing providers flexibility for individual patients.[88]

Value-Based Practice in Surgical Oncology

Because cancer surgery may frequently be associated with large physical, emotional, and financial demands, with often only a marginal survival benefit, the determination of value is prominent in this setting. Within the field, most recent efforts to improve perioperative outcomes and cost are through the development of enhanced recovery protocols and through preoperative optimization with prehabilitation programs.

Enhanced Recovery and Prehabilitation

Enhanced Recovery After Surgery (ERAS) is an evidence-based, multimodal, multidisciplinary approach to the care of the surgical patient. In short, the goal of any ERAS process is to achieve early recovery for patients undergoing major surgery. ERAS process implementation involves a team consisting of surgeons, anesthesiologists, nurses, and staff from units that care for the surgical patient. It has been shown that, regardless of the surgical site, ERAS programs result in major improvements in clinical outcomes and cost,[88] making ERAS an important example of value-based care applied to surgery.

Although cancer surgery may be curative, the efficacy of surgery depends heavily on whether patients' performance status and functional fitness will allow for successful postoperative recovery. Frailty is seen in patients with gastrointestinal malignancy and is a predictor of poor survival, including patients treated with curative intent.[89] Because ERAS focuses on in-hospital care in the immediate perioperative period, prehabilitation is a growing approach that is based on the principle that structured and sustained exercise over a period of weeks before surgery will optimize a patient's cardiovascular, respiratory, and muscular condition. Because several recent preoperative fitness programs involving patients with cancer show how prehabilitation may improve patient outcomes and reduce direct and indirect healthcare costs,[90] this approach is an important factor that influences not only the treatment and survival of patients undergoing major operations for malignancy, but also has important implications regarding the healthcare economy.

The American College of Surgeons (ACS) is the leading organizational body for improving overall surgical care in the nation. With regarding to oncology, the organization has created the ACS Cancer Programs, aimed at developing resources that enable providers to deliver comprehensive, high-quality, multidisciplinary, evidence-based, patient-centered care to patients with cancer. The various programs include the Commission on Cancer, the American College of Surgeons Clinical Research Program (ACS-CRP), the National Accreditation Program for Breast Centers, the National Accreditation Program for Rectal Cancer, the National Cancer Database, and the American Joint Committee on Cancer. Among other functions, these programs provide education and training opportunities, establish and promote evidence-based systems for the classification and management of cancer, and emphasize program structure, patient care processes, performance improvement, and performance measures across the country.

American College of Surgeons Clinical Research Program

Through a relationship between the Alliance for Clinical Trials in Oncology and the ACS Cancer Programs, the ACS-CRP was created to improve cancer care outcomes by disseminating validated management strategies. The program has several committees that work together to reach the program's overall goals. Within these, the Cancer Care Delivery Research Committee is currently developing the Value of Care Workgroup. Their specific mission is to improve care delivery processes by improving the infrastructure in defining value, measuring costs, developing multisite datasets, building value-based care models, and networking the various member sites—ultimately integrating value assessment into cancer care delivery research.[91]

Transforming Healthcare Resources to Increase Value and Efficiency

In 2019, the Harvard Business School's Institute for Strategy and Competitiveness partnered with the ACS and announced Transforming Health-care Resources to Increase Value and Efficiency. The program's mission is to assist providers in delivering value-based surgical care by improving patient outcomes while lowering costs. Focused on measuring the full cycle of care, the program is currently piloting their value measurement process for three surgical conditions at select institutions throughout the country: colon cancer, breast

cancer, and morbid obesity/bariatric surgery. Their goal is to use the results from the initiative to create a robust approach to measure and improve value at hospitals around the county.

Within the field of surgical oncology, although there has been growing recognition and emphasis to improve value of care delivery, the concept of complete value-cased care in the field remains in its infancy.

MD ANDERSON PRACTICE TIPS

- To enhance the value of care, interventions should aim at improving end points that matter to patients, providers, and society as a whole.
- Gathering reliable and valid PRO data, designing patient preference studies that use valid instruments and apply reliable and generalizable methods, and using the results to develop decision aids for shared decision-making strategies are recommended going forward.
- Efforts to promote value-based care in medical oncology should center on cost, drug pricing and reimbursement models, standardization of practice patterns, and the elimination of low-value care.
- Because cancer surgery may frequently be associated with large physical, emotional, and financial demands, efforts to improve outcomes and cost by developing enhanced recovery protocols and prehabilitation programs is recommended.
- When designing value-based models of care, it is important to consider how changing the incentives of providers, patients, and payers might impact the quality of care.
- Engagement in value workgroups through organizational bodies including the ASCO, the ASTRO, and the American College of Surgeons (ACS) will further enhance value-based care transformation nationwide.
